We put these expressions into Eq. (1), set $i_x{}^{(1)} + i_x{}^{(2)} = 0$ and calculate E_x. Integrating E_x along x quite similarly as was done in Ref. [1] we obtain the same formula for Q as Eqs. (22) and (24) in this reference or in a paper by the author⁴⁾. This is of course obvious as the use of the electrochemical potential is equivalent to the use of the electrical potential; both differ by the chemical potential which is the same in the points x_0, x_3 (see Fig. 1 of ref. 1)). The first term in Eq. (4) of ref. 1) is certainly equal to zero; μ is only the function of the composition and temperature of the semiconductor which must be the same in both points; there may be some doubt about the justification of the integration per partes but it is evident that we can suppose e. g. the contacts to be constructed so that μ is a continuous and differentiable function of x across them.

The final formula for the thermoelectric power is the same whether ε_g depends on T or not. The reason for this is that the generation of the thermoelectric power is connected with the flow of entropy as was first pointed out by Ehrenfest⁵⁾. In fact, we can write Eq. (1) in the form

$$i_x{}^{(k)} = \frac{\sigma^{(k)}}{e}\left(eE_x + \frac{d\mu_a}{dx} + S^{*(k)}\frac{dT}{dx}\right) \quad (3)$$

where $S^{*(k)} = (Q_a{}^{*(k)} - \mu_a)/T$ are the entropies of transfer. It is seen from this definition, that $S^{*(k)}$ are independent of the zero energy level and of ε_c, ε_v. Using $S^{*(k)}$ we can write the expression for the absolute thermoelectromotive power Q of a two band semiconductor in the form:

$$Q = -\frac{1}{e}\left[\frac{\sigma^{(1)}}{\sigma^{(1)}+\sigma^{(2)}} S^{*(1)} + \frac{\sigma^{(2)}}{\sigma^{(1)}+\sigma^{(2)}} S^{*(2)}\right] \quad (4)$$

The use of the internal electric field inside a two band semiconductor proved valuable also in the theory of photovoltaic effects⁶⁾ even if ε_g was not constant (cf. e. g. the case of ε_g varied by external pressure, the so called photopiezoelectric effect described in ref. 7)).

Theory of Thermoelectric Power of Ionic Crystals, III

By Eijiro HAGA

Department of Physics, Faculty of Science, Niigata University

(Received April 23, 1959; revised manuscript received July 23, 1959)

When temperature gradient is given in a specimen of AgCl doped with CuCl, its thermoelectric power changes with time owing to the thermal diffusion of copper ions, and then reaches its steady value. If the temperature gradient is removed after such a steady state is attained, the electronmotive force continues to exist for a while, but it decreases with time according as the copper ions diffuse again to the previous homogeneous distribution. The expressions for such processes are derived under proper assumptions. The time constant for them is estimated with use of the conductivity data of Ebert and Teltow. The information on the heat of transport of Cu^+ will be obtained if experiments on such processes are carried out.

§ 1. Introduction

On the mechanism of thermal diffusion of ions or atoms in solids the theoretical study has not been well developed.[1] Here we want to point out that we obtain an information about the heat of transport characterizing the behaviour of ions in thermal diffusion from the knowledge of the thermoelectromotive force. Recently, the theories of the thermoelectromotive force of $AgCl(Br)+CdCl_2(Br_2)$[2,3] and $NaCl+CdCl_2$[4] have been proposed and the former has been compared with the experiments.[5,6] When temperature gradient is set up in those crystals, the complexes (Cd^{++}-vacancy pairs) will diffuse in the crystal, and accordingly the free vacancies will be denoted from the complexes or conversely they will combine with the cadmium ions to form complexes. As a result of these processes, the concentration gradient of free vacancies and so the electric field, E, changes with time. The thermoelectric power is, however, independent of time as mentioned in (I)[3], since it does not depend on the concentration gradient of charge carriers. This time independence is due to the fact that the complexes are neutral and so do not contribute to the electric conduction.

In the case of $(AgCl+CuCl)$ specimens which will be considered in the present paper, the interstitial copper ions are supposed to diffuse instead of neutral complexes in the cases mentioned previously. Therefore, when temperature gradient is set up in the specimen, the thermoelectromotive force changes with time and reaches the steady value. In such a steady state, the concentration of copper ions varies along the specimen and its distribution can be expressed in terms of the value of the heat of transport of copper ions and other parameters. When the temperature gradient is removed after such the steady state is attained, the interstitial copper ions diffuse again and accordingly the residual electromotive force decays with time. From the analysis of such processes, the information on the heat of transport of the interstitial copper ions can be obtained. Besides, we shall analyse the conductivity data of Ebert and Teltow[7], and estimate, from such an analysis, the value of the time constant, τ, for the above processes.

§ 2. Thermoelectric Power

The electrical current densities of Ag^+ interstitials, vacancies and Cu^+ interstitials, j_i, j_v and j_{cu}, are given, respectively, by

$$j_i=\frac{\sigma_i}{e}\left(eE-\frac{kT}{c_i}\frac{\partial c_i}{\partial x}-\frac{Q_i^*}{T}\frac{\partial T}{\partial x}\right), \tag{1}$$

$$j_v=\frac{\sigma_v}{e}\left(eE+\frac{kT}{c_v}\frac{\partial c_v}{\partial x}+\frac{Q_v^*}{T}\frac{\partial T}{\partial x}\right), \tag{2}$$

$$j_{cu}=\frac{\sigma_{cu}}{e}\left(eE-\frac{kT}{c_{cu}}\frac{\partial c_{cu}}{\partial x}-\frac{Q_{cu}^*}{T}\frac{\partial T}{\partial x}\right), \tag{3}$$

where σ_i, c_i and Q_i^* are the partial conductivity, the mol fraction and the heat of transport of the Ag^+ interstitial, respectively, and σ_v, c_v, Q_v^*, σ_{cu}, c_{cu} and Q_{cu}^* are defined similarly. We shall assume that the charge neutrality and the local equilibrium expressed by

$$c_i + c_{cu} = c_v \,, \tag{4}$$

$$c_i c_v = N_0'/N_0 \cdot \exp(-\mu_F/kT) \tag{5}$$

are valid approximately, where N_0 and N_0' are the concentrations of the normal and interstitial sites of Ag^+, respectively, and μ_F is the Gibbs free energy of forming a pair of Frenkel defects. Then the concentration gradients of the Ag^+ interstitials and vacancies can be expressed in terms of that of the Cu^+ interstitials.

The thermoelectric power, Q, with the silver electrodes is obtained from the gradient of electrochemical potential of a silver ion as done in (I). Making use of Eqs. (1)~(5) we obtain

$$\begin{aligned} eQ = & -\frac{2kTt_{cu}c_v}{c_{cu}(c_i+c_v)} \cdot \frac{(c_{cu})_{x=L}-(c_{cu})_{x=0}}{\Delta T} - k\ln c_v + \alpha \\ & -\frac{1}{T}\left[t_i(h_F+Q_i^*+Q_v^*) + t_{cu}(Q_v^*+Q_{cu}^*) - Q_v^* + \frac{c_i t_{cu} h_F}{c_i+c_v} \right], \end{aligned} \tag{6}$$

where ΔT is the temperature difference between the ends of the specimen of the length L, and t_i and t_{cu} are the transport numbers of the Ag^+—and Cu^+—interstitials, respectively, and α is the notation used in (I).

Now, we calculate $(c_{cu})_{x=L}-(c_{cu})_{x=0}$ in Eq. (6) as a function of time t. Let us consider only the case that L is so long that the time constant, τ, is much longer than the time required to set up ΔT in the specimen. When ΔT is set up in the specimen at $t=0$, the local equilibrium will be established at the same time, and accordingly there will be more Cu^+ interstitials in the higher temperature side than in the lower one. Then, copper ions diffuse in the electric field which is determined by the condition that the total electric current vanishes. Hence, in the side where c_{cu} is increasing owing to the diffusion, the Cu^+ interstitials drop into the Ag^+ vacancies and, in the other side, they are donated from copper ions on the lattice sites so that the local equilibrium is approached. In response to such the current of copper ions, the Ag^+ interstitial concentration decreases or increases owing to the combination with vacancies or the inverse process. Such a combination or a generation contributes to the change of the concentrations of Cu^+ interstitials, Ag^+ interstitials and vacancies with time. On the other hand, the variation of the total concentration of copper ions, y, is only due to the x dependence of the current of Cu^+ interstitials:

$$\frac{\partial y}{\partial t} = -\frac{\partial (j_{cu}/eN_0)}{\partial x} \,. \tag{7}$$

Substituting the electric field E obtained from the condition $j_i + j_v + j_{cu} = 0$ to Eq. (3), we have

$$j_{cu} = -D_{cu}\left(\frac{\partial c_{cu}}{\partial x} + S\frac{\partial T}{\partial x}\right), \tag{8}$$

where

$$D_{cu} = \frac{2kT\sigma c_v t_{cu}(1-t_{cu})}{e c_{cu}(c_i+c_v)} \,, \tag{9}$$

$$S = \frac{c_{cu}(c_i+c_v)}{2kT^2 c_v}\left[\frac{c_i h_F}{c_i+c_v} - \frac{t_i}{1-t_{cu}}(h_F+Q_i^*+Q_v^*) + (Q_v^*+Q_{cu}^*)\right]. \tag{10}$$

Here σ is the total conductivity of the specimen. The mass action law between copper ions and silver vacancies

$$y = c_{cu}(1+c_v K) \,, \tag{11}$$

where K is the equilibrium constant, is assumed to be valid approximately. Then the left-hand side of Eq. (7) is expressed in terms of $\partial c_{cu}/\partial t$ from Eqs. (4), (5) and (11):

$$\frac{\partial y}{\partial t}=\frac{2c_v y/c_{cu}-c_{cu}}{c_i+c_v}\frac{\partial c_{cu}}{\partial t}\,. \tag{12}$$

In differentiating Eq. (8) with respect to x, the terms coming from the differentiation of D_{cu} and S are of the order of $(\partial T/\partial x)^2$, since the derivatives of c_i, c_v and c_{cu} with respect to x are obviously of the order of $\partial T/\partial x$. Hence, considering the terms in Eq. (7) up to the order of $\partial T/\partial x$, we have

$$\frac{\partial c_{cu}}{\partial t}=D\frac{\partial^2 c_{cu}}{\partial x^2}\,, \tag{13}$$

where

$$D=\frac{c_i+c_v}{2c_v y/c_{cu}-c_{cu}}\frac{D_{cu}}{eN_0}\,. \tag{14}$$

The boundary condition of the diffusion equation (13) is given by[8]

$$(j_{cu})_{x=0}=(j_{cu})_{x=L}=0\,, \tag{15}$$

which is rewritten as

$$\left(\frac{\partial c_{cu}}{\partial x}\right)_{x=0}=\left(\frac{\partial c_{cu}}{\partial x}\right)_{x=L}=-S\frac{\partial T}{\partial x} \tag{16}$$

from Eq. (8). The initial condition is given by

$$(c_{cu})_{t=0}=c_{cu}{}^0+\left(x-\frac{L}{2}\right)\left(\frac{\partial c_{cu}}{\partial T}\right)_{t=0}\frac{\partial T}{\partial x}\,, \tag{17}$$

where $c_{cu}{}^0$ is independent of x. Eq. (13) has been solved under the similar boundary and initial conditions to Eqs. (16) and (17) by Yokota.[9] We find easily the following solution:

$$\begin{aligned}c_{cu}=&\,c_{cu}{}^0-\left(x-\frac{L}{2}\right)S\frac{\partial T}{\partial x}\\&-\frac{4L}{\pi^2}\left[S+\left(\frac{\partial c_{cu}}{\partial T}\right)_{t=0}\right]\sum_{m=0}^{\infty}\frac{\cos\left[(2m+1)\pi x/L\right]\exp\left[-(2m+1)^2t/\tau\right]}{(2m+1)^2}\frac{\partial T}{\partial x}\,,\end{aligned} \tag{18}$$

where

$$\tau=L^2/\pi^2 D\,. \tag{19}$$

From Eq. (18) the difference of c_{cu} between the ends of the specimen is given by

$$\frac{(c_{cu})_{x=L}-(c_{cu})_{x=0}}{\Delta T}=-S+\left[S+\left(\frac{\partial c_{cu}}{\partial T}\right)_{t=0}\right]F\left(\frac{t}{\tau}\right)\,, \tag{20}$$

where

$$F(x)=\frac{8}{\pi^2}\sum_{m=0}^{\infty}\frac{\exp\{-(2m+1)^2x\}}{(2m+1)^2}\,. \tag{21}$$

The value of $F(x)$ is shown in Fig. 1, where the value of $\exp(-x)$ is also shown for comparison.

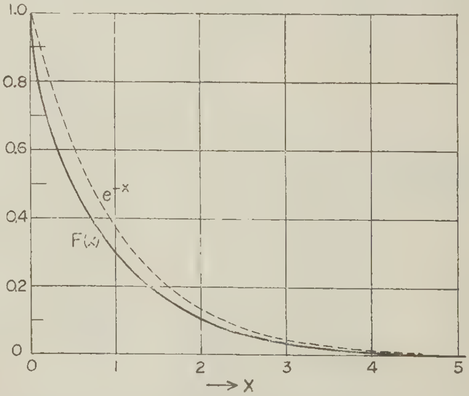

Fig. 1. The full line shows $F(x)$ vs x and the dashed line shows $\exp(-x)$ drawn for comparison.

From Eqs. (6) and (20) we obtain the expression for the thermoelectric power:

$$\begin{aligned}eQ=&-\frac{1}{T}\frac{t_i}{1-t_{cu}}(h_F+Q_i{}^*+Q_v{}^*)+\frac{Q_v{}^*}{T}-k\ln c_v+\alpha\\&-\frac{t_{cu}}{T}\left[\frac{c_i h_F}{c_i+c_v}+\frac{2kT^2c_v}{c_{cu}(c_i+c_v)}\left(\frac{\partial c_{cu}}{\partial T}\right)_{t=0}-\frac{t_i}{1-t_{cu}}(h_F+Q_i{}^*+Q_v{}^*)+(Q_v{}^*+Q_{cu})\right]F\left(\frac{t}{\tau}\right)\,.\end{aligned} \tag{22}$$

The value of $h_F+Q_i^*+Q_v^*$ is found by measuring the steady value of Q. Furthermore, we find the value of $Q_v^*+Q_{cu}^*$ by measuring the variation of Q with time. If the quantity of CuCl mixed is small, the difference between the initial and steady values of Q is small, since the terms of Q depending on time include the factor t_{cu}. Therefore, we have to mix a proper amount of CuCl in order to find the value of $Q_v^*+Q_{cu}^*$ from the easy measurements.

§ 3. Residual Electromotive Force

In the steady state in the presence of temperature difference between the ends of the specimen, $\varDelta T$, the concentration distribution of Cu^+ depends on Q_{cu}^* as mentioned above. Hence, when the temperature difference is removed, the information on Q_{cu}^* is obtained from the residual electromotive force, $\varDelta V$. Let us consider it in the present section. When $\varDelta T$ is removed at time $t=0$, the system will immediately attain the local equilibrium corresponding to the Cu^+ amount at each place. The potential difference between the ends of the specimen, $\varDelta V$, is given by the difference of the electrochemical potential of a silver ion:

$$e\varDelta V=\int_0^L\left(-eE+\frac{kT}{c_i}\frac{\partial c_i}{\partial x}\right)dx=-\frac{2kTt_{cu}c_v}{c_{cu}(c_i+c_v)}[(c_{cu})_{x=L}-(c_{cu})_{x=0}]\ . \tag{23}$$

The partial differential equation (13) and the boundary condition (16) with $\partial T/\partial x=0$ are valid at the present case also, while the initial condition is different. The latter is easily obtained as follows. Differentiating Eq. (11) with respect to x and making use of Eqs. (4), (5) and (18), we have, in the steady state,

$$\frac{\partial y}{\partial x}=\left[-\frac{2c_vy/c_{cu}-c_{cu}}{c_i+c_v}S+\frac{c_i(y-c_{cu})}{c_i+c_v}\frac{h_F}{kT^2}+c_vc_{cu}\frac{dK}{\partial x}\right]\frac{\partial T}{\partial x}\ . \tag{24}$$

In the moment when $\varDelta T$ is removed, we have

$$\frac{\partial y}{\partial x}=\frac{2c_vy/c_{cu}-c_{vu}}{c_i+c_v}\frac{\partial c_{cu}}{\partial x}\ . \tag{25}$$

We can equate Eq. (25) to Eq. (24), since the value of y does not change at the instant of elimination of $\varDelta T$. Thus we obtain the initial condition:

$$\left(\frac{\partial c_{cu}}{\partial x}\right)_{t=0}=\left[-S+\frac{c_i(y-c_{cu})}{2c_vy/c_{cu}-c_{cu}}\frac{h_F}{kT^2}+\frac{c_vc_{cu}(c_i+c_v)}{2c_vy/c_{cu}-c_{cu}}\frac{dK}{dT}\right]\frac{dT}{\partial x}\ . \tag{26}$$

Now Eq. (13) is solved as

$$\frac{(c_{cu})_{x=L}-(c_{cu})_{x=0}}{L}=\left(\frac{\partial c_{cu}}{\partial x}\right)_{t=0}F\left(\frac{t}{\tau}\right) \tag{27}$$

with $(\partial c_{cu}/\partial x)_{t=0}$ given by Eq. (26). From Eqs. (23), (26) and (27), we obtain the expression for $\varDelta V$:

$$\frac{e\varDelta V}{\varDelta T}=\frac{t_{cu}}{T}\left[\frac{c_ih_F-2kT^2c_v^2dK/dT}{2c_vy/c_{cu}-c_{cu}}-\frac{t_i}{1-t_{cu}}(h_F+Q_i^*+Q_v^*)+(Q_v^*+Q_{cu}^*)\right]F\left(\frac{t}{\tau}\right)\ . \tag{28}$$

Here it should be remarked that the right-hand side is equal to the factor in Eq. (22) depending on time, as easily seen from Eq. (24) with $\partial c_{cu}/\partial x$ in place of $-S\partial T/\partial x$, since y is independent of x in the moment when $\varDelta T$ is set up. Thus we find the value of $Q_v^*+Q_{cu}^*$ by measuring $\varDelta V$.

§ 4. Estimation of Time Constant

Ebert and Teltow has measured the electrical conductivity of AgCl doped with CuCl of several concentrations.[7] The ratio of the electrical conductivity of an impure specimen to that of the pure specimen, z, is written as, from Eqs. (4) and (5).

$$z=\frac{\xi(1+\phi')+1/\xi\cdot(\phi-\phi')}{1+\phi}, \qquad \xi=\frac{c_v}{x_0}, \tag{29}$$

where ϕ and ϕ' are the ratios of the mobilities of the Ag$^+$—and the Cu$^+$— interstitial to that of the Ag$^+$ vacancy, respectively, and x_0 is the concentration of the Frenkel defect in the pure AgCl. From the minimum value of z drawn against y, the value of ϕ' is found by making use of the values of ϕ found from the conductivity data of AgCl doped with CdCl$_2$. Such values of ϕ' are shown in Fig. 2.

Eq. (11) is rewritten, in terms of ξ, as

$$\frac{y}{x_0(\xi-1/\xi)}=1+x_0K\cdot\xi\,. \tag{30}$$

Therefore, when the left-hand side of Eq. (30) is plotted against ξ at a fixed temperature, the plots are expected to be on a straight line passing (0, 1). From the gradient of this line the equilibrium constant K is to be obtained. Fig. 3 shows such a plot at 275°C, where the value of x_0 found for AgCl doped with CdCl$_2$ is used. Fig. 2 shows also the value of K obtained in such a way, which is represented as

$$K=\exp\left[\frac{0.94}{kT(ev)}-8.4\right]. \tag{31}$$

The values of c_i, c_v and c_{cu} are obtained by making use of the value of ξ obtained from the measured value of z and Eqs. (4) and (5).

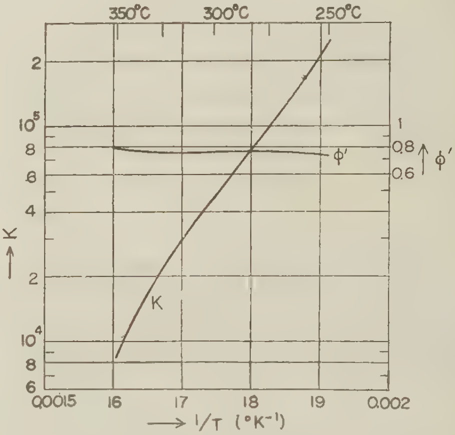

Fig. 2. The equilibrium constant, K, and the mobility ratio of the Cu$^+$ interstitial to the Ag$^+$ vacancy, ϕ', drawn against $1/T$ (°K^{-1}).

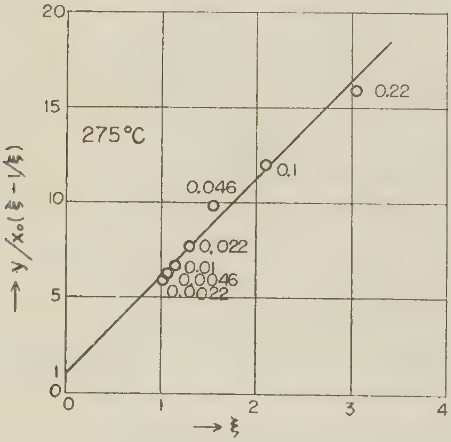

Fig. 3. $y/x_0(\xi-1/\xi)$ *vs* ξ at 275°C. The values in the figure show those of y in Mol-%.

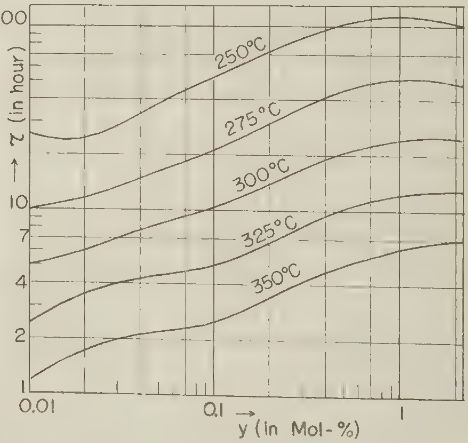

Fig. 4. The time constant, τ, in hour *vs* y in Mol-% for L=1 cm.

Also, the values of t_i and t_{cu} are obtained from

$$t_i=\frac{\phi}{z\xi(1+\phi)}, \qquad t_{cu}=\frac{\phi'}{z(1+\phi)}\left(\xi-\frac{1}{\xi}\right). \tag{32}$$

Thus, the time constant, τ, is estimated as shown in Fig. 4 L=1 cm.

The author wishes to express his sincere thanks to Mr. Yokota, Mr. Miyatani and Mr. Endo for their kind advices and discussions. The present work was supported by the research grant of the Ministry of Education.

On the Crystal Growth of Cadmium Sulphide

By Sumiaki IBUKI

Research Laboratory, Mitsubishi Elec. Mfg. Co.,
Amagasaki, Japan

(Received December 1, 1958)

The crystal growth of CdS has been investigated in detail mainly by the method of sublimation and recrystallization in the flow of nitrogen gas, with special reference to the process of growth and the forms of grown crystals, and the conditions have been searched for under which various kinds of crystal forms such as needle, lamina, plate, rod, block, twin and whisker forms are grown. To this end, the degree of vaporization in sublimating region, the temperature and saturated vapor pressure in growing region, the thermal decomposition, the origination of growth as well as the effect of dislocation upon crystal growth have been investigated. Further, the degree of perfection and luminescence of grown crystals have also been observed.

§ 1. Introduction

In the course of investigating physical properties of cadmium sulphide (CdS) and its industrial applications, it is essential to establish the growing formula of CdS single crystals. Thus, in the present study, the author has observed in detail the crystal growth of CdS, paying special attention to the process of growth and the forms of grown crystals, and has searched for the conditions under which various kinds of crystal forms are grown.

For preparing CdS single crystals, three different methods have been used. Thus, the author at first adopted the so-called Frerichs's method[1], and next used the method of sublimation of CdS powder in the flow of inert gas[2] and finally studied the method of recrystallization of crystalline powder in a sealed quartz vessel[3]. The first method is rather complicated on account of too many variables, and the second is, on the contrary, comparatively favorable for controlling the growth of single crystals, while the last one is fitted to obtaining relatively thick and big crystals.

In the present paper are presented some results obtained mainly by the second method, together with discussions on some interesting facts observed.

§ 2. Method of Sublimation in the Flow of Nitrogen Gas

Molten CdS is obtainable only at high temperature and at high pressures[4], and the solid CdS generally begins to sublime as the temperature rises. To prepare single crystals starting from CdS powder, therefore, we must at first vaporize CdS powder by sublimation and then crystallize by condensing the vapor. The author has performed this process by sublimating polycrystalline powder of CdS in the flow of nitrogen gas and then leading the vapor into lower temperature zone where CdS deposits and crystallizes[2)].

The experimental apparatus used is shown schematically in Fig. 1. The crystal growth was performed in a combustion tube made of quartz. To begin with, the electric furnace was heated up and, at the same time, the flow of nitrogen gas was led through the tube. After the temperature at the center of the tube has been raised up to about 1,050°C～1,150°C, a quartz boat containing CdS powder was inserted into the center of the combustion tube, and then a quartz pipe (i.e. cooler), which was cooled by the flow of nitrogen gas, was inserted from the exit side.

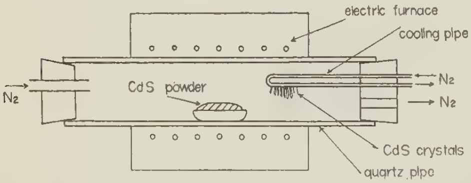

Fig. 1. Crystal growing apparatus.

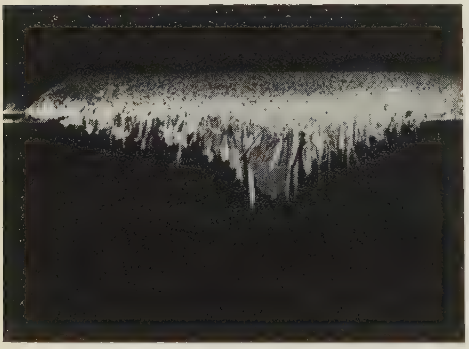

Fig. 2. Grown crystals on the cooler.

With the rise of the temperature of the boat, CdS began gradually to sublime. The vapor was carried by the flow of nitrogen gas towards the exit and the crystal growth of CdS started on the surface of the cooler whose temperature was between 800°C and 1,000°C. After a few hours single crystals grew up to dimensions as large as 10～20 mm in length and 2～10 mm in width. It was observed that crystals were grown also on the surface of the tube wall at about the same time. The heating of the furnace was stopped when CdS powder in the boat was sublimed thoroughly, but the flow of nitrogen gas was continued until the temperature of the furnace became as low as 400°C. Fig. 2 shows single crystals grown on the surface of the cooler which was drawn out from the combustion tube when its temperature was lowered to room temperature. It is to be noted that in performing these processes the purification of CdS powder and the cleaning of nitrogen gas as well as of the combustion tube have been made thoroughly.

§ 3. Factors affecting the Crystal Growth by the Method of Sublimation

We shall next discuss several factors affecting the crystal growth by the method of sublimation. Most important ones are the sublimation temperature of CdS powder, the velocity of flow of nitrogen gas, the temperature of region where crystals are grown and the vapor pressure of CdS, etc.

(1) *Sublimation temperature of CdS powder*

The pressure of nitrogen gas surrounding the subliming CdS is nearly equal to atmospheric pressure. In order to supply the vapor necessary for sustaining the crystal growth, therefore, the minimum temperature of the region of sublimation should be as high as 1,050°C. The forms of crystals grown at this temperature are usually needles or laminas. By raising the temperature, the vapor pressure of CdS increases and crystals of plate- and rod-shapes are liable to growup. But, in these circumstances, both the vaporization of impurities and the degree of thermal decomposition increase.

(2) *Sublimation speed and saturated vapor pressure of CdS*

As mentioned already, CdS powder was sublimed in a quartz boat whose area is about 7 cm^2. The sublimation speed in case when the velocity of flow of nitrogen gas is very small is as shown in Table I, but in practice the sublimation speed depends upon the grain size, weight and surface area of the powder as well as upon the rate of flow of nitrogen gas. Moreover, the vapor pressure in subliming region and the rate of supply of vapor are determined by the sublimation speed and the rate of flow of nitrogen gas. For instance, needle-shape crystals are likely to grow up in case when the rate of flow of nitrogen gas is increased, and by increasing the weight of powder, rod-shape crystals are more likely to grow up. If, we use helium in place of nitrogen gas, there is a tendency that needle-shape crystals grow up more easily.

The second factors affecting growing crystals are the temperature of growing region, the saturated vapor pressure corresponding to the said temperature and the degree of supersaturation of CdS. The author has therefore attempted to calculate the saturated vapor pressure of CdS. In Table I and Fig. 3 are shown those values for higher temperatures which were calculated from the weight of sublimed CdS, the volume of flow of nitrogen gas and the maximum temperature of growing region. On the other hand, the so-called method of molecular effusion was adopted to compute the values for lower temperatures. Thus, as shown in Fig. 4, CdS held in a quartz container whose upper cover has a small hole of diameter of 0.06 mm was kept in the quartz tube and then the tube was evacuated. The tube was then inserted into an electric furnace kept at a definite temperature so as to sublimate CdS, and after having kept the tube at a constant temperature for a long time, CdS was rapidly cooled and the loss of weight of CdS was measured.

Table I. Sublimation speed in flowing nitrogen gas and saturated vapor pressure.

Temperature °C	Sublimation speed g/hr	Saturated vapor pressure mmHg

Temperature T(°C)	Sublimated Weight G(mg)	Measured time τ(hr)	Sublimation speed (g/hr)	Saturated vapor pressure p(mmHg)
650	1.2	48	2.50×10^{-5}	0.0122
700	0.9	8	1.13×10^{-4}	0.0571
750	2.3	8	2.88×10^{-4}	0.150
800	3.0	3	1.00×10^{-3}	0.526
900	10.4	2	5.20×10^{-3}	2.90

In performing the present experiment, special attention was paid to the following points: (1) as specimens sufficiently pure CdS crystals were used which had been prepared by sublimation and recrystallization in a quartz tube; (2) the degree of vacuum of the tube was kept superior to 10^{-5} mmHg; and (3) the time duration of keeping the electric furnance at a definite temperature was made sufficiently long, so that the periods necessary for heating and cooling of CdS could be neglected.

The results obtained are shown in Table II, and by using the data the saturated vapor pressure of CdS can be calculated as follows.

Now, according to Knudsen, the saturated vapor pressure P is given by

$$P=\frac{WG}{\sqrt{\rho\tau}}\,, \qquad (1)$$

where ρ is the density of CdS vapor, G is the weight of CdS spouted from the small outlet (being of 0.06 mm in diameter) during the period τ, and W is the flowing resistivity of the outlet which is connected with the area A of the outlet by the relation:

$$W=\frac{\sqrt{2\pi}}{A}\,. \qquad (2)$$

If we regard CdS vapor as an ideal gas, its density ρ is given by

$$\rho=\frac{M}{RT}\,, \qquad (3)$$

where M is the molecular weight of CdS, T is its temperature and R is the gas constant.

Thus, combining (1), (2) and (3), we have

$$P=\sqrt{\frac{2\pi RT}{M}}\cdot\frac{1}{A}\cdot\frac{G}{\tau}\,. \qquad (4)$$

The values of P as calculated by this equation are given in the fifth column of Table II and are shown graphically in Fig. 3. In Fig. 3 are also shown for comparison the data obtained by A. D. Pogorelyi[5] (curve P), C. M. Hsiao and A. W. Schlechten[6] (curve H), and B. K. Veselovskii[7] (curve V). It will be seen that the present author's data are somewhat larger than the others'.

An empirical formula for P fitting our data is found to be

$$\log_{10}P=9.36-\frac{10.39\times10^3}{T}\,. \qquad (5)$$

(3) *Thermal decomposition of CdS*

The thermal decomposition of sublimed vapor surrounding heated CdS must not be looked over in the discussion of the sublimation of CdS. Since, in our measurement, the stoichiometric ratio of Cd : S remained unchanged before and after the sublimation, it may be supposed that CdS sublimed as molecules. However, we are obliged to consider that there are some possibilities of causing the thermal decomposition of CdS vapor in accordance with Pogorelyi's report[5] and with the fact that a little deposits of Cd metals are sometimes observed on lower temperature parts of the cooler during the process of crystal growth.

Thus, we shall now calculate the degree of thermal decomposition of CdS, which is expressed by

$$\mathrm{CdS\ (solid)}\rightarrow\mathrm{Cd\ (gas)}+\tfrac{1}{2}\mathrm{S_2\ (gas)}\,. \qquad (6)$$

If, in this case, K_p denotes the equilibrium constant of reaction, the equilibrium pressures for gaseous Cd and S_2, denoted by $P_{\mathrm{Cd\ (gas)}}$ and $P_{\mathrm{S_2\ (gas)}}$ respectively, are given by the equation:

$$K_p=P_{\mathrm{Cd\ (gas)}}\cdot P^{1/2}_{\mathrm{S_2\ (gas)}}\,. \qquad (7)$$

The constant K_p can also be expressed in terms of the difference of free energy ΔF_T before and after the occurrence of the chemical transformation as follows:

$$\Delta F_T=-RT\log K_p\,, \qquad (8)$$

while, ΔF_T itself can be calculated by the equation:

$$\Delta F_T=-T\int_0^T\frac{\Delta H_T}{T^2}dT+iT\,, \qquad (9)$$

where i is a constant relating to the difference of entropy and ΔH_T is the difference of heats of formation and is expressed in terms of the difference of specific heats at constant pressure ΔC_p as:

$$\Delta H_T=\Delta H_0+\int_0^T\Delta C_p dT\,, \qquad (10)$$

where ΔH_0 is the difference of heats of formation at absolute zero temperature.

Thus, by (8), (9) and (10), the constant K_p can be obtained as a function of temperature by substituting following numerical values[8]:

$$\left\{\begin{array}{lll} C_p(\mathrm{CdS})=12.9+0.90\times10^{-3}T & & (\mathrm{cal/mol}),\\ C_p(\mathrm{Cd})\ =\ 5.0 & & (\mathrm{cal/g\text{-}atom}),\\ C_p(\mathrm{S_2})\ =\ 6.5+0.001T & & (\mathrm{cal/mol});\end{array}\right.$$

$$\left\{\begin{array}{lll} \Delta H_{298}(\mathrm{CdS})=-34{,}500 & & (\mathrm{cal/mol}),\\ \Delta H_{298}(\mathrm{Cd})\ =\ 26{,}970 & & (\mathrm{cal/g\text{-}atom}),\\ \Delta H_{298}(\mathrm{S_2})\ =\ 29{,}690 & & (\mathrm{cal/mol});\end{array}\right.$$

$$\left\{\begin{array}{lll} \Delta F_{298}(\mathrm{CdS})=-33{,}600 & & (\mathrm{cal/mol}),\\ \Delta F_{298}(\mathrm{Cd})\ =\ 18{,}690 & & (\mathrm{cal/g\text{-}atom}),\\ \Delta F_{298}(\mathrm{S_2})\ =\ 18{,}280 & & (\mathrm{cal/mol}).\end{array}\right.$$

If, then, we take into account that the value of $P_{\mathrm{Cd\ (gas)}}$ is twice as large as that of $P_{\mathrm{S_2\ (gas)}}$, these equilibrium vapor pressures can be calculated as function of temperature. The results are shown in Table III.

Comparing the author's numerical values given in the table with calculated data by S. Shionoya[9] on the equilibrium vapor pressures of gaseous Zn and S_2 from thermally decomposed ZnS, it is found that they are consivered to be appropriate, because the vapor pressure of S_2 from CdS at 1,000°C is about twenty times as large as that from ZnS and is nearly one-third of saturated vapor pressure of CdS.

Since, however, it is desirable that the vapor pressures of gaseous Cd and S_2 are as small as possible, it is necessary to prevent further progress of thermal decomposition by the use of pure nitrogen free from water-vapor or oxygen.

Table III. Equilibrium vapor pressure of gaseous Cd and S_2 from thermally decomposed CdS

Temperature °C	$P_{S_2 (g)}$ mmHg	$P_{Cd (g)}$ mmHg
600	8.49×10^{-4}	1.70×10^{-3}
700	1.53×10^{-2}	3.06×10^{-2}
800	1.59×10^{-1}	3.17×10^{-1}
900	1.09	2.18
1,000	5.47	10.9
1,100	21.4	41.8
1,200	69.3	139
1,300	191	382

(4) *Discussion on saturated vapor pressure*

Calculating the vapor pressure by the use of Eq. (4), it was found that the saturated vapor pressure of CdS in the temperature range as measured by the author varies from 0.01 mmHg up to 4 mmHg. In comparison with the data for the effusion of mercury the flow of vapor through the small hole of the vessel may be regarded as molecular so far as the vapor pressure is less than 0.5 mmHg, because the dimension of the hole is as small as 0.06 mm in diameter. Further, since there exists no transition point in the above-mentioned temperature range, the vapor pressure higher than 0.5 mmHg may still be estimated by Eq. (4), notwithstanding that the flow is no more molecular.

The values of vapor pressure as calculated by the gas transportation method are also plotted against the temperature in Fig. 3. It will readily be seen that they are slightly larger than those calculated by Eq. (4), but inclinations of these two curves, as well as those of curves P, V and H, are all the same, indicating that the value obtained by the author for the energy necessary for sublimation is nearly equal to those obtained by Hsiao⁶⁾ and Veselovskii⁷⁾. Also, the author's values are several times as large as the equilibrium vapor pressures of thermally decomposed CdS.

From these considerations it can be said that the author's values for saturated vapor pressure are appropriate, though, as mentioned already, they are somewhat larger than Pogorelyi's⁵⁾ and Veselovskii's values⁷⁾, but it seems that Hsiao's values⁶⁾ are too small.

§ 4. Aspects of Crystal Growth

In this section, aspects of crystal growth by sublimation method will be described in some detail.

(1) *General view*

As soon as the boat containing CdS powder was inserted into the center of the combustion tube and the cooler was set from the exit side, the sublimation of CdS immediately began to occur, and its vapor was carried downstream by the flow of nitrogen gas and was condensed on the cooler. At the beginning, grains of relatively large size were deposited at the place of higher temperature, while at the place of lower temperature smaller grains were deposited. With the progress of sublimation and the increase of vapor pressure, however, these grains grew

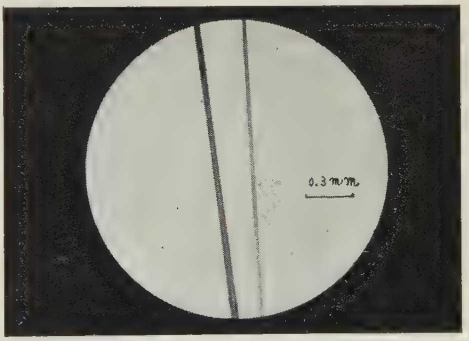

Fig. 5. Needle-shape crystals.

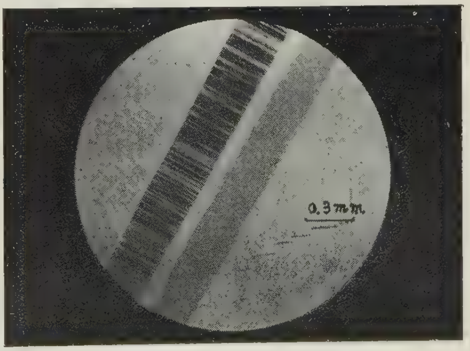

Fig. 6. Laminar crystals.

up and needle-shape crystals as shown in Fig. 5 broke out from nuclei sprouted on the grains. In the case of higher vapor pressure, laminar crystals as shown in Fig. 6 were apt to grow up. Since, in the present experiments, the vapor pressure became still higher, fine needle-shaped and laminar crystals did not grow up. In regions of higher temperatures plate-shape crystals as shown in Fig. 7 were grown up in conformity with the degree of supersaturation, and the dimensions of plates increased to as large as 25×25×1 mm when kept under appropriate conditions. In regions of still higher temperatures, rod-shape crystals as shown in Fig. 8 were grown up slowly.

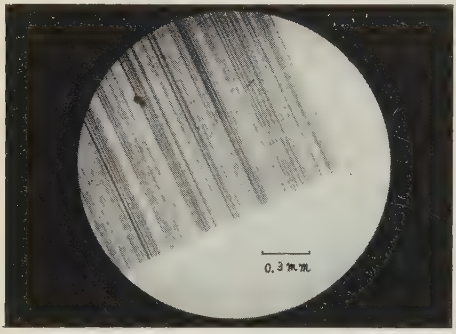

Fig. 7. Plate-shape crystal.

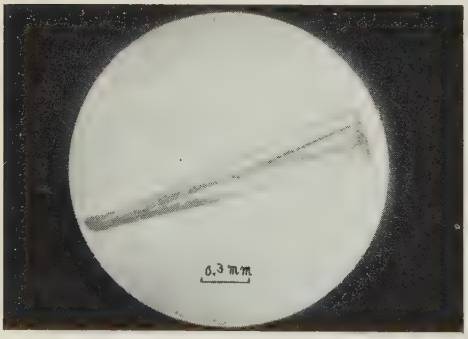

Fig. 8. Rod-shape crystal.

Fig. 2 shows the appearance of the cooler drawn out of the tube when the present experiments were finished. It is found that rodshape crystals, and plate- and clear needle-shape ones are likely to grow up in the regions of 950°C∼1,050°C and 880°C∼960°C respectively, while grown crystals have a tendency to take the forms of complicated needles, laminae and dendrites in the region of 800°C∼850°C and sometimes fine whiskers in the lower region of 650°C∼780°C. Further, orange grains of crystals and yellow powder are found in the regions of 880°C∼750°C and 750°C∼500°C respectively and sometimes a small amount of metallic Cd is obtained in the lower temperature region.

(2) *Growth of needle-shape crystals*

It has been reported by Sears[10] that the screw dislocations may be nuclei of needle-shape crystalls, and in reality these dislocations were observed to lie scattered on the crystalline grains. It was observed, however, that these crystals began to grow abruptly from granular crystals with growing directions parallel to the gradient of vapor density, just at the moment when the sectional areas at the tips of granular crystals became as to fit the degree of supersaturation of the vapor. Under adequate conditions the growing speed of needles was very large, taking sometimes the value of 1 cm/min in case when the diameter of needles were several tens microns.

(3) *Growth of laminar crystals*

It was observed that girdle-shaped or laminar crystals were originated at the side faces of needles, as shown in Fig. 9. Clear crystals free from striations were grown up at the start, but, with the increase of vapor pressure, striations and protuberances appeared on the flat surfaces of the crystals and

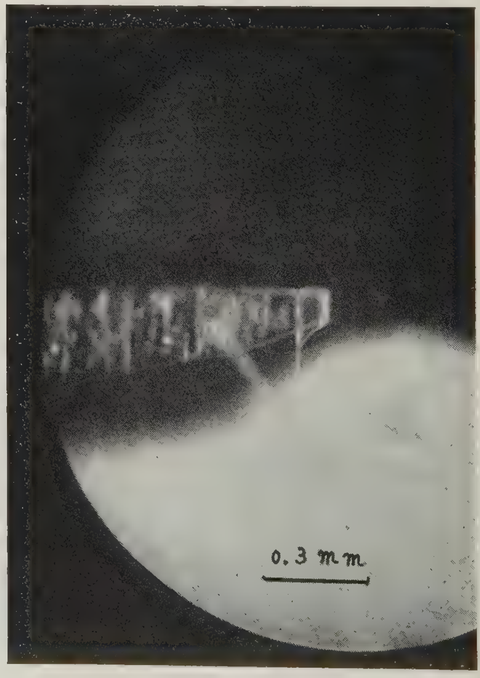

Fig. 9. Growth of laminar crystal,

then changed to be twinlike, because the temperature of growing region was as low as 800°C∼850°C. In conformity with the increase of supersaturation, crystals became of stalactic or granular forms. Under some conditions crystals of the form of thin plate adhered to them.

In short, clear laminar crystals cannot be obtained in the region of 800°C∼850°C as long as the vapor pressure fluctuates or increases. But, if we keep the vapor pressure at a constant value, we can obtain large laminar crystals. In fact, the author was able to produce by Frerichs's method a laminar crystal of as large as about 100×5 ×0.2 mm.

The flat plane of the laminar crystal corresponds to the $(11\bar{2}0)$ plane of the hexagonal type and its growing direction is in most cases perpendicular to the c-axis. In some crystals, however, their growing directions are oblique to the c-axis, and moreover, in some of them the spiral growth is observed.

(4) *Growth of plate-shape crystals*

Plate-shape crystals originated in the region of 880°C∼980°C were grown up continually as long as suitable conditions were kept throughout the process. At first, crystals grew along the direction perpendicular to the c-axis in the $(11\bar{2}0)$ plane, but, as the vapor pressure was increased, the growth in that direction was stopped and the widths of the crystals were increased due to the growth parallel to the c-axis.

If, during the process, there occurred fluctuations in the vapor pressure or mixing of impurities, crystals of various forms were grown up as shown in Figs. 10, 11, 12 and 13. Fig. 10 shows 'islands' due to the

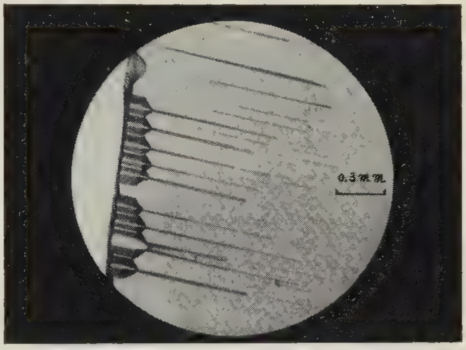

Fig. 10. Growth of 'Island'.

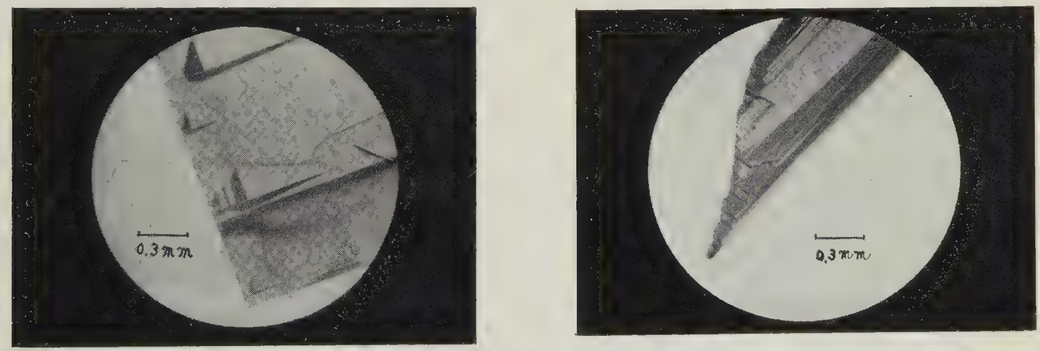

Fig. 11. Growth end.

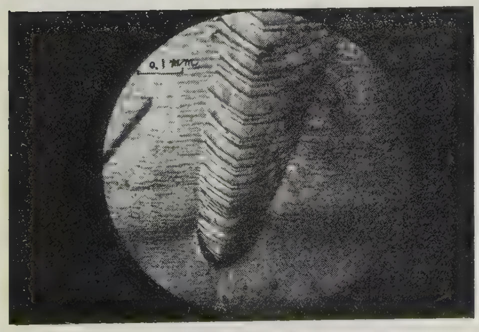

Fig. 12. Variation of growth speed by dislocation.

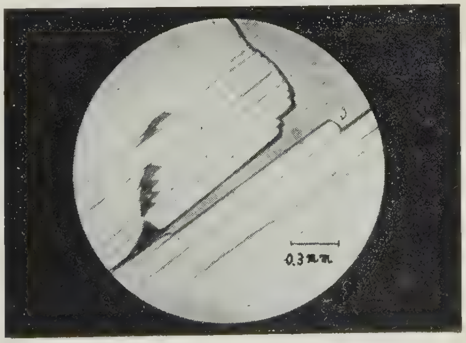

Fig. 13. Growth of needle-shape crystals.

occurrence of dislocations and Fig. 11 shows crystals having remarkable irregularities at their growing edges, while Fig. 12 gives a crystal whose growing speed was altered by dislocation lines. Further, Fig. 14 shows needles grown up from the edge of a plate-shape crystal as well as two-dimensional crystals grown up again from these needles.

Striations on the surfaces of crystals as shown in Fig. 7 are also due to such fluctuations in the vapor pressure.

In case when there was any difference in the vapor pressure along the direction of $[1\bar{1}00]$ axis, there was grown up a crystal as shown in Fig. 14 whose edge makes a certain angle with the c-axis.

Thus, it may be concluded that in order to obtain the normal crystal growth it is essential to keep the vapor pressure constant. In fact, by keeping the vapor pressure constant for several hours we were able to obtain sometimes large single crystals of plateshape as large as 20×20×1 mm.

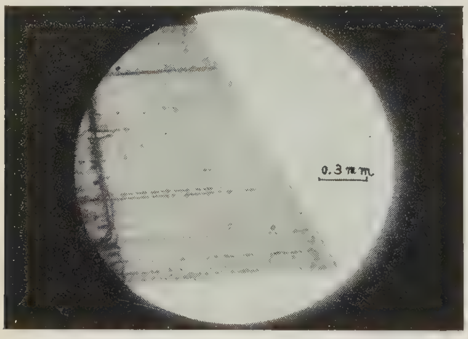

Fig. 14. Growth end and c-axis.

(5) *Growth of rod-shape crystals*

As mentioned already, rod-shape crystals were grown up in the temperature region of 950°C~1,050°C.

In general, needle-shape crystals grown up in the lower temperature region have uniform sectional areas and extend in the direction of the c-axis, having in most cases hexagonal pyramids as their tips. In the case of rod-shape crystals grown up in the higher temperature region, on the contrary, their sectional areas increase along the direction of crystal growth as shown in Fig. 8, suggesting that rod-shape crystals are composed of needle-shape crystals whose growing directions are somewhat inclined to the c-axis. In some cases, tips of the crystals are flat, concave or hollow-ringed (cf. Fig. 15).

The growing process of rod-shape crystals is not quite clear, however. Judging from the fact that the sectional areas increase rather rapidly along the direction of crystal growth, it is not likely to consider above mentioned shape to be due to mosaic structure. It is also impossible to consider these rods to be twins or random assemblies of many crystals.

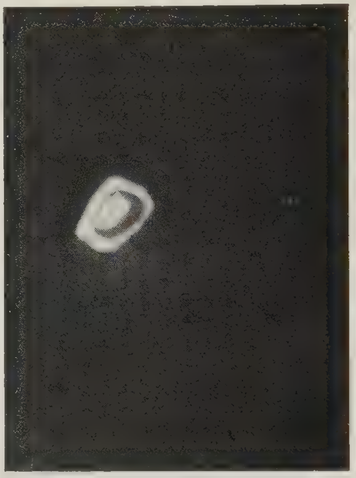

Fig. 15. Top of rod-shape crystal.

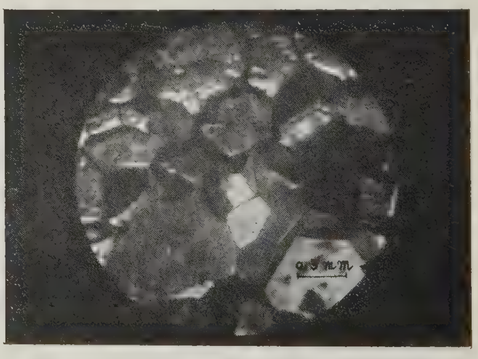

Fig. 16. Block crystals.

(6) *Growth of block crystals*

In the region whose temperature was higher than 1,100°C, block crystals as shown in Fig. 16 were grown up frequently*. These crystals were formed massively, because the growing speed along the c-axis was slow and was nearly equal to those in other directions. The directions of the c-axes of various block crystals are disordered.

---

* Similar block crystals are frequently observed in the case of crystal growth at high temperature in a sealed quartz vessel.

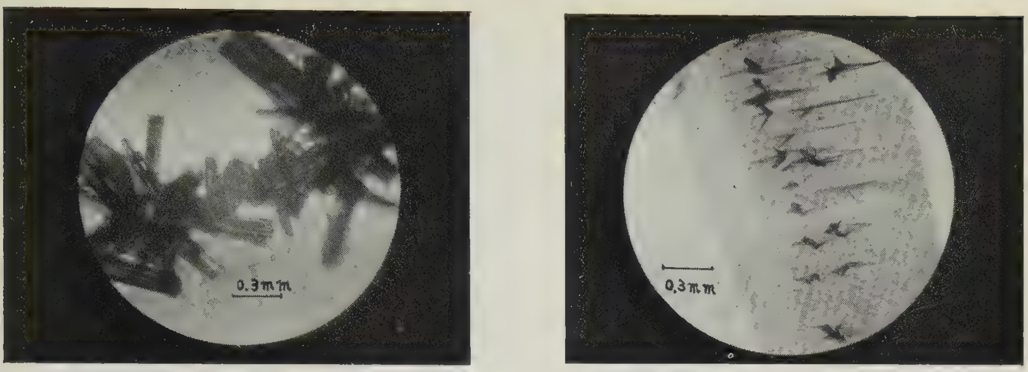

Fig. 17. Crystals grown at low temperature region.

It is to be added here that the growth of block crystals by the method in the flow of nitrogen gas is seriously affected by impurities.

(7) *Growth of network crystals*

In case when the flow velocity of nitrogen gas was very large, it was frequently observed that network or slender fibre crystals were grown up at low temperature region of 650°C～780°C. Since, in this case, the vapor was cooled down rapidly, crystals of small size and complex form were grown up. Curious forms as shown in Fig. 17 were observed rarely, and sometimes slender and long whiskers as shown in Fig. 30 with diameters of several microns were observed.

(8) *Growth of twin crystals*

Twin crystals were frequently grown up when the flow velocity of nitrogen gas was fairly large and the pipe was cooled down sufficiently. It was frequently observed that in some of these twins the twin plane is perpendicular to the surface in which the two wings are lying, and in this case there are two kinds of twins: in one kind the angle between the c-axis and the twin plane is 28.5°

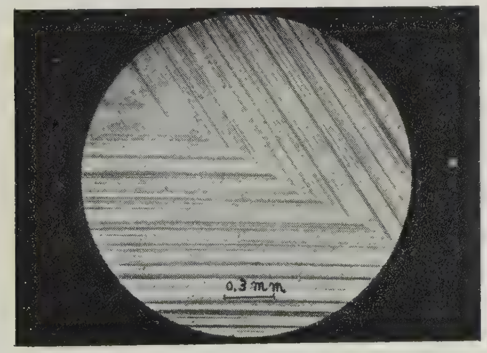

Fig. 18. 28.5° twin.

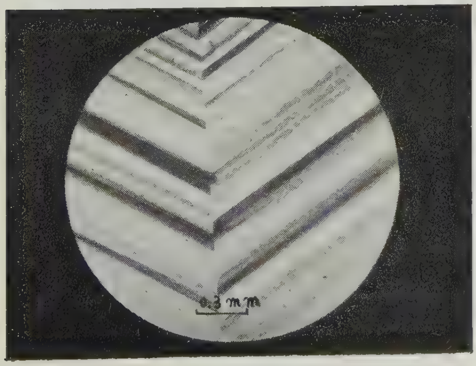

Fig. 19. 58° twin.

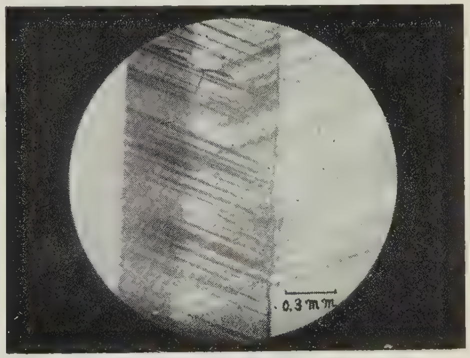

Fig. 20. 73° twin.

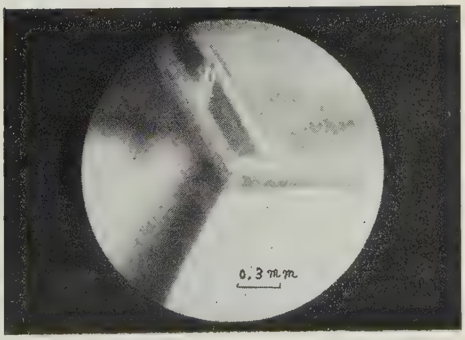

Fig. 21. Repeated twin.

as shown in Fig. 18, while in the other the said angle is 58° as shown in Fig. 19. Moreover, we observed some twins in which the two crystals make an angle of 120° with each other and the angle between the line of intersection of these two crystals and the c-axis is 73° or 69.5° as shown in Fig. 20. Also, the repeated twins having three wings separated mutually by an angle of 120° as shown in Fig. 21 were rarely observed.

The growth of these twin crystals may perhaps be due to several kinds of causes, namely (1) the branching of needle-shape crystals under favorable vapor pressure, (2) the branching of plate-shape crystals in the course of crystal growth as shown in Fig. 22, and (3) the irregularities broken out on the surfaces of plate-shape crystals.

§ 5. Observations on the Grown Crystals

(1) *Inspections by X-rays*

It was found out by X-ray observations that a typical plate-shape crystal as shown in Fig. 7 is a single crystal of hexagonal type with lattice constants a=4.136 Å and c=6.714 Å and its surface corresponds with the (1120)-surface. Striations on the surface of this crystal are parallel to the c-axis.

Fig. 23 shows the Laue photograph of a plate-shape crystal and Fig. 24 gives the rotational diffraction photograph of a needle-shape crystal as obtained by rotating it

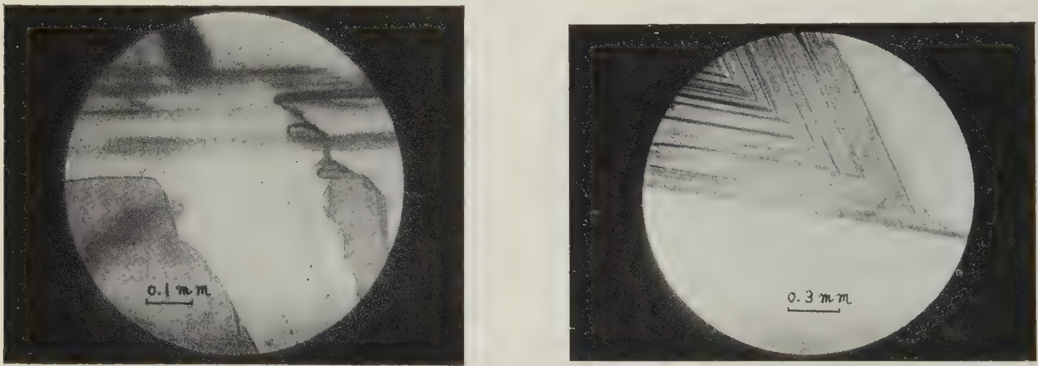

Fig. 22. Growth of twin.

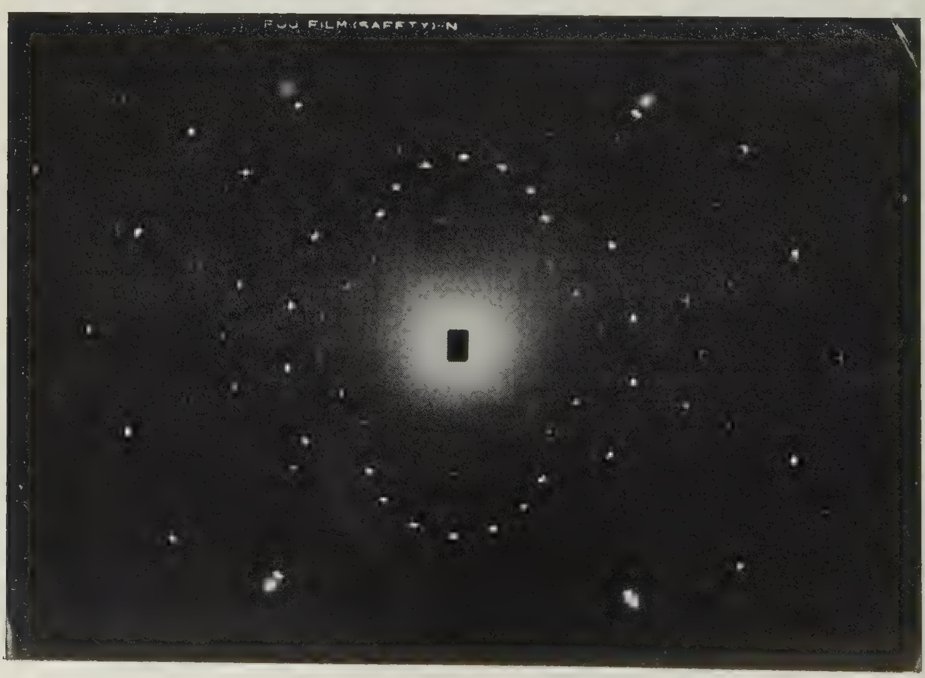

Fig. 23. X-ray Laue photograph.

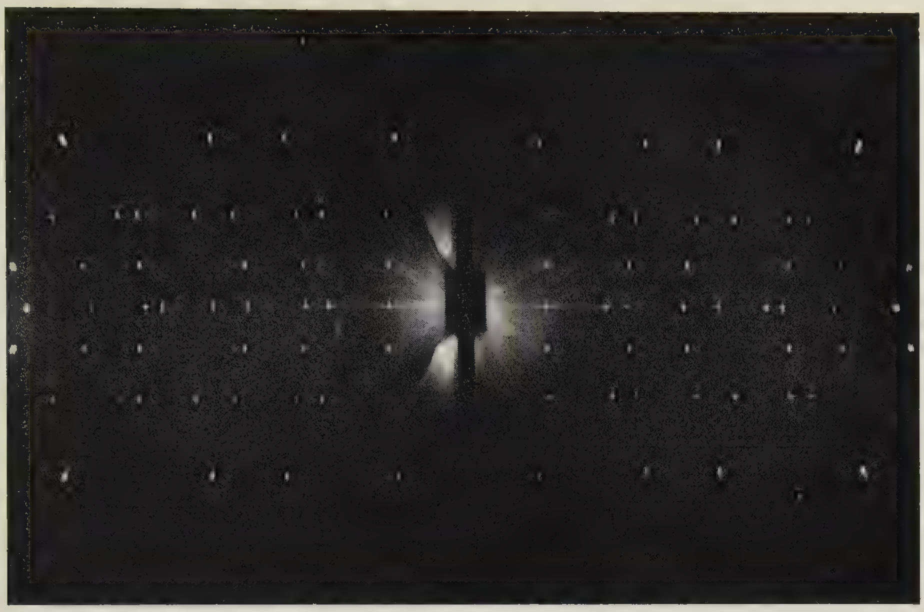

Fig. 24. X-ray rotation photograph.

around its c-axis. No strain nor any disorder is found in these photographs except diffused dispersions which are supposed to be due to lattice vibrations.

Observation of Debye photographs of rod-shape and block crystals shows that they are also of hexagonal type.

(2) *Inspections by electron-rays*

A transmission photograph of electron-rays through a very thin plate-shape crystal with thickness of about 300 Å is given in Fig. 25.

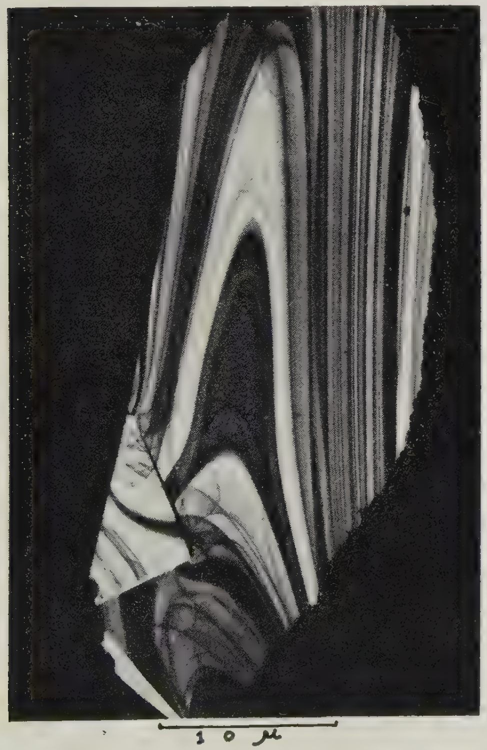

Fig. 25. Transmission photograph by electron-rays.

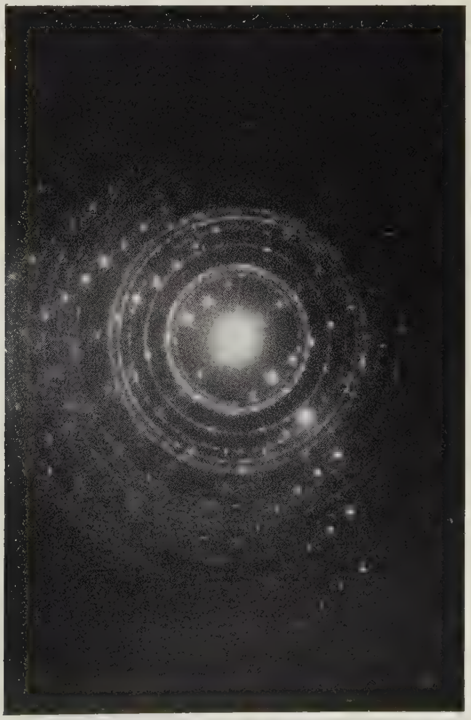

Fig. 26. Electron diffraction photograph (Rings are referred to ZnO).

In this figure are observed interference stripes of equal thickness, which indicate that the crystal structure is clear even in extremely thin parts.

Fig. 26 gives the electron diffraction photograph of the crystal where microscopic picture is shown in Fig. 25. From Fig. 26 it is found that the surface of the thin plate corresponds to the (1120)-surface and that this diffraction pattern can be interpreted by taking $a=4.136$ Å and $c=6.714$ Å.

(3) *Results of spectroscopic analysis of the specimens*

In Table IV are shown the results of spectroscopic analysis on the degree of impurities contained both in the crystalline powder as used in the present experiment and in the grown crystals. It can be generally said that detected quantities of impurities of impurities are somewhat more in such crystals that were grown up in lower and higher temperature regions.

Table IV. Spectrochemical analysis results of impurity contained in CdS.

	Powder %	Crystal %
Si	0.01 —0.001	0.01 --0.001
Fe	0.001—0.0001	0.001—0.0001
Al	0.0001	0.0001
Mg	0.001	0.001—0.0001
Ca	0.001	0.001—0.0001
Ag	0.001–0.0001	0.001—0.0001
Cu	0.001—0.0001	0.001—0.0001

(4) *Visual and optical observations*

By visual inspections of single crystals it is noticed, first of all, that there are striations on their surfaces which, as mentioned before, were caused by the variation of grown velocitiy. Some of the striations start on the way of crystal growth or form the "islands" as shown in Fig. 10. The starting-points of these striations and islands can be connected by a straight line which seems to be concerned with the line of dislocation. In Fig. 12 it is observed that the growing speed is changed due to the dislocation appeared in the central part of the picture. Further, it is supposed that in case when needle-shape crystals were grown up from plate-shape ones, as shown in Fig. 13, the dislocations exposed on the side faces of the latter play an important role.

Next, it was found that due to the difference of growing speeds along the $[1\bar{1}00]$ axis and the c-axis, the edge of grown crystal makes a certain angle with the c-axis as shown in Fig. 14. Values of the said angle hitherto observed were 10°, 23.5°, 28.5°, 35°, 38.5°, 41°, 47°, 53°, 55°, 58°, 65°, 69.5°, 73°, 79.5° and 90°, and among them most frequently

-	$\sqrt{3}a$	$2\sqrt{3}a$	$3\sqrt{3}a$	$4\sqrt{3}a$	$5\sqrt{3}a$	$6\sqrt{3}a$	

observed values were 47°, 58°, 69.5°, 73°, 79.5° and 90°. By taking into account that crystal grows by steps of unit cell, these angles can be calculated by the use of lattice constants ***a*** and ***c***. Both the measured and calculated values are given in Table V.

The atomic arrangements of twins whose two wings lie in a plane as shown in Fig. 18 and 19 are represented in Figs. 27 and 28. In case of twins in which the angle between the line of intersection of two crystals and the c-axis is 73° or 69.5°, considerable amounts of atomic displacements from normal site should be necessary for stable atomic arrangements even if we restrict our considerations to the line of intersection of two crystals, so that the two planes should intersect with each other by an appropriate and definite angle, giving rise to produce vacancies on the line of intersection which have possibilities of trapping impurities.

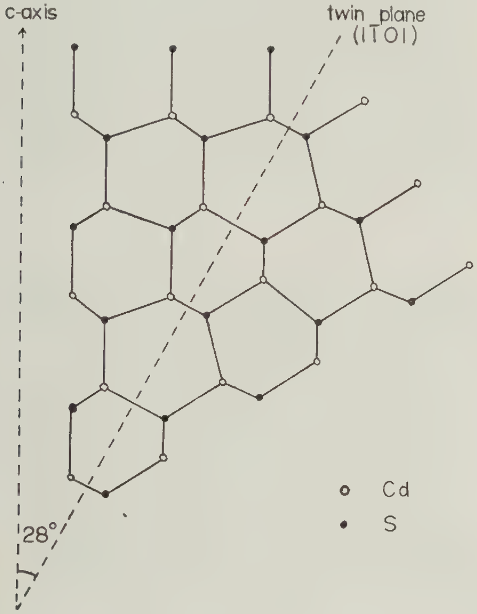

Fig. 27. Atomic arrangement of 28° twin, projected to (11$\bar{2}$0) plane.

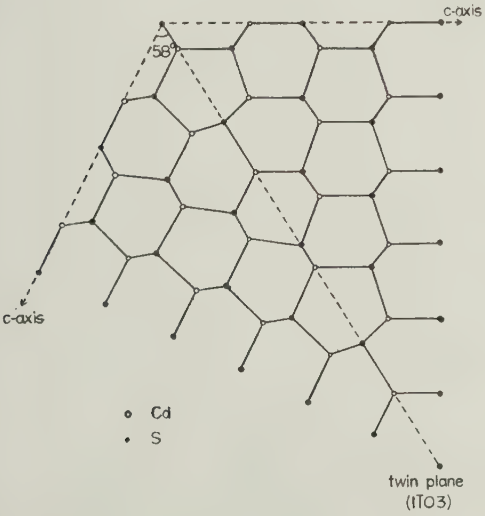

Fig. 28. Atomic arrangement of 58° twin, projected to (11$\bar{2}$0) plane.

Crystals as shown in Fig. 7 are quite uniform even when they are inspected by polarized light. However, any irregularities of crystals and variations in their thickness as well as twin boundaries can be detected by polarized light. The maximum transmission of polarized light through a crystal is obtained when the plane of polarized light is parallel to the c-axis.

As an addendum, a visible transmission curve through a plate-shape crystal with size of 10×10×0.33 mm is shown in Fig. 29.

(5) *Perfect crystals*

Many 'whiskers' were observed among needle-shape crystals grown up in low temperature region, and some of them were of nearly perfect crystal structure and were

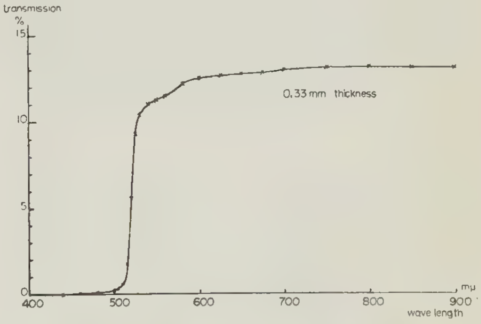

Fig. 29. Spectral transmission curve.

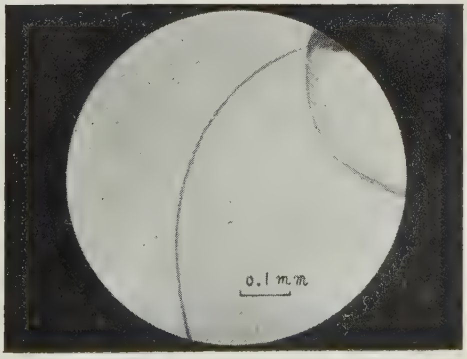

Fig. 30. Elastically bended needle crystal.

easily bent elastically in the form of a circular arc. A typical one is shown in Fig. 30. If, in this case, we denote the radius of cross-section of a whisker and its radius of curvature by r and R respectively, the magnitude of extension e of the whisker is given by the formula:

$$e=r/R\,. \tag{11}$$

If we take $r=15.5\mu$ and $R=1.4\,\text{mm}$ this formula gives $e=1.1\times10^{-2}$. This value seems to be adequate as compared with the corresponding values 1.5×10^{-2} and 1.1×10^{-2} for Cu[11] and Zn[12] respectively.

(6) *Luminescence*

Red luminescence was emitted when CdS crystals containing very small amount of silver or copper were irradiated by 3650 Å ultraviolet rays. In this case, however, luminescence was not always emitted uniformly from the whole parts of crystals but strongly emitted locally from the boundaries or irregularities of crystals as shown in Figs. 31 and 32. On the other hand, it might be possible that luminescence is unusually strong at the edge of a crystal because of its high refractive index, even though the whole part of the crystal radiates uniform luminescence. In reality, crystals containing more amount of silver or copper radiate from their whole parts, but even in those cases luminescence is rather strong at irregularities of crystals. In another case, luminescence is not always strong in all irregular parts of crystals as shown in Fig. 32, and in some cases there can be seen fairly different intensities along the boundaries.

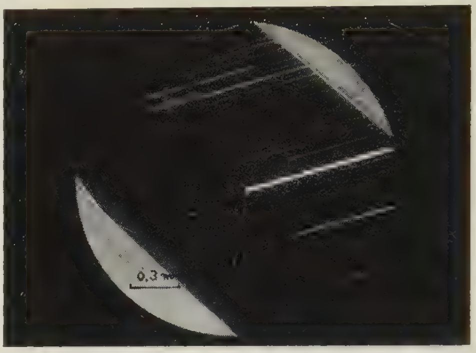

Fig. 31. Luminescence (White lines are red luminescent by 3650Å UV light.).

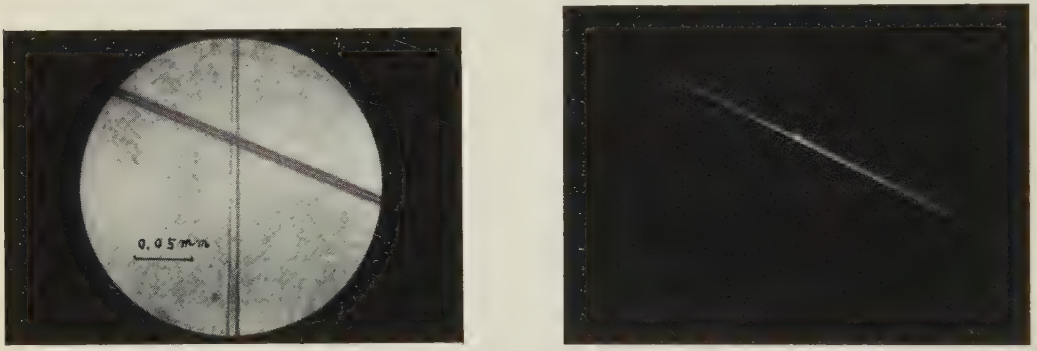

Fig. 32. Transmission (left) and luminescence (right).

In short, it may be concluded that luminescence is strong at specific irregularities or boundaries, and this phenomenon can be utilized as one useful means to search for irregularities of crystals. Moreover, the aspects of luminescence change according to the heattreatment of crystals and this phenomenon is also a notable fact, because it seems to be related with the movement of impurities, irregularities or dislocations.

There was no luminescence from the axis of intersection of 28.5° or 58° twins, but strong radiation was observed from the axis of intersection of 69.5° or 73° twins. The latter phenomenon seems to be related with the fact that impurities are likely to be captured by vacancies which are produced in the process of crystal growth.

§ 6. Summary and Conclusion

In the present paper, the author has discussed the process of growth of CdS single crystals by the method of sublimation and recrystallization in the flow of nitrogen gas and inspected grown crystals in detail. The results obtained may be summarized in the following lines.

In order to obtain any required crystal shape it is quite essential to keep the vapor pressure continuously at a definite value. Values of the vapor pressure suitable for the growth of specific kinds of crystal seapes are as follows: 8∼35 mmHg for the growth of rod-shape crystals; 2∼13 mmHg for plate-shape crystals; 0.4∼3 mmHg for thick needles of about one-tenth mm in diameter and 0.005 ∼0.05 mmHg for fine needles of scores of microns in diameter.

In the course of observations on growing crystals, the author has paid special attention to the following two points: one point is to ascertain the origins of crystal growth and the other is to search for dislocations which were easily found out, since the CdS crystals were thin and transparent, and, at the same time, to study the effect of those dislocations upon the crystal growth.

For instance, it has been recognized that needle-shape crystals were grown up from screw dislocations, while whiskers were grown up from irregularities of the cooler in the highest temperature region where the CdS vapor was condensed. As to the growth of laminar crystals from the side-faces of needle-shape ones as shown in Fig. 9, it has been supposed that at first a needle-shape crystal grows up in the form of spiral and then a laminar crystal begins to grow up form the growing tip of the spiral just at the moment when the tip has become in such a direction along which the vapor-density gradient is appropriate. It has also been observed that dislocations have serious influences upon the growth of needle-shape crystals from grains or from plate-shape crystals, the occurrence of striations on plate-shape crystals, the variation of growing velocities, the origination of twins, luminescence and so on.

In general, CdS single crystals are yellow in color, transparent and thin, and are also chemically stable in air, so that they are quite suitable for investigating optically the process of crystal growth and internal irregularities. They are also very suitable for studying the profound characteristics of CdS peculiar to semiconductors, such as visualization of dislocations, the relation to luminescence, the appearance of penetrated impurities as well as properties of perfect crystals. In a future paper, the author intends to carry out investigations on these matters by making use of various forms of clear and large single crystals obtained in the present experiment.

Acknowledgement

In conclusion, the author wishes to express his sincere thanks to Professors Y. Uchida and K. Tanaka of Kyoto University, Professor R. Kiriyama of Osaka University, Assistant Professor S. Shionoya of Yokohama University and Dr. H. Yamashita in our laboratory for their kind guidance. The author's thanks are also due to Mr. Seto of Kyoto University, Mr. S. Maruyama of Osaka Women's College and members in our laboratory for their instructive suggestions and cooperations.

Induced Conductivity of CdS by β- and γ-rays

By Sumiaki IBUKI

Research Laboratory, Mitsubishi Elec. Mfg. Co., Amagasaki, Japan

(Received December 1, 1958)

Properties of CdS crystals were investigated under irradiation by β-rays from 10 *mc* of Sr^{90} or from the accelerator of Van de Graaff type and γ-rays from 1 *c* of Cs^{137} or from 200 *c* of Co^{60}. The ohmic contact of electrodes and the crystal uniformity were first inspected, and some properties concerning the induced conductivity of CdS crystals by β- and γ-rays were discussed in comparison with those observed when the crystals were irradiated by visible light. It has been concluded that the sample crystals grown by the author's method are uniform and that they have low trap density and high sensitivity for β- or γ-rays. It was also shown that the elementary phenomena of the induced conductivity in the case of β- or γ-ray irradiation were quite similar to those in the case of visible-light irradiation, and that the number of electrons excited into the conduction band by a β-particle was about one hundred times larger than that by a γ-particle of 1.3~1.5 Mev.

§ 1. Introduction

It has been well known that the CdS single crystal is a high sensitive photoconductor and its electric resistivity is decreased by irradiation of X-, γ-, β- and α-rays[1)-4)]. By making use of the above property of the crystal, some trials have been made[5)] to use the crystal as the detector of γ-rays.

The author successfully obtained large single crystals of CdS as reported in the previous papers[6)]. In the present paper will be reported several properties of these crystals induced by irradiation of β- and γ-rays as well as visible light and some interesting results particularly about the elementary process of photoconductivity and the efficiency of irradiation for β- or γ-rays.

§ 2. Samples and Electric Contacts

Samples used in the present experiment were plate-shape crystals which were cloven parallel to the c-axis of the CdS single crystal. In order to examine the electrode contacts, voltage *versus* current (V-I) charac-

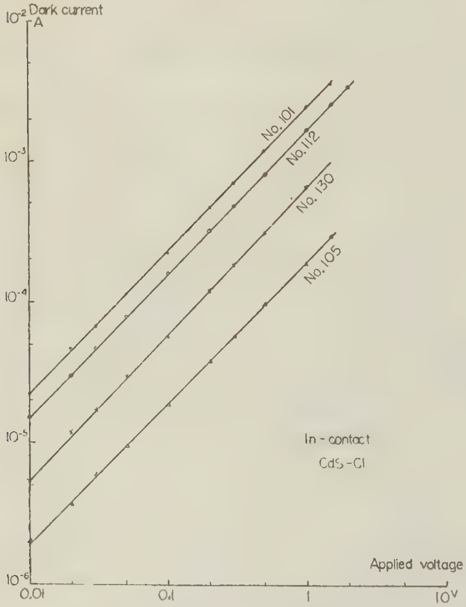

Fig. 1. Voltage dependence of dark current.

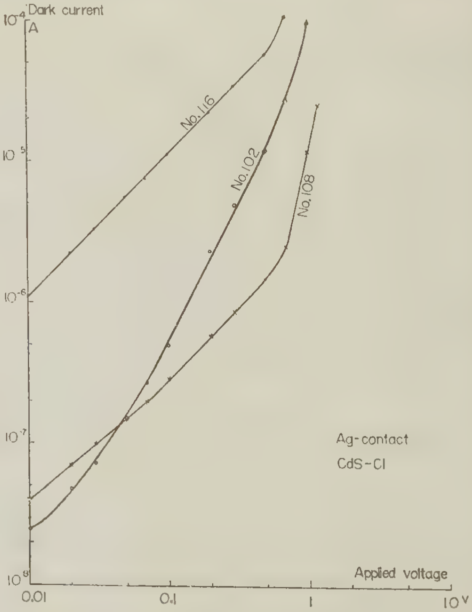

Fig. 2. Voltage dependence of dark current.

teristics at low applied voltage were measured for the electrodes of several kinds of materials, namely, In, Ag-paste, evaporated Ag and Acquadag. The results are shown in Figs. 1∼4. Among these materials evaporated In was most favorable to the electrode as already reported⁷⁾; the so-called barrier effect at the contact parts was not observed and the V-I curve was a straight line down to low voltage region as shown in Figs. 1 and 3. Moreover, $1/f$ noise caused by electrode contact was very little in the case of In electrode in comparison with the cases of other materials.

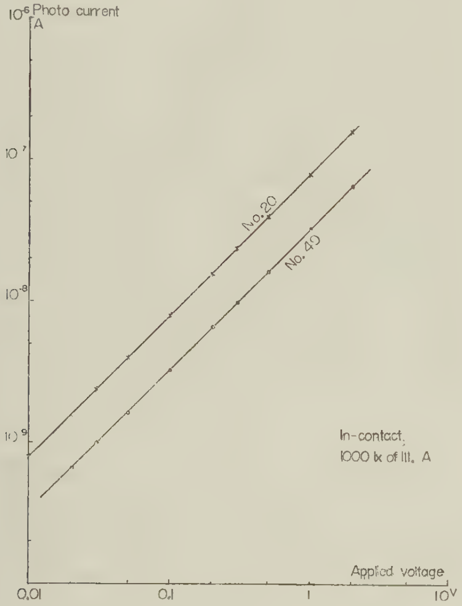

Fig. 3. Voltage dependence of photocurrent.

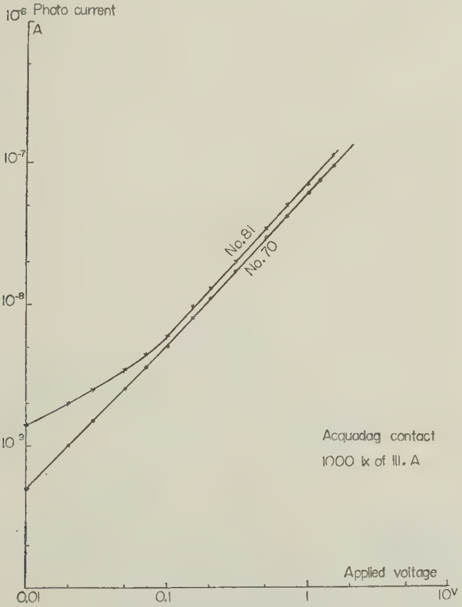

Fig. 4. Voltage dependence of photocurrent.

The uniformity of sample crystals was examined by the following experiments. First, a sample crystal was uniformly illuminated on its whole surface area by light flux and a shutter was inserted so as to cut the light flux as shown in the inset in Fig. 5. Then

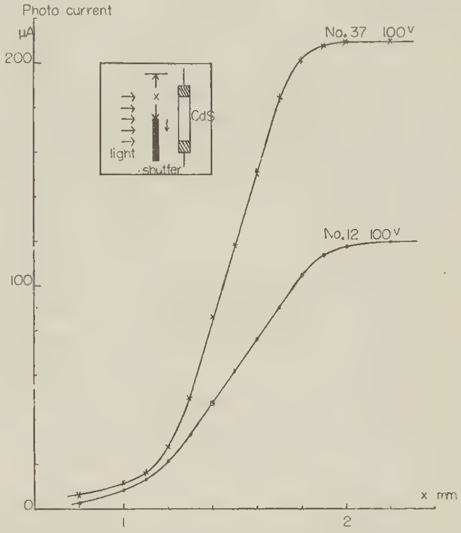

Fig. 5. Uniform characteristics of crystals.

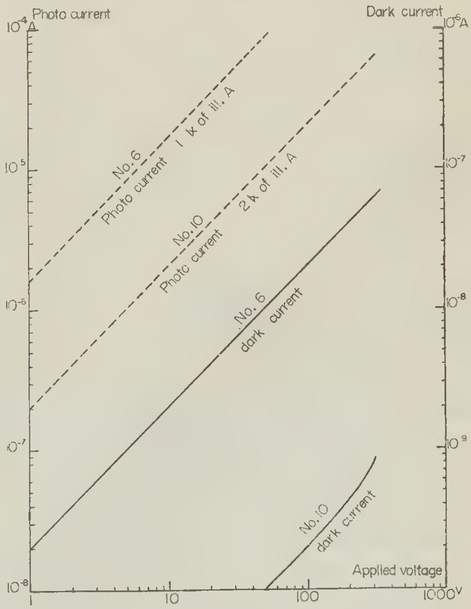

Fig. 6. Voltage dependence of dark and photocurrent.

the relation between the irradiated area and the photocurrent induced in the crystal was measured by moving the shutter from the one electrode side towards the other side. The curve showing this relationship is shown in Fig. 5. It has been reported[8),9)] that uniform ZnS and CdS crystals are hardly obtainable and curves similar to that in Fig. 5 fluctuate. But CdS crystals produced by the author are exceedingly uniform and hence the potential gradient is equal everywhere in the whole crystal, as can be seen from Fig. 5.

§ 3. Some Properties of Photoconductivity

Some properties of the CdS crystal irradiated by visible light was previously investigated in order to compare them with the effects induced by irradiation of β- and γ-rays.

V-I curves of the dark current and the photocurrent excited by the light from illuminant A are shown in Fig. 6. The photocurrent increases linearly with applied voltage up to high voltage region, but the dark current seems to be influenced by space charge in high voltage region.

Photocurrent characteristic *versus* light intensity is given in Fig. 7. The photocurrent increases almost linearly with light intensity in lower intensity region, but its increasing rate approaches a half power of light intensity in higher intensity region. As will be discussed in § 5, a knick point appears on the curve in Fig. 7 for the light intensity, at which the density of excited free photoelectrons becomes equal to that of traps.

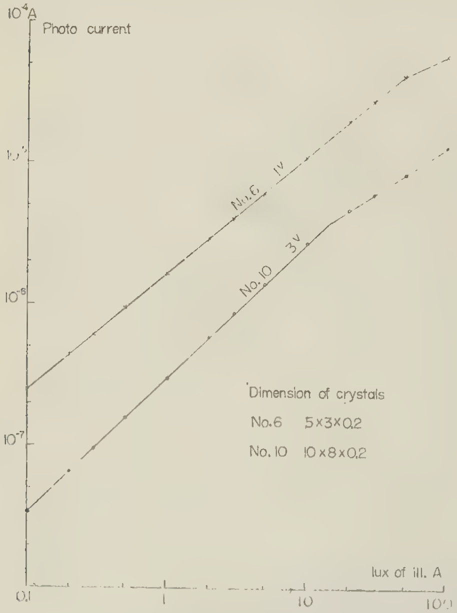

Fig. 7. Photocurrent-irradiation characteristics.

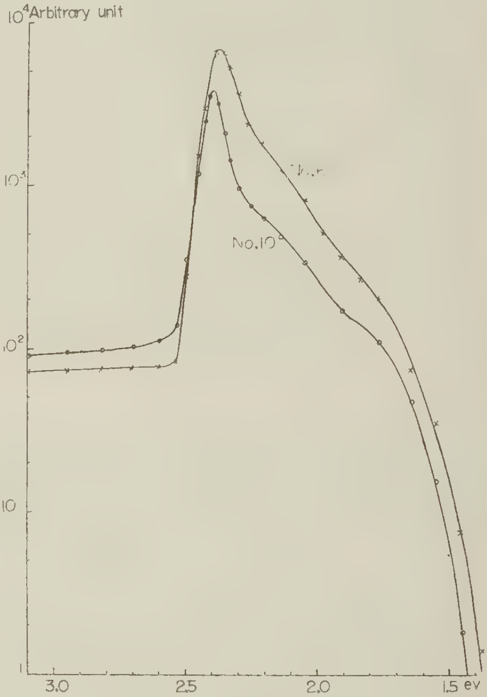

Fig. 8. Spectral sensitivity.

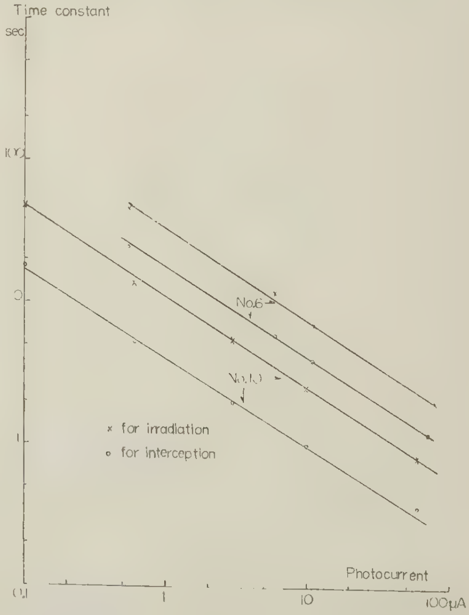

Fig. 9. Time constant-photocurrent characteristics (50 V).

The spectral sensitivity of photoconductivity in the visible region is given in Fig. 8. In this figure there are found one strong peak at absorption edge and several small humps at longer wavelength side, whose positions agree well with those of the optical absorption peaks.

The time constant was measured when the crystal put in dark was exposed to the visible light or when the irradiating light was shut off. The results are shown in Fig. 9, by taking photocurrent as the abscissa in order to compare below them with those for β- and γ-rays. It will be seen from this figure that the time constant decreases with increasing photocurrent and its magnitude at the instant of irradiation is larger than that at the instant of shut-off. Besides these facts, we have also observed that the time constant seems to decrease to some extent when the applied voltage is raised, and that high sensitive crystals show larger time constant, while low sensitive crystals smaller one.

§ 4. Properties for β- and γ-rays

Some properties of CdS crystals were investigated for β- and γ-rays irradiation. The voltage dependence of the current excited by β-rays from 10 *mc* of Sr^{90} is shown in Fig. 10. It will be seen that the conductivity of the crystal changes from $1\times10^{-8}\Omega^{-1}\,cm^{-1}$ to $1\times10^{-4}\Omega^{-1}\,cm^{-1}$ by the irradiation at a distance of 5 cm from the β-ray source. The crystals prepared by the author have far higher sensitivity than those used by Hollander5), their conductivity being $5\times10^{-5}\Omega^{-1}\,cm^{-1}$ by the irradiation of β-rays at a distance of 5 mm apart from 5 *mc* source. In the author's experiments the number of electrons, which knocked the area of 5×3 mm of the crystal, is calculated to be 1.8×10^5 per second and then the current induced in the crystal is 60 μA, namely 3.8×10^{14} electrons per second under the applied electric field of 500 V/cm. It is estimated, therefore, that the amplification of 2.1×10^9 is performed in the CdS crystal.

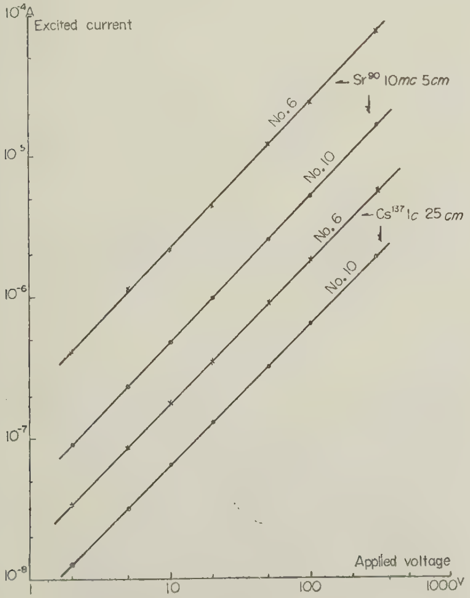

Fig. 10. Voltage dependence of excited current by radio isotope.

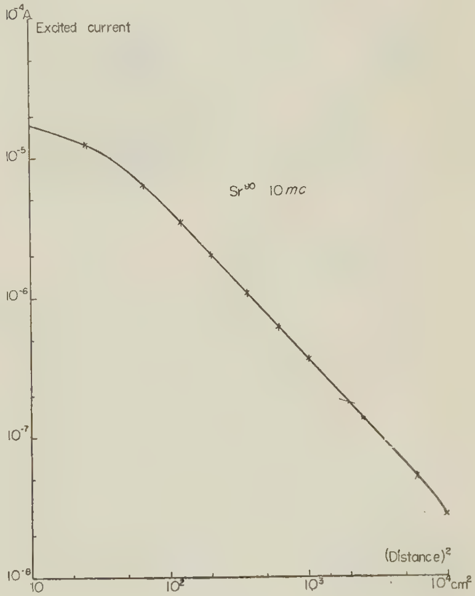

Fig. 11. Distance dependence of excited current (50 V, No. 6).

The excited current characteristic plotted against the distance from the β-ray source to the CdS crystal is given in Fig. 11. The current range in this figure covers just the range in which the linear relationship holds between the photocurrent and the light intensity. Near the β-ray source the induced current does not increase inversely proportional to the square of the distance, because the source has a disk shape of 30 mm in diameter and 5 mm in thickness. On the contrary, the current shows a tendency to fall off rather rapidly at large distances from the source because of the effect of the absorption of β-rays by air. In the intermediate range, however, the current increases just inversely proportional to the square of the distance.

The absorption of β-rays from Sr^{90} by various aluminium plates was measured. The geometry of experimental arrangements and the results obtained are given in Fig. 12. It will be seen that remarkable absorption occurs in the case of aluminium plates of thickness of 0.1~0.3 mm, and this fact can be explained by the absorption of low energy β-rays generated by the back scattering due to the source and its holder. Taking the point A on the absorption curve as the base-point, the half-thickness for 2.2 Mev β-rays from Sr^{90} becomes 0.6 mm for aluminium, namely 162 mg/cm². This value is nearly equal to 150 mg/cm² which is calculated from the well-known formula:

$$a=0.046E^{3/2}\ (\mathrm{gr/cm^2})\,, \qquad (1)$$

where a is the half-thickness and E the maximum energy. The intensity of β-rays transmitted through the substance of d cm in thickness is given by

$$I=I_0 \exp(-Kd)\,, \qquad (2)$$

where K is the absorption constant in cm^{-1} and I the intensity of the incident rays. The absorption curve approximately fits the above equation between the points B and C in Fig. 12, but it deviates from this equation in the part between the points D and E corresponding to large thickness of aluminium plate. This deviation can be explained by the effects of Bremsstrahlung X-rays. Considering the point F in this figure as the practical range R mg/cm of β-rays from Sr^{90}, R becomes 1080 mg/cm², which corresponds to about 4 mm in thickness. This value agrees fairly well with the value of 1060 mg/cm² calculated from the equation[10]:

$$R=0.542E-0.133\ (\mathrm{mg/cm^2})\,. \qquad (3)$$

Even when the geometry of experimental arrangements was changed, the shape of absorption curve was changed only slightly and the half-thickness and the practical range remained nearly constant. Thus the absorption of β-rays by aluminium plate can be measured with satisfactory precision and reproducibility by the use of CdS crystals.

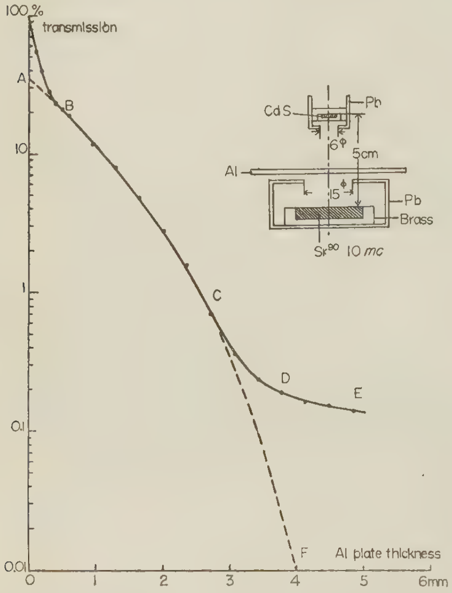

Fig. 12. Absorption of β-rays from Sr^{90} by Al plate.

Time constant was measured when the CdS crystal was irradiated by β-rays from Sr^{90} or when it was screened off from them, and it was found, as expected from the results in the case of visible light, that the time constant at the instant of irradiation-on was

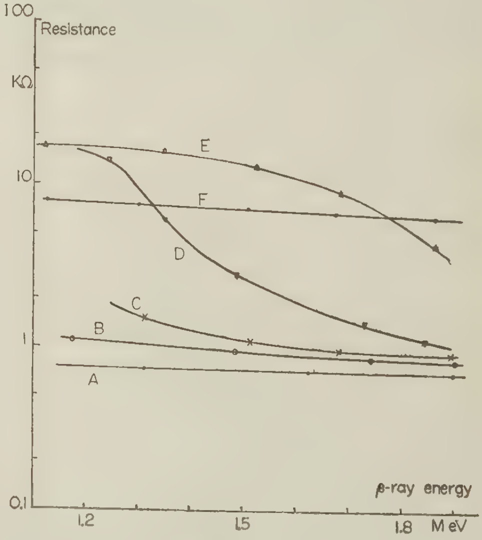

Fig. 13. β-rays irradiation characteristics from Van de Graaff generator (No. 1).
A irradiating current 0.1 μA
B 0.025 μA
C 0.025 μA+1 mm thickness Al plate
D 0.025 μA+2 mm thickness Al plate
E 0.025 μA+3 mm thickness Al plate
F 0.0015 μA

somewhat longer than that at the instant of screening-off, and that the magnitudes of both these time constants were nearly equal to those for visible light respectively in case when the conductivity of the crystal for β-ray irradiation was the same as that for visible light irradiation.

In Figs. 13 and 14 are shown the results of measurements on the resistance and the energy characteristics for exciting particle of the CdS crystal when it is irradiated by β-rays from the accelerator of Van de Graaff type manufactured in our laboratory. In Fig. 13 the conductivity of the crystal seems to increase slightly with the increase of the energy of exciting β-rays, but taking the focusing effects of β-rays into account, it may be considered that the conductivity is almost flat in the range from 1 to 2 Mev. In Fig. 14, which shows the conductivity *versus* exciting β-ray intensity, the conductivity becomes to be proportional to a half power of exciting intensity at the exciting current of 2.4×10^{-11} A, namely the number of irradiating electrons of 1.1×10^{9} electrons/cm³ sec, and then it tends to saturate at 7.5×10^{-9} A, namely 3.1×10^{11} electrons/cm³ sec. For irradiation of β-rays from Van de Graaff the *V-I* characteristic of the CdS crystal was also linear in low voltage range, but the resistivity of the crystal was decreased by the high density irradiation of β-rays because the temperature of the crystal was raised. The time constant was less than one second in the whole intensity range of exciting current in Fig. 14.

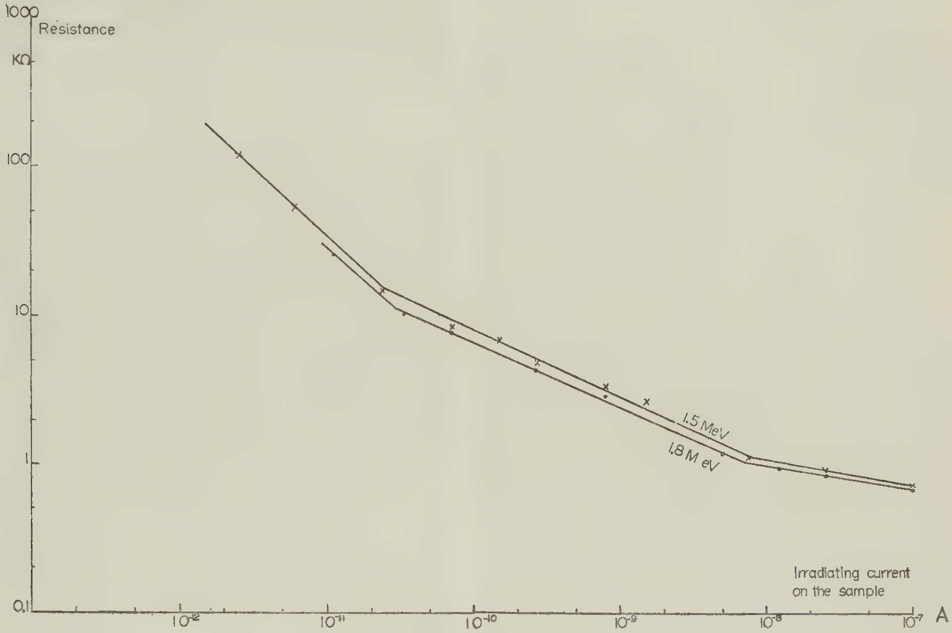

Fig. 14. β-rays irradiation characteristics from Van de Graaff generator (No. 1).

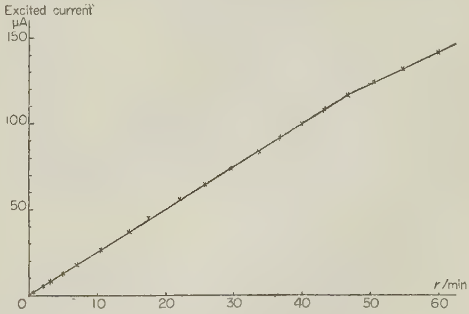

Fig. 15. Co⁶⁰ irradiation characteristics (No. 10, 90 V).

Some experimental results in the case of γ-ray irradiation are given below. Fig. 15 shows the intensity dependence of excited current for irradiation of γ-rays from 200 *c* of Co⁶⁰. The current increases proportionally to the irradiating intensity from 10 to 2800 *r*/hr, but a knick appears at 2,850 *r*/hr, where the electric resistance of the CdS crystal is 750 kΩ. This value agrees well with that of the resistance at the knick of the photocurrent curve in Fig. 4.

The experiments were also carried out for the irradiation of γ-rays from 1 *c* of Cs^{137}. The *V-I* characteristic of the CdS crystal was linear as in the case of β-ray irradiation. The relation between the excited current and the irradiated intensity was linear in the range from 0.4 to 40 *r*/hr, when the crystal was exposed at various distances from the γ-ray source. In the experiments of the sample No. 6 the number of γ-particles, which knocked the area of 5×3 mm of the crystal at 25 cm apart from 1 *c* of Cs^{137}, were calculated to be 7.1×10^5 particles/sec, and then the electron current excited by these γ-particles was 5μA, namely 3×10^{13} electrons/sec under the electric field of 500 V/cm. It is concluded, therefore, that the amplification of 4.4×10^7 is performed in the CdS crystal and the degree of amplification is about fiftieth of that for β-ray irradiation. From the above facts it may be concluded that the electron current excited by γ-rays is generally less and hence the time constant is larger than those for β-rays when the number of irradiating particles is the same for both γ- and β-rays excitations. The time constants in the case of irradiating-on and -off of γ-rays were approximately the same as those in the case of β-ray irradiation so long as the conductivity of the crystal had the same value on irradiation. It is interesting, however, that under the irradiation of γ-rays of 0.4~40 *r*/hr from Cs^{137} the induced current turned to zero as soon as the applied voltage was cut off and it did not returned to the former value without the time lag of a few second after the voltage was re-applied.

§ 5. Discussions

Let us consider first the elementary process of the photo-conductivity of CdS crystals. Writing $Q\,\text{cm}^{-3}\,\text{sec}^{-1}$ for the number of electrons excited by light into conduction band and $M\,\text{cm}^{-3}$ for the density of traps, then the time rate of change in the density n of photoelectrons in conduction band is given by

$$dn/dt=Q-Bn(n+M)\,, \qquad (4)$$

provided that photoelectrons have the same recombination coefficient B for both hole and trap, and that the number of thermally excited electrons is very small. At the stationary state $dn/dt=0$ and then

$$Q=Bn(n+M)\,. \qquad (5)$$

For low light intensity $n\ll M$ and Eq. (5) becomes

$$n=Q/BM\,. \qquad (6)$$

In this case photoelectrons mainly recombine with traps and the photocurrent, which is proportional to n, will increase linearly with the increase of exciting light intensity. On the other hand, for intense light $n\gg M$ and Eq. (5) leads to

$$n^2=Q/B\,. \qquad (7)$$

Then the recombination of photoelectrons occurs only with holes because the traps are filled and the photocurrent will be proportional to a half power of light intensity. Thus the curve of photocurrent *versus* light intensity will show a knick point at the light intensity satisfying the condition $n=M$. These behaviors of photocurrent are seen in both curves in Fig. 7 and the knick appears at the point corresponding to the photocurrent of 40μA and the illumination of 50 lux under the applied voltage of 1 V for the sample No. 6 or to 4μA and 14 lux under 3 V for the sample No. 10.

In general the photocurrent in a sample is expressed by

$$I=e\tau\mu\, Vn'/L^2\,, \qquad (8)$$

where V is the applied voltage, L the distance between electrodes, and e, τ and μ are the charge, the life time and the mobility of photoelectron respectively. Here n', the number of photoelectrons, is related to the density by $n=n'/$(sample volume). By using the values of quantities in Eq. (8) measured at the knick point in Fig. 7, the density of traps M can be calculated because $n\simeq M$ at this point: that is, we have $M\simeq2.6\times10^{15}\,\text{cm}^{-3}$ for the sample No. 6, whose dimension is $5\times3\times0.2$ mm, by using $I=40\mu$A, $L=0.5$ cm, $V=1$ V and $\tau=80$ m sec and $M\simeq1.4\times10^{14}\,\text{cm}^{-3}$ for the sample No. 10, whose dimension is $10\times8\times0.2$ mm, since $I=4\mu$A, $L=1$ cm, $V=3$ V and $\tau=50$ m sec, where the value of μ is taken as $100\,\text{cm}^2$/volt. sec.

Furthermore, by making use of the above values of $n(\simeq M)$ and τ at the knick point, the magnitude of the capture cross section s of a hole for a photoelectron can be obtained from the equation:

$$\tau=1/vsn\,, \qquad (9)$$

where v is the thermal velocity of photoelectron; that is, taking $v=10^7$ cm/sec at room temperature, $s \cong 5\times10^{-22}$ for the sample No. 6 and $s \cong 2\times10^{-20}$ for the sample No. 10.

Next the sensitivity of CdS crystals for β- and γ-rays will be discussed. Writing F for the number of exciting particles and η for the efficiency by these particles to produce the conducting electrons, then from Eq. (8)

$$\eta=\frac{I}{e.F}\cdot\frac{L^2}{\tau\mu V}\,, \tag{10}$$

because $n'=F\eta$. From this equation it is possible to compare the efficiency for β-rays from Sr^{90} with that for γ-rays from Cs^{137} or from Co^{60}. From Figs. 10 and 11 the sample No. 6 has the exciting current of 2μA under the applied voltage of 100 V for β-ray irradiation at a distance of 20 cm from 10 *mc* of Sr^{90} and for γ-ray irradiation at a distance of 25 cm from 1 *c* of Cs^{137} respectively. Therefore, taking the number of particles which knocked the sample in each case, the following ratio can be calculated from Eq. (10), namely:

$$\eta_{Sr^{90}}/\eta_{Cs^{137}}=65,\ \text{for No. 6}\,, \tag{11}$$

because the valves of time constant are the same under the same excited current for β- or γ-rays irradiation. For the sample No. 10 the following valves can be obtained in the same way:

$$\left.\begin{array}{l}\eta_{Sr^{90}}/\eta_{Cs^{137}}=42,\ \text{for No. 10}\,,\\ \eta_{Sr^{90}}/\eta_{Co^{60}}=30,\ \text{for No. 10}\,.\end{array}\right\} \tag{12}$$

From the above values in Eqs. (11) and (12) it may be concluded that the efficiency of exciting the electrons by β-rays of Sr^{90} is about fifty times larger than that by γ-rays of Cs^{137}. Here it should be noted that the ratio of efficiency is calculated in the linear range of excited current *versus* irradiation intensity.

Further, by making use of Eq. (10), it will be tried to obtain the absolute values of η for both β- and γ-particles having the same energy. The electric resistance of the sample No. 1 has the value of 15 KΩ for the irradiation of 2.2×10^{-11} A of 1.5 Mev β-rays from the accelerator of Van de Graaff type, as shown in Fig. 14. Substituting $V=15$ V, $I=$ 1 mA, $L=0.5$ cm, $\tau=50$ m sec and $\mu=100$ cm²/volt. sec into Eq. (10), the value of η becomes

$$\eta=1.5\times10^5 \text{ for a β-particle of 1.5 Mev.} \tag{13}$$

In the experiments of the γ-irradiation from 200 *c* of Co^{60} the sample No. 10 shows the excited electron current of 120μA and the life time of 50 m sec under the applied voltage of 90 V for the exciting intensity of 47.5 *r*/min, as shown in Fig. 15. Substituting these values and $\mu=100$ cm²/volt. sec into Eq. (10), the value of η is given by

$$\eta=3.2\times10^3 \text{ for a γ-particle of 1.3 Mev.} \tag{14}$$

These results show that about 10^2 times of conducting electrons are more produced in the above grade crystals by a single β-particle than a single γ-particle, both being nearly of the same energy of 1.3∼1.5 Mev. Here it should be noted that the calculation has been carried out by using the experimental values near the knick points in Figs. 14 and 15.

The lower limit for detecting β-and γ-rays depends on the dark resistance of CdS crystals; for example, it is possible for the sample No. 6 to detect such a small number of β-particles as 5×10^2 particles/cm² sec at the position apart 2 m from 10 *mc* of Sr^{90}. But in this case the sample crystal shows a large time constant of about 3 minutes.

Lastly let us discuss how the energy of exciting β- or γ-rays is consumd in CdS crystals. It may be considered that some parts of the energy are used for the excitation of electrons and some parts for the generation of lattice imperfections. For the heavy irradiation of β-rays from Van de Graaff generator the following phenomena were observed: the increase of dark current, the decrease of photocurrent and the change in the characteristic of photocurrent *versus* irradiating intensity after irradiation. These facts clearly indicate the production of lattice imperfections, but it cannot be decided how much of incident energy is dissipated to the generation of imperfections or to the excitation of electrons, because the ratio of the number of produced lattice imperfections to that of excited electrons has not been defined in this report. However, the following consideration may be allowed for rough estimation of energy dissipation; the energy for one electron excitation is estimated to be about 2 ev from the measurements of the spectral sensitivity of photoconduction, and the energy for the generation of one lattice imperfection seems to be 6∼10 ev because the energy of sublimation is about 2.1 ev for CdS crystals11). On the other hand, for the irradiation of 1.5

Mev β-rays from Van de Graaff generator the absorbed energy is roughly estimated as 900 Kev per single β-particle, because the specific gravity of CdS is 4.82 and hence the CdS crystal of 0.2 mm in thickness absorbs 60% of incident energy. Of this absorbed energy, the energy of about 300 Kev may be dissipated to electron excitation because $\eta=1.5\times10^5$ and the energy for exciting one electron is 2 ev, and the great part of remaining energy of about 600 Kev to the generation of lattice imperfections. Thus the lattice imperfections of about 10^4 may be produced by a single β-particle because of their generation energy of 6～10 ev.

§ 6. Summary

The ohmic contact of evaporated In and the uniformity of CdS crystals produced by the author have been verified in § 2. The behaviors of photoconductivity described in § 3 have been explained by the elementary process as discussed in § 5 and it has been shown that the CdS crystals have low trap density and high sensitivity. The properties of CdS crystals induced by β- and γ-rays irradiation, which are given in § 4, are similar to those induced by visible light and the behaviors of exciting current can also be comprehended by the same process of conductivity as for the photoconduction. But it has been confirmed in § 5 that the exciting efficiencies for β- and γ-rays are very much larger than that for visible light; the efficiencies for β-and γ-rays of 1.3～1.5 Mev have been calculated to be about 10^5 and 10^3 respectively.

Acknowledgement

The author would like to express his sincere thanks to Professor Y. Uchida for continual encouragements and valuable discussions. He is also very much indebted to Dr. H. Yamashita, Mr. G. Imamura, Mr. S. Ogura, and Mr. K. Miyashita in our laboratory for their kind advices and discussions.

Accurate Determination of Hydrogen Positions in NH_4Cl by Electron Diffraction

By Shigeya KUWABARA

Department of Physics, Faculty of Science, Hiroshima University, Hiroshima, Japan

(Received February 9, 1959)

The hydrogen position in NH_4Cl was determined by the difference Fourier syntheses from the electron diffraction Debye-Scherrer ring intensity data at a room temperature and a low temperature (−40°C). The primary extinction effect for strong reflections such as (110) plane was corrected from the variation of their intensities by changing the accelerating voltages between 20 and 60 kv. By the use of the least square method, the temperature factors were determined from higher order reflections whose atomic scattering factors are not affected by ionization.

The difference Fourier syntheses showed the coordinate (xxx) of the hydrogen atoms to be $x=0.153$ for both the room temperature and the low temperature phases, when the atomic scattering factors for ionized atoms $N^{-0.45}$, $Cl^{-0.81}$ and $H^{+0.315}$ were taken. Only the room temperature phase showed the rotatory vibration of the hydrogen atoms. The result of our experiment was compared with those of X-ray, neutron and other electron diffraction data.

§ 1. Introduction

The crystal structure determination by electron diffraction was performed at first by Laschkarew and Usyskin[1] on ammonium chloride in 1933 and, since then, this method has been extensively developed mainly by Pinsker *et al.*[2] and Cowley[3]. Though the electron diffraction method in crystal structure determination has not so well established yet as the *X*-ray diffraction and neutron diffraction methods, it possesses some merits compared with the latter two. While the *X*-ray diffraction method gives the electron distribution and the neutron diffraction gives the position of neuclei, the electron diffraction method can bring us a direct information of the potential distribution in crystals and is more sensitive to the existence of light neuclei, especially of hydrogen, than the *X*-ray method as is clear from Fig. 1[4], in which the atomic scattering factors for *X*-rays f (Fig. 1a) and for electrons E (Fig. 1b) of N, Cl and H atoms are shown; E is given by

$$E=(me^2/2h^2)(Z-f)/\sin^2\theta/\lambda^2) , \qquad (1)$$

where Z is the atomic number and m, e, h, λ and θ have their usual meaning. Further, the electron diffraction method is sensitive to the displacement of electron cloud in atoms. For instance, if an atom is ionized positively the scattering factor E increases in the region of small $\sin\theta/\lambda$ values. In general, the atomic scattering factors for electrons become respectively larger or smaller for lower scattering angles when the atoms are ionized positively or negatively. In the latter case, in particular, the atomic scattering factors may become zero or even negative. The comparison of the distribution maps obtained by *X*-ray diffraction, neutron diffraction and electron diffraction methods will be, therefore, fruitful for detecting the distortion of electron cloud from a spherical electron distribution of atoms in crystals caused by, say, the atomic bonding.

The serious defect of the electron diffraction method is due to the complicated dynamical diffraction effect, in particular the effect of primary extinction[5,6]. However, this effect can be corrected or at least partly removed by changing the wave length of electrons[7], or the grain size of samples[6], or by the use of intensity statistics[8].

The crystal structure of ammonium chloride is well known, and the position of hydrogen atoms in it was determined for both the room temperature and the low temperature phases by *X*-ray[8] and neutron diffraction[10,11] methods and for the room temperature phase by the electron diffraction method[1,12]. However, the results concerning the hydrogen position in these works are not in agreement with each other. In the present study, the structure analysis of ammonium chloride was performed by the electron diffraction method with an accurate intensity measurement, and the result was compared with those of other workers. The structure of the low temperature phase of ammonium chloride was also studied for comparison with that of the room temperature phase.

§ 2. Experimental Procedures

To avoid the effect of the moisture of the atmosphere, specimens were prepared by evaporating ammonium chloride in the electron diffraction camera onto thin collodion films which were put on the surface of fine meshes used for electronmicroscopy. After evaporation, twelve photographs with different exposure times were taken for each specimen. The diffraction patterns were examined carefully by tilting the specimen films about 50–70° so as to detect a preferred orientation if any: a slight texture with the (111) plane parallel to the specimen films was observed when the thickness of the evaporated films was thin (*cf.* Fig. 2), while no preferred orientation was observed for the thick films.

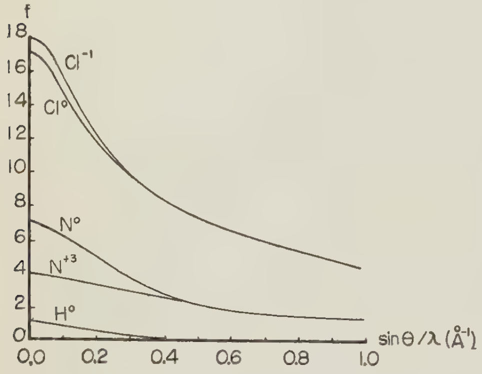

Fig. 1 (a). Atomic scattering factors for X-rays. The values of Cl^{-1}, and N^0 were given by Berguhuis et al., and Cl^0, N^{+3} and H^0 by James and Brindley[4].

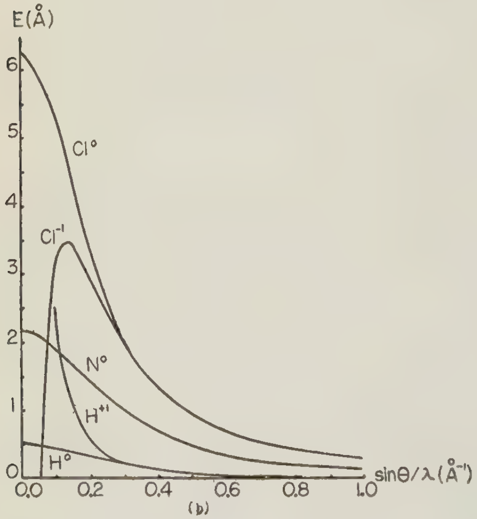

Fig. 1 (b). Atomic scattering factors for electrons. The value of Cl^{-1} was calculated by (1) from the data of Berguhuis et al., N^0 and H^0 were given by Ibers, and Cl^0 and H^{+1} by Vainstein[4].

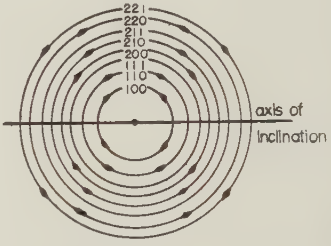
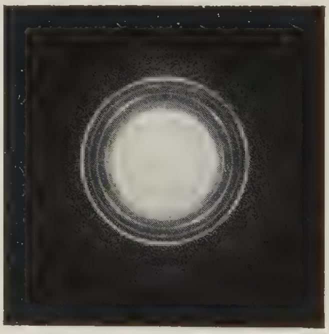


(a)



(b)

Fig. 2. Schematical diagram (a) and the real pattern (b) of NH_4Cl when the specimen film which has the texture with (111) plane parallel to it is inclined to the electron beam with 70° (the angle between the film normal and the beam).

Films of the thicknesses about 300–400° A gave the best diffraction patterns free from texture and strong background. The accelerating voltage was changed from 20 to 60 kv.

A special low temperature specimen holder was used to study the low temperature phase ammonium chloride, the construction of which was the same as that described by Honjo *et al.*[13] Dry ice or liquid air was used as the cooling reagent. Most of the experiment at low temperature were performed at −40°C, The Karle and Karle method[14] was used to measure the integrated intensities of stronger reflections. The microphotometer used was *Rigakudenki MP*-1 type. Special precautions were taken to avoid the so-called Schwarzschild-Villiger effect, and the battery of 200 *AH* was used as a light source to minimize the fluctuation of the galvanometer deviation. The *Fuji Process Hard* photographic plates were used and they were developed by diluted solutions (1 : 1) of *D*-72 developer at 20±1°C for 2 min. The photographic density-intensity curves were linear up to $D=0.7$ for the higher accelerating voltages (60 kv), and 0.5 for lower voltages (20 kv). Usually D values less than 0.8∼1.0 were used for the intensity measurement.

After subtracting the smooth backgrounds from the total intensity curves, the integrated intensities of the Debye-Scherrer rings were measured from the microphotometer traces. In this case, however, the effect of the collodion films could be neglected because of the large thickness of the specimen films. As is shown in Fig. 5, the peaks of stronger reflections are seen clearly though those of weaker reflections are obscure for the lower exposure time microphotometer traces. However, for the higher exposure time relatively weaker reflections such as (222) and (420) could be seen clearly in the traces (each top corner of Fig. 5). Six microphotometer traces were measured for each photographic plate, and each of the traces with different exposure times was patched together to give the total integrated intensities. For very weak reflections such as (400) and (421), however, visual method was applied because the peaks of reflected intensities are obscured by the emulsion grain of the photographic plates.

§ 3. Experimental Results

The room temperature phase of ammonium chloride exists in the temperature range between −30.5°C and 180.3°C. The lattice constant is $a=3.866°\text{A}$. According to the neutron diffraction data[10] the space group is given by O_h^1-Pm3m and the hydrogen atoms occupy with the same probability each of the sets of tetrahedra around the nitrogen atom, which are shown by the dark small circles and the opened small circles, respectively, in Fig. 3, and the hydrogen atoms show the rotatory vibrations. Below the temperature −30.5°C appears the low temperature phase, of which the lattice constant is almost the same as that of the room temperature phase, however, the space group is given by $T_d^1-P\bar{4}3m$ and the hydrogen atoms can occupy only one of the sets of the tetrahera with no rotatory vibration[11].

** The mean errors of the measurement are given in this table for all the microphotometered intensities. Those for the visual estimation are about fifteen percent. The systematic errors are difficult to estimate. However, if these errors are taken into account, the total errors of the intensity measurement will become larger than those given in this table.

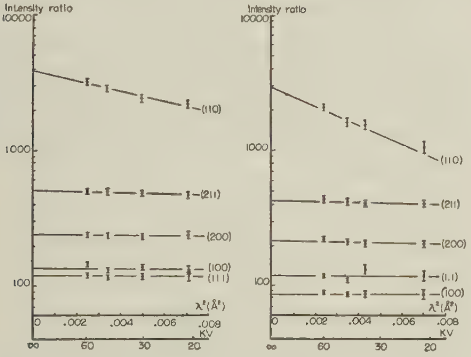
a) ***Room temperature phase.*** An example of the Debye-Scherrer rings for the room temperature phase of NH$_4$Cl without preferred orientation is shown in Fig. 4a. Examples of the microphotometer traces are shown in Fig. 5a. In Table I the measured intensities are tabulated, where the values except the one marked by asterisk are the averages obtained from all the experiments. The values with brackets show the results obtained visually. The value with asterisk was obtained by correcting the primary extinction effect which will be described later. The values obtained by Stasova and Vainstein[12)] and Laschkarew and Usyskin[1)] are listed together for comparison. Their values were normalized so as to result in general fits with our values, where the (100) and (110) reflections were omitted because of the larger discrepancies from our results. The discrepancy for the (100) reflection seems to be due to the difference in the estimation of the background which is considerably steep in the region of small sin θ/λ values*. Excepting these two reflection, their results coincide generally well with that of the present experiment.

(i) *Correction of primary extinction effect.* The large discrepancy in the intensity of the (110) reflection between the results of Stasova and Vainstein and Laschkarew and Usyskin in Table I suggests that the intensity of this strong reflection is considerably affected by the primary extinction effect. This effect was corrected in the present experiment by the extrapolation method[7)]. Fig. 6a shows an example of the results of this procedure for the room temperature phase. It is evident that the (110) reflection is accompanied by a large primary extinction effect, while this effect is negligible for the other reflections. The value corrected by this method is given in Table I with asterisk.

---

* A sector camera of Tokyo Institute of Technology was used to examine the (100) intensity obtained from the present experiment. However, the results was the same within the experimental error.

(ii) *Direct Fourier synthesis.* As the first step of the analysis, the potential distribution along a body diagonal was obtained by the three dimensional Fourier synthesis from the observed intensity values. The signs of the structure factors were determined by assuming the centrosymmetrical structure of the room temperature phase as quoted before. For the evaluation of the structure factors of component reflections in the multiple rings as in the case of (221) and (300), *etc.* the coordinate of hydrogen atoms $x=0.154$ obtained from the neutron diffraction data[10,11] was used, the effect of the temperature factors being neglected. The result of this Fourier synthesis is shown in Fig. 7, giving the coordinate $x=0.15-0.17$. However, since the peak of the hydrogen atom in the figure is quite broad, and moreover, the effect of the temperature factor was not taken into account, the reliable value of the hydrogen coordinate may not be obtained by the direct Fourier synthesis as above.



(a) (b)

Fig. 6. Calibration of the primary extinction effect. (a) Room temperature phase. (b) Low temperature phase (−40°C).

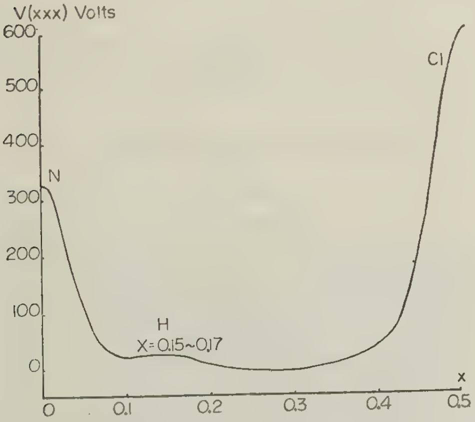


Fig. 7. Potential distribution along a body diagonal direction.

(iii) *Evaluation of the temperature factors.* The knowledge of the temperature factors is very important for determining the exact position of the hydrogen atoms. In order to know the general behavior of the thermal vibration of the component atoms in the crystal, the difference Fourier synthesis was performed by assuming the neutron diffraction data[10] $B=B_N=B_{Cl}=B_H=2.0Å^2$ for the temperature factors and $x=0.154$ for the hydrogen coordinate. The latter is needed for the sake of the intensity evaluation of multiple rings. The normalization of the observed structure factors was performed by the condition[15]

$$\sum|S_{hkl,obs}|=\sum|S_{hkl,cal}|,$$

where $S_{hkl,obs}$ and $S_{hkl,cal}$ are the observed and calculated structure factors. The summations were carried out for all the reflections observed. The three dimensional difference Fourier synthesis along a body diagonal is shown in Fig. 8a, where the peak of the hydrogen atom is seen clearly at the coordination $x=0.155$. However, infavorable peaks and valleys are found at and near the positions of N and Cl atoms. When the temperature factor B is taken $1.1Å^2$ [12], the difference synthesis gives $x=0.148$, and valleys are found at the positions of N and Cl atoms, as is shown in Fig. 8b.

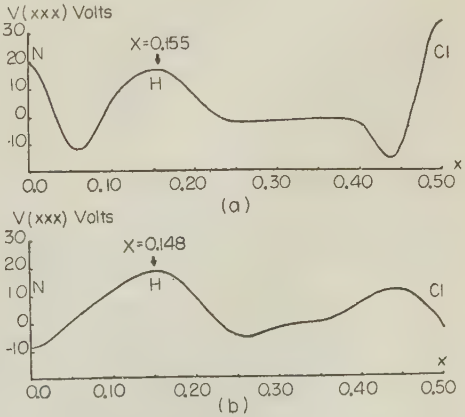

Fig. 8. Three dimensional difference Fourier syntheses of room temperature NH_4Cl along a body diagonal with $B=2.0$ (a) and $B=1.1$ Å² (b).

The above two examples show that the position of the hydrogen atom is affected strongly by the temperature factors. Fig. 9 shows this effect schematically.

The calculated structure factors showed the best agreement with the observed values for $B=1.3 Å^2$. The two dimensional difference Fourier synthesis was performed by the use of this B value in order to confirm the existence of an anisotropic thermal vibration of the hydrogen atom as was revealed by the neutron diffraction study[10]. The result is shown in Fig. 10, where the rotatory vibration of the hydrogen atom is recognized clearly. The half angle of the rotatory vibration was estimated to be $\alpha=12°$, which coincides with the value obtained by neutron diffraction.

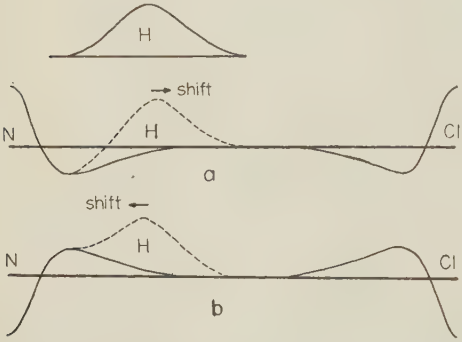

Fig. 9. Schematical representation of the effect of temperature factor to the hydrogen position in the difference Fourier syntheses.
a) The case when B factor is too large.
b) The case when B factor is too small.

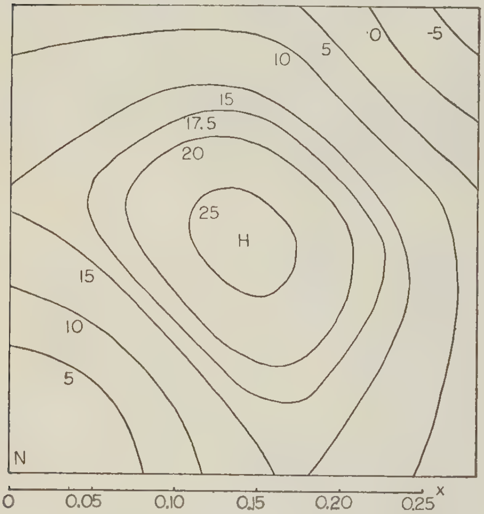

Fig. 10. Two dimensional difference Fourier synthesis of room temperature phase NH_4Cl along (001) axis with $B=1.3 Å^2$ and the parameter $x=0.154$, the anomalous thermal vibration due to the hydrogen atoms being neglected in getting each structure factor from the observed multiple reflections. The contour lines are shown in *Volts·*Å unit.

The temperature factor for each atom can be determined more accurately by the following procedures. Let B_N', B_{Cl}' and B_H' be the true temperature factors, and B_N, B_{Cl} and B_H the calculated temperature factors. Then the calculated and the observed structure factors can be given by

$$\begin{aligned} S_{hkl,cal}=&E_N \exp(-B_N \sin^2\theta/\lambda^2) \\ &+(-1)^{h+k+l}E_{Cl}\exp(-B_{Cl}\sin^2\theta/\lambda^2) \\ &+\tfrac{1}{2}E_H\exp(-B_H\sin^2\theta/\lambda^2)\sum[\quad], \end{aligned} \tag{3}$$

and

$$\begin{aligned} KS_{hkl,obs}=&E_N \exp(-B_N' \sin^2\theta/\lambda^2) \\ &+(-1)^{n+k+l}E_{Cl}\exp(B_{Cl}'\sin^2\theta/\lambda^2) \\ &+\tfrac{1}{2}E_H\exp(-B_H'\sin^2\theta/\lambda^2)\sum[\quad], \end{aligned} \tag{4}$$

where K is the scaling factor, and the notation $\sum[\quad]$ in the last terms in (3) and (4) represents the contribution of the hydrogen atoms accompanied with rotatory oscillation[10] and is given by

$$\begin{aligned} \sum[\quad]=&\sum[J_0(2\pi\sqrt{W}\sin\alpha) \\ &\times\cos\{2\pi\cos\alpha(hx+ky+lz)\}], \end{aligned}$$

and

$$w=(hy-kx)^2+(lx-hz)^2+(kz-ly)^2 .$$

J_0 is the *zero*th order Bessel function, and x, y, z are the coordinate of the eight statistical position of the hydrogen atoms in the assumed structure. From (3) and (4) we obtain approximately

$$\begin{aligned} S_{hkl,cal}-&KS_{hkl,obs} \\ =&E_N\Delta B_N\sin^2\theta/\lambda^2+(-1)^{h+k+l}E_{Cl}\Delta B_{Cl}\sin^2\theta/\lambda^2 \\ &+\tfrac{1}{2}E_H\Delta B_H\sin^2\theta/\lambda^2\sum[\quad], \end{aligned} \tag{5}$$

where

$$\Delta B_N=B_N'-B_N,\ \Delta B_{Cl}=B_{Cl}'-B_{Cl}$$

and

$$\Delta B_H=B_H'-B_H .$$

These unknown values of K, ΔB_N, ΔB_{Cl} and ΔB_H can be determined by the least square method. The calculation was carried out for all the observed reflections except those of lower orders, (100)-(300), for which the effect of ionization of atoms may be appreciable. The temperature factors thus obtained deviated considerably from the initial value

$B=1.3\text{Å}^2$. The final results are

$$B_N=1.33,\quad B_{Cl}=1.22 \text{ and } B_H=2.38\text{Å}^2 \qquad (6)$$

for $x=0.154$ and $\alpha=12°$. It is not essentially important to assume these x and α values at least for the determination of the temperature factors of N and Cl.

Fig. 11 shows the two dimensional difference Fourier synthesis using the above factors. Three dimensional synthesis is shown in Fig. 12 by the full line. The coordinate of the hydrogen atom revealed by this figure is $x=0.152$.

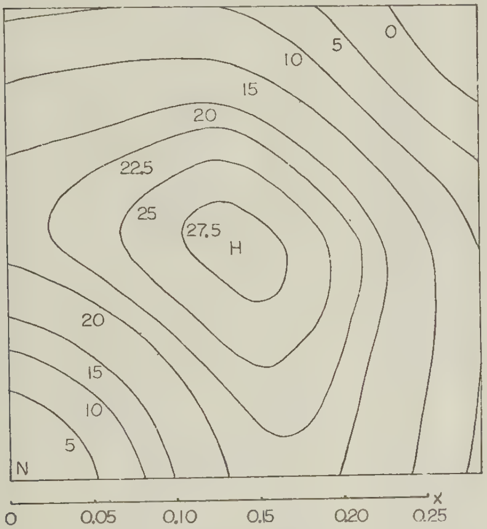

Fig. 11. Two dimensional difference Fourier synthesis of room temperature phase NH_4Cl along (001) axis with $B_H=2.38$, $B_N=1.33$, $B_{Cl}=1.22\text{Å}^2$ $\alpha=12°$ and $x=0.154$. The contour lines are shown in *Volts·*Å unit.

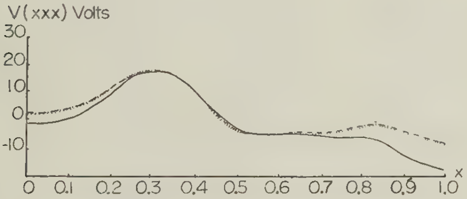

Fig. 12. Three dimensional difference Fourier syntheses of room temperature phase NH_4Cl along the body diagonal with $B_N=1.33$, $B_{Cl}=1.22$, $B_H=2.38$ Å^2 and $\alpha=12°$. Full line shows the case calculated from the neutral atoms with $x=0.154$, and the chain line the case of $N^{-0.46}$, $Cl^{-0.81}$ and $H^{+0.315}$ with $x=0.153$, for both of which the unobserved structure factors were not included in the syntheses. If they are taken into account, the result is given by the dotted line for the latter case.

(iv) *Ionization effect.* As is shown in Fig. 12, there is a deep valley at the position of Cl atom, and moreover, the discrepancy between the observed and calculated structure factors for lower order reflections is considerable (*cf.* Table III). These facts seems to show that the atomic scattering factors for the neutral atoms used in the present calculation are not adequate as the result of the ionization of atoms in the crystal. This effect may change the position of hydrogen atoms considerably.

As is shown in Fig. 1a, the change of the atomic scattering factors for *X*-rays by ionization effect takes place only in the region of small value of $\sin\theta/\lambda$, and the deviation of the values for ionized atoms from those for neutral atoms may be approximated to be linear to the $\sin\theta/\lambda$ in the range of $\sin\theta/\lambda=0-0.4\text{Å}^{-1}$. By multiplying $\sin^2\theta/\lambda^2$ to (1), we get the following expressions:

$$E'=E\sin^2\theta/\lambda^2=(me^2/2h^2)(Z-f) \qquad (7)$$

or

$$\Delta E'=-(me^2/2h^2)\Delta f\,. \qquad (8)$$

Since $\Delta E'$ is proportional to the change of atomic scattering factor for *X*-rays Δf, $\Delta E'$ may be also linear to $\sin\theta/\lambda$ in the range of $\sin\theta/\lambda=0-0.4\text{Å}^{-1}$. Then we can put

$$\begin{aligned}\Delta E_N'&=C_N\Delta(\sin\theta/\lambda)\\ \Delta E_{Cl}'&=C_{Cl}\Delta(\sin\theta/\lambda) \qquad (9)\\ \Delta_H'&=C_H\Delta(\sin\theta/\lambda)\,,\end{aligned}$$

where $\Delta(\sin\theta/\lambda)=0.4-\sin\theta/\lambda$, and C_N, C_{Cl} and C_H are the parameters to be determined. From (3) and the above expressions, we get

$$\begin{aligned}&\sin^2\theta/\lambda^2(S_{hkl,obs}-S_{hkl,cal})\\ &\quad=C_N\Delta(\sin\theta/\lambda)\exp(-B_N\sin^2\theta/\lambda^2)\\ &\qquad+(-1)^{h+k+l}C_{Cl}\Delta(\sin\theta/\lambda)\exp(-B_{Cl}\sin^2\theta/\lambda^2)\\ &\qquad+\tfrac{1}{2}C_H\Delta(\sin\theta/\lambda)\exp(-B_H\sin^2\theta/\lambda^2)\sum[\quad]\,. \qquad (10)\end{aligned}$$

C_N, C_{Cl} and C_H can be determined for a given value of x by the least square method with the condition of the neutrality of total charges in the crystal

$$C_N+C_{Cl}+4C_H=0\,. \qquad (11)$$

When the values of C_N, C_{Cl} and C_H are known, the extrapolated values of Δf to the zero scattering angle give the charge of each atom.

In Table II the calculated values of the formal charges of the atoms for the several x values are tabulated. Because of the rela-

Table II. Variation of formal charges with the coordinate x.

tively small contribution of the hydrogen atoms for the large $\sin\theta/\lambda$ region, the temperature factors (6) may remain unchanged by ionization of the atoms. Then, the x value may be determined by the condition of the minimum reliability factor of the structure factors. The best agreement between the observed and the calculated structure factors was found for $x=0.153$ and charges of the atoms $N^{-0.45}$, $Cl^{-0.81}$ and $H^{+0.315}$. Table III shows the comparison of the observed and calculated values of the structure factors. The calculated structure factors for neutral atoms are also given in this table to show the large discrepancy in the region of small $\sin\theta/\lambda$ values. The structure factors corresponding to the unobserved reflections, the intensities of which would be considerable if they could be observed, are given by bars, and the ones corresponding to the reflections, the intensities of which would be very weak or practically zero even if they could be observed, are given by 0.00's. When the reflections which were not observed in the experiment are excluded the reliability factors become 0.08 and 0.10 for the ionized atoms $N^{-0.45}$, $Cl^{-0.81}$ and $H^{+0.315}$, and for the neutral atoms, respectively, however, when the calculated structure factors of the unobserved reflections corresponding to the very weak intensities, even if they could be observed, are taken into account the reliability factors become 0.10 and 0.12, respectively.

Table III. The observed and calculated structure factors for room temperature phase NH_4Cl with $x=0.153$.

The chain line of Fig. 12 shows the three dimensional difference Fourier synthesis for this ionized atoms, the unobserved structure factors being neglected in the calculation. The peak value of the hydrogen atom estimated in this figure gives $x=0.152$.

(v) *Final result.* Through all the procedures of Fourier syntheses mentioned above the contribution of the unobserved reflections has not been taken into account. When all of these values are calculated and the difference Fourier synthesis is extended up to the range of $\sin\theta/\lambda=1.05\,\text{Å}^{-1}$(*hkl*=554), we obtain the curve as dotted in Fig. 12. The coordinate x estimated from this figure gives 0.153. As there is no shift in the coordinate, this result is satisfactory.

The standard deviations of the potential and the coordinate of the hydrogen atom can be estimated by the following expressions which are analogous to those of *X*-rays[16)].

$$\sigma(V)=(h^2/2\pi\,\mathrm{mea}^3)\{\sum(|S_{hkl,obs}|-|S_{hkl,cal}|)^2\}^{1/2}\,, \tag{12}$$

$$\sigma(x)=(h^2/\mathrm{mea}^4)\frac{\{\sum h^2(|S_{hkl,obs}|-|S_{hkl,cal}|)^2\}^{1/2}}{\partial^2 V/\partial x^2}\,. \tag{13}$$

The results thus obtained are $\sigma(V)=2$ volts and $\sigma(x)=0.003$ when the $S_{hkl,obs}$ and $S_{hkl,cal}$ corresponding to the observed reflections are used in the calculation. Even when the S_{hkl}'s corresponding not only to the observed reflections but also to the ones which would be very weak even if they could be observed are taken into account, these standard deviations were almost the same.

b*) *Low temperature phase. Examples of Dabye-Scherrer rings and the microphotometer traces for the low temperature phase are shown in Figs. 4b and 5b, respectively. In Table IV the result of the intensity measurement is given, all the values of which were averaged from the experiment at −40°C. The value with asterisk was given by correcting the primary extinction effect. Fig. 6b shows an example of the result of such a correction for low temperature phase.

* See the foot-note of Table I.

The temperature factors were calculated by almost the same method as is described in (*iii*) of ***a***). In the present case, however, the structure factors have imaginary parts[11)], so only the real parts of the structure factors were used to determine the temperature factors assuming the coordinate of the hydrogen atoms $x=0.154$*. The results are given by

$$B_N=0.48,\ B_{Cl}=0.41 \text{ and } B_H=2.48\,\text{Å}^2. \tag{14}$$

In the calculation, the structure factors of lower order reflections were omitted by the same reason as was mentioned in ***a***).

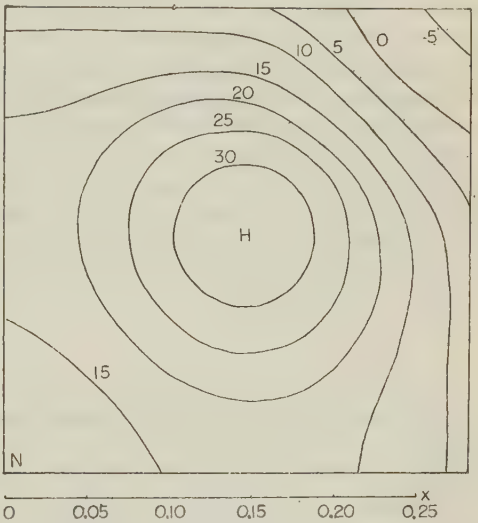

Fig. 13. Two dimensional difference Fourier synthesis of low temperature phase NH_4Cl (−40°C) along (001) axis with $B_H=2.48$, $B_N=0.48$, $B_{Cl}=0.41\,\text{Å}^2$ and $x=0.154$. The contour lines are shown in *Volts*·Å unit.

Fig. 13 shows the result of the two dimensional difference Fourier synthesis calculated for the neutral atoms, where the shape of the potential near the center of the hydrogen atom is not distorted as in Fig. 11 for the room temperature phase. In Fig. 14, the three dimensional difference synthesis is given along the direction of the body diagonal of

---

* The real parts of the observed structure factors are given by

$$S^{\text{real}}_{\text{obs}}=|S_{\text{obs}}|\frac{S^{\text{real}}_{\text{cal}}}{|S_{\text{cal}}|}\,.$$

the crystal for the neutral atoms. The coordinate thus determined was $x=0.152$, which is the same as the case of room temperature phase. It is shown that there is a deep valley at the position of Cl atom, too.

Ionization effect was calculated in the same way as before, but in this case only the real parts of the structure factors were used. The changes of the formal charges of the atoms with the change of the coordinate x are the same as Table II.

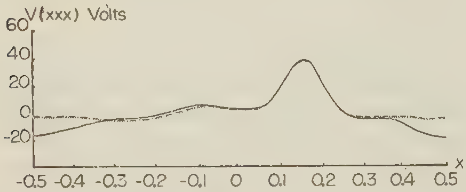

Fig. 14. Three dimensional difference Fourier syntheses of low temperature phase NH_4Cl (−40°C) along the body diagonal with $B_N=0.48$, $B_{Cl}=0.41$, $B_H=2.48$ Å^2. Full line shows the case calculated from neutral atoms with $x=0.154$, and the chain line the case of $N^{-0.45}$, $Cl^{-0.81}$ and $H^{+0.315}$ with $x=0.153$, for both of which the unobserved structure factors were not included in the syntheses. If they are taken into account, the result is given by the dotted line for the latter case.

The best agreement between the observed and the calculated structure factors was found when the coordinate was $x=0.153$, which is the same as in the case of the room temperature phase. In Fig. 14, the chain line shows the difference synthesis, where only the observed reflections were used in the calculation, and the dotted line the synthesis, where all of the structure factors which were not observed in the experiment were added in the calculation up to the region to $\sin\theta/\lambda=1.05$ Å^{-1}. These syntheses were carried out for the ionized atoms $N^{-0.45}$, $Cl^{-0.81}$, and $H^{+0.315}$ corresponding to $x=0.153$. The estimated values of the coordinate were 0.152 and 0.153, respectively. The latter case is satisfactory because of no shift in the coordinate.

Table V shows the observed and the calculated structure factors of these ionized atoms and of the neutral atoms. The reliability factors were 0.08 and 0.11 for the ionized and neutral atoms, respectively, when the contribution of the unobserved structure factors, which correspond to the very weak reflections even if they could be observed in the experiment, are taken into account, and 0.05 and 0.08 when only the observed reflections are used. The standard deviations of potential and coordinate were the same as in the case of room temperature phase for both the cases where the unobserved structure factors were neglected and taken into account.

Table V. The observed and calculated structure factors for low temperature phase NH_4Cl with $x=0.153$.

§ 5. Discussion

a) Characters of the Fourier maps. As is shown in Figs. 11 and 13, the difference of the potential shape of the hydrogen atom is not spurious but gives the fundamental difference of the behavior of the hydrogen atoms in the crystal: the distortion of the hydrogen potential for the room temperature phase shows distinctly the existence of the rotatory vibration of the hydrogen atoms and there is no such a distortion for the low temperature phase. The peak height of the hydrogen atom for the room temperature phase is about half of that of the low temperature phase (Figs. 12 and 14). This will confirm the consistency of the models assumed in the calculation of Fourier syntheses.

b) *Ionization effect.* It is interesting that the value of the coordinate of the hydrogen atom and the ionization effect are the same for both room temperature and low temperature phases. It should be emphasized that the formal charges in the crystal are not integers but the fractional numbers: this crystal can be recognized as partly ionic and partly covalent. Such a conclusion was also obtained from the electron diffraction data of Li_2O[17]. Thus the electron diffraction method is very useful to detect the ionization effect of the crystals.

As is shown from the dotted lines in Figs. 12 and 14, the backgrounds are not perfectly flat nor zero. This may be due to the fact that we used the atomic scattering factors for the isolated atoms modified by the method mentioned in § 3***a***) (*iv*). Such a method is an approximation and moreover the true atomic scattering factors in the crystal may be different from those of the isolated atoms. Then the more detailed discussion can not be given until we will get the accurate knowledge of the scattering factors in the crystals.

c) *Comparison with the other experiments.* In Table VI the results of the other experiments are listed for comparison. Temperature factors obtained by neutron diffraction coincide with those of X-ray diffraction for the room temperature phase. However, they are larger than those of the present experiment, though the intensity ratios of our experiment coincide generally well with those of Stasova and Vainstein for the room temperature phase. Such a discrepancy could not be explained.

Though the coordinate of the hydrogen atoms obtained by X-ray is very small, our results coincide with those of neutron diffrac-

Table VI.

Method	Workers	Temperature	x (N-H distance)	Temperature factors			
				B_N	B_{Cl}	B_H	(Å^{-2})
Neutrons	Levy and Peterson[10]	r. t.	0.154±0.003 (1.03±0.02Å)	2.0	2.0	2.5	($\alpha=12°$)
	Goldschmidt and Hurst[11]	liq. air	0.154±0.003 (1.03±0.02Å)	0.44	0.17	3.1	
X-rays	Watanabe and Yamada[9]	r. t.	0.140±0.004 (0.94±0.03Å)	2.0	1.9	—	
		−60°C	0.140±0.004 (0.94±0.03Å)	1.8	1.3	—	
Electrons	Laschkarew and Usyskin[1]	r. t.	0.142±0.010 (0.95±0.07Å)	—	—	—	
	Stasova and Vainstein[12]	r. t.	0.146±0.006 (0.98±0.04Å)	$1\leq B<2$			
	Present author	r. t.	0.153±0.003 (1.02±0.02Å)	1.33	1.22	2.38	($\alpha=12°$)
		−40°C	0.153±0.003 (1.02±0.02Å)	0.48	0.41	2.48	

tion. Assuming the results of X-rays and neutron diffraction are both correct, the potential distribution of the 1*s* electron[9] and the nucleus[10] of the hydrogen atom can be given as in Fig. 15. As shown in (1), the contribution of electron is quite opposite to that of nucleus, so the potential due to the 1*s* electron is negative. The quantity which is given by electron diffraction synthesis is the resultant potential. As is seen in this figure, the shift of the peak value is so small ($\Delta x=0.001$) that the position of the peak of the resultant potential is almost the same as that of the nucleus. Thus the value $x=0.153$ of our experiment coincides with the resultant peak within the experimental error.

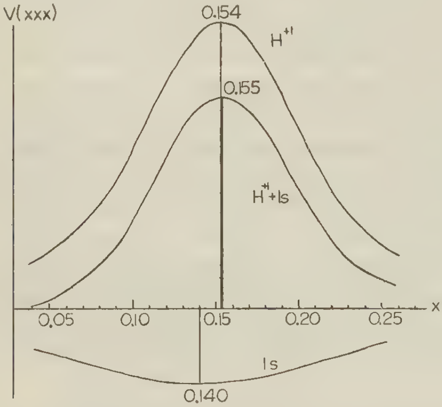

Fig. 15. Potential of nucleus and 1*s* electron of hydrogen atom.

The intensity ratios of the experiment of Stasova and Vainstein are almost the same as those in the present experiment except the (100) and (110) reflections. However, the coordinate of the hydrogen atom is much smaller than ours. If they determined the position of hydrogen atom by paying much attention for the factors which were mentioned in § 3*a*), the same value would result as in the present experiment.

d) *The effect of complex scattering factors.* So far we did not consider the effect of the phase shift due to the complex atomic scattering factors[18,19,20]. However, since in our experiment the accelerating voltage was high (60kv max.) and the atoms are light, the effect of the phase shift on the intensities, if any, is only ~5 percent for the reflections of higher scattering angles, being less than the error of the intensity measurement, ~15 percent, in such a region.

Acknowledgement

Finally the author wishes to express his hearty thanks to Prof. S. Miyake for his kind suggestion of this experiment and discussion. He is also indebted to Prof. T. Watanabe, Prof. G. Honjo and Dr. J. M. Cowley for their kind advice and discussions. His thanks are also due to Prof. H. Tazaki for his interest and encouragement through the experiment, Mr. Y. Yamada for his discussion and Mr. N. Kitamura for the allowance for using the sector camera in some part of the experiment.

The Magnetic Investigation of Mn^{++}, Co^{++}, Ni^{++}, Cu^{++} Ammine and Anhydrate Salts

By Kiyoshi KIDO and Takashi WATANABE

Department of Physics, Faculty of Science,
Tokyo Metropolitan University, Tokyo, Japan

(Received August 29, 1958)

The object of this paper is to investigate how the magnetic interaction and the crystalline field depend on the number of coordinations in the complex salts. As the results of our measurements, it is found that the magnetic susceptibilities of $Mn(NH_3)_6Cl_2$, $Mn(NH_3)_2Cl_2$, $Mn(NH_3)Cl_2$, $MnCl_2$, $Co(NH_3)_6Cl_2$, $Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$, $CoCl_2$; $Ni(NH_3)_6Cl_2$, $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$, $NiCl_2$; $Cu(NH_3)_4SO_4 \cdot H_2O$, $Cu(NH_3)_2SO_4$, $CuSO_4$ follow well the Curie-Weiss law in the temperature range from 90°K to 600°K. Any appreciable deviation from the Curie-Weiss law has not been observed, and it seems that the Curie constant C and the Weiss temperature θ in the equation $\chi_m = C/T+\theta$ generally increase as the coordination number proceeds lower.

§ 1. Introduction

$Mn(NH_3)_6Cl_2$, $Co(NH_3)_6Cl_2$, $Ni(NH_3)_6Cl_2$ and their diammine and monoammine salts are stable, and their physical and chemical properties were investigated by Biltz¹⁾. When heated in vacuum, the hexammine salts convert successively into di- and monoammine salts at fixed temperatures. The transformation points are given in Table I and Fig. 3.

The values of the susceptibility of anhydrated chloride of iron group given by Starr, Bitter and Kaufmann²⁾, and Bizett, Tisäi and Terrier³⁾ are in very close agreement with our results above 90°K, while the values for $Cu(NH_3)_4SO_4 \cdot H_2O$ by Volger⁴⁾ are partially different from ours. For $CuSO_4$ anhydrate the measurement was carried out by de Haas and Gorter⁵⁾ and Borovik-Romanov, Karasik and Kleines⁶⁾.

The crystal structures of $Mn(NH_3)_6Cl_2$, $Co(NH_3)_6Cl_2$, $Ni(NH_3)_6Cl_2$,⁷⁾ $MnCl_2$, $CoCl_2$, $NiCl_2$,⁸⁾ $Cu(NH_3)_4SO_4 \cdot H_2O$⁹⁾ and $CuSO_4$¹⁰⁾ are readily known, yet the structures of the salts with intermediate coordinations are not certain.

§ 2. Apparatus used and Preparation of Samples

The method used for measuring the susceptibility at various temperatures is one of the Weiss-Föx principle that has been constantly used by one of the authors¹¹⁾. In the present measurement, the whole moving part was enclosed by a glass tube and was kept in vacuum or in dry air as shown schematically in Fig. 1.

For the measurement at high temperature a heating chamber made of quartz as shown in Fig. 2 (a) was attached to the above-mentioned glass tube and a platinum wire of 0.5 mm in diameter was antimagnetically wound around the quartz tube for heating the chamber. For the measurement at low temperature a chamber made of copper block was attached and the lower part of the chamber was dipped dry ice or liquid nitrogen as required as shown in Fig. 2 (b). The magnet

M pole center of electromagnet.

used is of the Weiss-II type and a magnetic field of about 6000 oersted is obtained in the air gap between pole pieces at a distance of 3.2 cm apart.

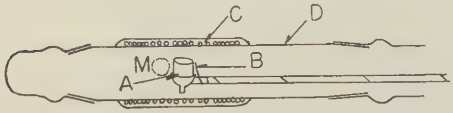

Fig. 2 (a). Schematic picture of heating oven.

C heater of *Pt* wire, D quartz tube,
M pole center of electromagnet.

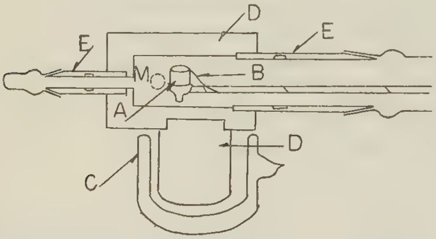

Fig. 2 (b). Schematic picture of cryoelement.
C De'war vessel, D copper block,
E blass tube.

As standards the following compounds were used:

H_2O $\chi_g=-0.720\times10^{-6}$,
$Fe(NH_4)$alum $\chi_g=30.4\times10^{-6}$ (at 290°K) and
$CuSO^4\cdot5H_2O$ $\chi_g=5.97\times10^{-6}$ (〃)

χ_g being the gram susceptibility, and for the diamagnetic correction the following values of molecular susceptibility were used:

H_2O $\chi_m=-13.0\times10^{-6}$,
SO_4^- $\chi_m=-39.0\times10^{-6}$,
NH_3 $\chi_m=-14.5\times10^{-6}$,
Cl^- $\chi_m=-22.1\times10^{-6}$.

A copper-constantan thermoelement of 0.06 mm in diameter calibrated by the melting points of Cd, Zn and Sn metals, sublimation point of dry ice and boiling point of liquid nitrogen was attached to the sample vessel as shown in Figs. 2 (a) and (b). A correction for the temperature difference between the thermocouple and the sample was done by comparing the temperature of the thermocouple with the temperature deduced from the χ_g value of $Fe(NH_2)$-alum in the range from 90°K to 300°K. This result was reproduced within an accuracy of ±1.5°K in the ranges 90°K∼110°K and 200°K∼300°K. The error in observation of magnetic susceptibility χ_g lay within ±0.5%.

Preparation of samples.

$Mn(NH_3)_6Cl_2$, $Co(NH_3)_6Cl_2$:—The recrystallized salts of $MnCl_2\cdot4H_2O$ and $CoCl_2\cdot6H_2O$ were dehydrate, being kept at 200°C for 4 hours. The anhydrated salts thus obtained were shutt off from air, and were held in ammonia gas flowing slowly until these salts converted into white powder of $Mn(NH_3)_6Cl_2$ and pink powder of $Co(NH_3)_6Cl_2$. To avoid decomposition, these salts were kept in ammonia gas atmosphere.

$Ni(NH_3)_6Cl_2$:—By dissolving 25 grams of recrystallized $NiCl_2\cdot6H_2O$ in 200 cc of water and adding conc. NH_3 aqueous solution to this solution until a green precipitation disappears, clear deep purple solution was obtained. Next 100 cc of saturated NH_4Cl aqueous solution being added, sparking blue micro crystals precipitated in the solution. In this condition it was left for 24 hours, and then filtered. The mico crystals were washed by a mixture of saturated NH_4Cl solution and NH_3 aqueous solution, and they were held in a desicator containing water free CaO during a few days.

$Cu(NH_3)_6SO_4\cdot H_2O$:—Conc. NH_3 aqueous solution of excess more than 4 equivalent being added in the saturated $CuSO_4\cdot5H_2O$ solution, the solution changed to dark blue solution of copper tetrammine sulfate. Alcohol being added very slowly to the solution thus obtained, micro crystals of $Cu(NH_3)_4SO_4\cdot H_2O$ precipitated in the solution. In this condition it was left for 24 hours and then filtered. The precipitation was washed by alcohol and left in water free CaO desicator during a few days.

Extra pure grade reagents of $MnCl_2\cdot4H_2O$, $CoCl_2\cdot6H_2O$, $NiCl_2\cdot6H_2O$ and $CuSO_4\cdot5H_2O$ prepared by Kanto Chemical Co. were recrystallized and used for the test.

$Mn(NH_3)_2Cl_2$, $Mn(NH_3)Cl_2$, $Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$, $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$ and $Cu(NH_3)_2SO_4$ were obtained by thermal decomposition of hexammine chlorides of Mn^{++}, Co^{++}, Ni^{++} and copper tetrammine monohydrate sulfate in vacuum.

The decomposing temperature of hexammine, diammine and monoammine given by Biltz[1)] are shown in the following Table I. In Table I, the results obtained by the present authors are also included in the second column,

Table I.

	$6NH_3$		$2NH_3$		NH_3	
	Biltz	Present authors	Biltz	Present authors	Biltz	Present authors
$MnCl_2$	318°K	290°K	463°K	440°K	546°K	500°K
$CoCl_2$	362	340	510	480	574	520
$NiCl_2$	398	380	519	500	583	540

	$4NH_3H_2O$	$2NH_3$
	Present authors	Present authors
$CuSO_4$	290°K	260°K

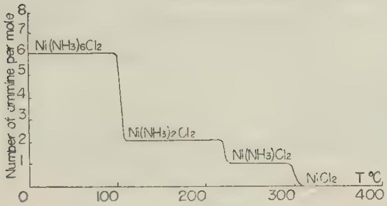

Fig. 3. Diagram of equilibrium temperature range in various coordination Ni^{++} salts.

and the decomposition temperatures of nickel ammine chloride complexes obtained by the authors are shown in in Fig. 3.

The color of each intermediate coordination compound is as follows.

$Mn(NH_3)_2Cl_2$	white
$Mn(NH_3)Cl_2$	whitely pink
$Co(NH_3)_2Cl_2$	violet
$Co(NH_3)Cl_2$	blue
$Ni(NH_3)_2Cl_2$	green
$Ni(NH_3)Cl_2$	yellow green
$Cu(NH_3)_2SO_4$	cobalt.

Anhydrated manganous, cobaltous and nickel chloride were obtained by dehydration at 200°C for 4 hours, and anhydrated copper sulfate at 260°C for 4 hours in vacuum.

§ 3. Results of the Observation

The magnetic susceptibilities of paramagnetic salts above mentioned obey the Curie-Weiss law,

$$\chi_m=\frac{C}{T+\theta}\,, \tag{1}$$

where χ_m is the molar susceptibility. Introducing the observed value of χ_m in the above relation (1), we get the value of C and θ. Magnetic moment p (Bohr magneton unit) is given as

$$p=\frac{1}{\beta}\sqrt{\frac{3kC}{N}}=2.839\sqrt{C}\,, \tag{2}$$

where k, β and N are the Boltzmann factor, the Bohr magneton and the Avogadro number respectively.

(1) $Mn(NH_3)_6Cl_2$, $Mn(NH_3)_2Cl_2$, $Mn(NH_3)Cl_2$, $MnCl_2$ (Table II and Fig. 4)

(2) $Co(NH_3)_6Cl_2$, $Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$, $CoCl_2$ (Table III and Fig. 5)

(3) $Ni(NH_3)_6Cl_2$, $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$, $NiCl_2$ (Table IV and Fig. 6)

§ 4. Discussion of the Results

In the hexammine complex salts $Mn(NH_3)_6\cdot Cl_2$, $Co(NH_3)_6Cl_2$, and $Ni(NH_3)_6Cl_2$, the octahedral complex ions of $M(NH_3)_6^{+2}$-type and the

Cl^- ions form anti-calcium difluoride type structure (anti-CaF_2) as shown in Fig. 8, and each divalent metal ion at the center is surrounded by the octahedron of six ammonia molecules. And this octahedral complex ion is surrounded by eight Cl^- ions (cubic symmetry) and the Cl^- ion by four complex ions (tetragonal symmetry). Since each ion is completely equivalent in the coordination in space, if the symmetry character of these hexammine chloride salts keeps complete O_h symmetry it is suggested that these salts are dominated by cubic field and anisotropy does not appear. On this assumption, the distances between nearest Cl–Cl and metal-metal ions can be calculated by use of the X-ray data[7] of the powdered salt, and the results are given in Table VI. The observed value of θ, however, is not small except for $Mn(NH_3)_6Cl_2$. It may be considered that the effect of lower part of crystalline field or spin orbital coupling without exchange interaction cannot be neglected, and then small displacement of the Cl^- ion and NH_3 molecule may happen.

The crystal structures of diammine and monoammine salts are not yet certain. Diammine complex salts may belong either to the planar four coordination of $CuCl_2 \cdot 2H_2O$ type, to the tetragonal coordination of $Zn(NH_3)_2Cl_2$

type or to the chain like polynuclear complex salt of $Cd(NH_3)_2Cl_2$ type. Anhydrated chloride salts $MnCl_2$, $CoCl_2$ and $NiCl_2$ form layer crystal structure D_{3d} of $CdCl_2$ type[8].

The symmetry of $Cu(NH_3)_4SO_4\cdot H_2O$ structure is orthorhombic bipyramidal and its crystal structure is shown in Fig. 9 as the cross-sectional view in the *b–c* plane which was determined by Mazzi[9] and Zemann[9]; unit cell constants are $a=7.07$, $b=12.12$, $c=10.66kx$ ($\pm 1\%$). This salt contains four copper ions in unit cell, differing from $CuSO_4\cdot 5H_2O$. The structure of the copper sulfate pentahydrate is of monoclinic symmetry and has two copper ions in unit cell. And $Cu(NH_3)_4SO_4\cdot H_2O$ has a chain of $-H_2O-Cu-H_2O-Cu-$ along the *c*-axis (Fig. 9).

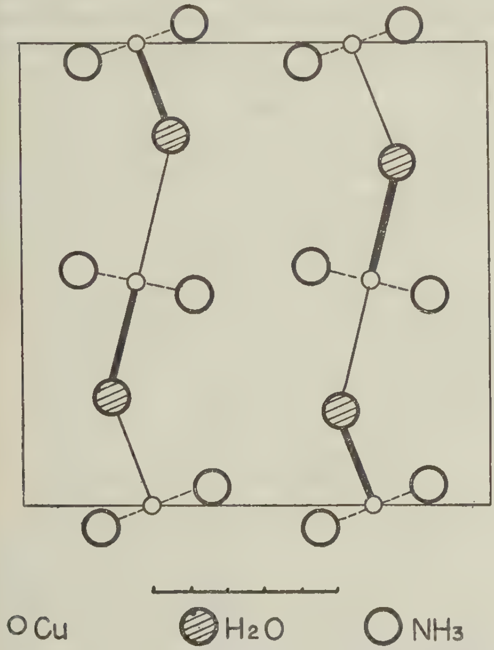

Fig. 9. Projection of the unit cell of $Cu(NH_3)_4SO_4\cdot H_2O$ on its (100) plane. After F. Mazzi.

The crystal structure of $Cu(NH_3)_2SO_4$ is unknown. The structure of the copper sulfate anhydrate $CuSO_4$ has been determined by Hammel[10] and has nearly rhombic symmetry and contains four copper ions in unit cell.

The origin of the Weiss temperature θ is due mainly to the influence of the anisotropic crystalline field and the exchange interaction. So if the splitting caused by crystalline field is small, the Weiss temperature θ can be expressed by the following relation after Van Vleck,

$$\theta=\frac{\Sigma_n W(n)}{k\Sigma_n{}^1}-\frac{\Sigma_n\Sigma_{n'}W(n)|M(nn')|^2}{k\Sigma_n\Sigma_{n'}|(nn')|^2}. \qquad (3)$$

Let us consider the spectroscopic energy $W(n)$ of the energy level of one ion, where n stands for a combination of quantum numbers. $M(n,n')$ are the matrix elements of magnetic moment of the ion in the direction of magnetic field. The index in the summation sign indicates that in the summation over the different levels n' the original level n is excluded. It may be shown, however, that this becomes zero in isotropic substances, as does also its average value in any powder. Therefore an anisotropic effect in powder, if any, may be faint from the above hypothesis.

A relation between the Weiss temperature and the exchange interaction energy J is given by the expression;

$$\theta=\frac{2zJS(S+1)}{3K}, \qquad (4)$$

where z is the number of ions at the nearest neighbour sites, J the energy of exchange interaction, and S the spin quantum number.

In the case of powdered sample a part of the exchange interaction is isotropic. Therefore, neglecting the Weiss constant due to anisotropy we estimate isotropic exchange interaction alone. We also neglect the Weiss constant due to magnetic dipole interaction as it may be of order of magnitude smaller than $10^{-2}\,cm^{-1}$.

i) Mn^{++}, $3d^5\,{}^6S_{5/2}$.

In this case, since the orbital level is singlet, the level is not splitted by a crystalline field and hence an anisotropy caused by the crystalline field does not remain. Thus θ in (3) becomes zero, and therefore the Weiss temperature θ is supposed to be equal to the isotropic exchange interaction. In the manganous salts which were measured by the present authors, the Weiss temperature is very small in magnitude compared with other salts. They may probably be normal paramagnetic salts at very low temperature. Especially in the manganous hexammine chloride $Mn(NH_3)_6Cl_2$, the value of θ is too small for estimating the Weiss temperature in the temperature range of the present experiment. In the case of $MnCl_2$ as shown in Table II, θ equals 4°C, so the exchange energy can be estimated as

$J=0.15\ \mathrm{cm}^{-1}$. Moreover, it seems reasonable that the g-value for the manganous hexammine chloride has been estimated to be 2.00 from the experimental results of molar susceptibility. The g-values for the diammine and the monoammine and the anhydrate salts are smaller than the g-value of the hexammine salt. These g-values are tabulated in Table VII.

Table VII.

	g
$Mn(NH_3)_6Cl_2$	2.00 ± 0.03
$Mn(NH_3)_2Cl_2$	1.98 〃
$Mn(NH_3)Cl_2$	1.97 〃
$MuCl_2$	1.96 〃

Table VIII.

	g
$Co(NH_3)_6Cl_2$	2.46 ± 0.03
$Co(NH_3)_2Cl_2$	2.51 〃
$Co(NH_3)Cl_2$	2.63 〃
$CoCl_2$	2.67 〃

ii) Co^{++}, $3d^7\ {}^4F_{5/2}$.

In the cobaltous salts, the value of θ for $Co(NH_3)_6Cl_2$ is positive, differing from the others as seen in Table III, so this salt is expected to show an antiferromagnetic behaviour at very low temperature.

In Table VIII, the g-values of cobaltous salts are given which are all quite apart from 2.00. It seems that the effect of spin-orbit coupling[12] and anisotropic field cannot be neglected from these results. A more detailed discussion on the present problem may be reserved to the future because of lack of experimental results on the susceptibility measurement of the single crystal and on the paramagnetic reasonance of these salts. The exchange energy can be evaluated by a relation (4), and we get, $J=0.8\ \mathrm{cm}^{-1}$ for $Co(NH_3)_6Cl_2$, and $J=2.0\ \mathrm{cm}^{-1}$ for $CoCl_2$.

iii) Ni^{++}, $3d^8\ {}^3F_4$.

In nickel hexammine chloride, we get $\theta=6.5°K$. In Date's experiment, the paramagnetic resonance line at liquid helium temperature could not be observed for the single crystal of this salt[13].

The g-value for this salt is in fair agreement with those of the other dilute nickel salts such as nickel ammonium Tutton.

In the diammine and the monoammine salt, the $\chi-T$ relation deviates slightly from the Curie-Weiss law at about 90°K and θ is negative and it may show a metamagnetic behaviour at low temperature. In Table IX, the g-values evaluated from the observed molar susceptibility of powdered nickel salts are shown. The exchange energies obtained from (4) are $J=0.7\ \mathrm{cm}^{-1}$ for $Ni(NH_3)_6Cl_2$ and $J=10\ \mathrm{cm}^{-1}$ for $NiCl_2$.

iv) Cu^{++}, $3d^9\ {}^2D_{5/2}$.

The crystal structure of copper tetrammine sulfate monohydrate $Cu(NH_3)_4SO_4\cdot H_2O$ is different from that of the copper sulfate pentahydrate as shown in Fig. 9. According to the experiments of paramagnetic resonance, the g-value of $Cu(NH_3)_4SO_4\cdot H_2O$ is rather smaller than that of the $CuSO_4\cdot 5H_2O$[14),15),16)]

Table IX.

	g
$Ni(NH_3)_6Cl_2$	2.24 ± 0.03
$Ni(NH_3)_2Cl_2$	2.26 〃
$Ni(NH_3)Cl_2$	2.28 〃
$NiCl_2$	2.32 〃

Table X.

	g
$Cu(NH_3)_4SO_4\cdot H_2O$	2.0 ± 0.03
$Cu(NH_3)_2SO_4$	2.22 〃
$CuSO_4$	2.43 〃

As shown in Table X the g-value of cupric tetramine sulfate monohydrate is nearly equal to that obtained by paramagnetic resonance. Date has found in his experiment that the absorption line of the paramagnetic resonance shows an extremely large broadening at the temperature below 20.4°K. The exchange energy of this salt is estimated of $J=0.9\ \mathrm{cm}^{-1}$.

Since the orbital ground level of Cu^{++} ion is singlet in tetragonal crystalline field and there is no effect caused by a crystalline field, the exchange energy may be considered as purely isotropic. The Weiss temperature θ of the copper tetrammine sulfate monohydrate is obtained as $\theta=4°C$ which is fairly different from 15°C as given by Volger.

For the salts of copper diammine sulfate and copper sulfate anhydrate, the Weiss temperatures are all positive and larger than that of copper tetrammine sulfate monohydrate and the g-values are larger also (Tables V and X). In the above calculation of exchange energy, the number of nearest neighbour ions z was taken as 6 and 4 in the hexammine salt and anhydrated salt respectively.

§ 5. Conclusion

According to the fact mentioned above we may conclude as follows:

1) For the salts with the same kind of positive ions, the value of θ decreases as the coordination number increases.

The above results can be explained by the consideration that in the hexammine salts or other ammine salts the crystalline field becomes more symmetrical than in the anhydrated salts, and since the distance between metal ions is longer than that of anhydrated salts for ammine ligands, the exchange interaction decreases as the coordination number increases. In the case of hexammine complex their crystal structures are more symmetrical than the other salts, but θ is not small except for Mn^{++}. It may show that the splitting of ground level due to lower symmetry or exchange interactions is so complicated that it cannot simply be explained.

2) The Weiss temperature θ increases in magnitude as

$$Mn^{++} < Co^{++} < Ni^{++} .$$

This behaviour can be found in all salts of any coordination in the present experiment except for $Co(NH_3)_6Cl_2$.

3) As for the g-values, Co^{++} has the largest value (2.46–2.67), while for Mn^{++} and Cu^{++} they are nearly 2.00 except anhydrated salts.

In the Co^{++}, the lowest level is triplet, with fourfold spin degeneracy, which will split into a number of doublets by the combined effect of the spin-orbit coupling and a tetragonal or trigonal field as shown in Fig. 10. Regarding the large anisotropy on the g-value found in the experiment of paramagnetic resonance, the effect of spin-orbit coupling may be seen of more importance than that of tetragonal or trigonal field[12)].

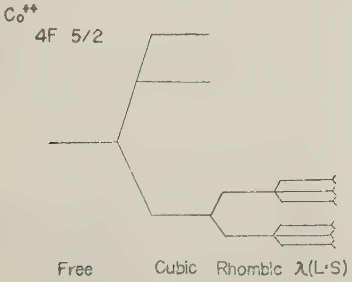

Fig. 10. Schematic energy level of Co^{++} ion in crystalline electric field,

The present experiment was carried out in the temperature range from 90°K to 600°K. All salts show normal paramagnetic behaviour in the above temperature range. Furthermore, in the experiment at lower temperatures, magnetic properties of these paramagnetic salts are expected to present more interesting phenomena and the problem is reserved for a future investigation.

Acknowledgement

The present authors wish to express their sincere thanks to Assist. Prof. Kanomata of our university who has helped us in constructing an apparatus and to Dr. Oyagi of Tokyo University of Education and to Mr. Takamoto of Gakushuin University for their kind advice in purifying the samples.

Our thanks are also due to Dr. Haseda of Tohoku University for his kind advice shown by him in performing the observation at low temperature and to Mrs. Nose who helped us in the present experiment.

The liquid nitrogen used in the experiment was kindly supplied by Dr. Monna of Nippon Oxygen Co.

Effect of the Basic Strength of Attached Groups on Light Absorption Spectra, IV. Proton Dissociations of Some Aromatic Molecules in Their Excited State

By Reikiti Itoh

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received March 27, 1959)

A general standard of the classification is given for the acid-base character of some aromatic molecules with special reference to the change of the character after and before the first excitation. The criterion is $\Delta q \gtreqless 0$, Δq being the change in the π-electron density of the special member of the attached group after and before the excitation. This corresponds to $pK_{a_1} \lesseqgtr pK_{a_2}$ where pK_{a_1} and pK_{a_2} are the proton dissociation constants in the ground and the excited state respectively. Examples are the case of acridon cation which gives $\Delta q=0.099$ corresponding to $pK_{a_2}-pK_{a_1}=2.48$ (observed value 2.6) and the case of 3-oxyacridine which gives $\Delta q=-0.18$ corresponding to $pK_{a_2}-pK_{a_1}=-4.52$ (observed value, if any, -5.27). Though the cases of naphthylamine and naphthol were treated in the previous paper III, some corrections about the term values and the discussion of the paper III are given in the present paper.

§ 1. Introduction

Recently, several authors have treated the excited state of some aromatic molecules based on the spectroscopic experiments. Among those authors, Förster¹⁾, Weller,²⁾ Koizumi and Mataga³⁾ have discussed about the derivatives of naphthalene; α- and β-naphthol, and α- and β-naphthylamine etc. Afterwards, Perkampus,⁴⁾ Weller⁵⁾ and Kokubun⁶⁾ have discussed about the excited state of the nitrogen hetero cycles; acridine, phenazine and their oxyderivatives. Molecules in the former group have smaller pK values after the first excitation; while those in the latter group have larger pK value after the excitation except 3-oxyacridine. All these are the results deduced by analyzing spectroscopic data on the light absorption or fluorescent emission. However, no theoretical explanation of these experiments on the basis of the molecular orbital treatment have appeared so far. The aim of the present paper is to give an explanation of the proton dissociation in the excited state of these molecules based on the semi-empirical molecular orbital method.

In the previous papers I⁷⁾ and II⁸⁾, the induction effect on the light absorption spectra in the alkylamino group was discussed on the ground of

$$\alpha_j-\alpha_i=k(pK_{b_i}-pK_{b_j}), \qquad (1)$$

where α_i is the coulomb integral of the ith group.* If we use the acidic strength of the group, the equation may be written in the form,

---

* There are several alkylamino groups such as, in the order of decreasing $|\alpha|$ value, NH_2, $NHCH_3$, NHC_2H_5, $N(CH_3)_2$, $NCH_3C_2H_5$ and $N(C_2H_5)_2$ etc.

$$\alpha_j-\alpha_i=k(pK_{aj}-pK_{ai}),$$

because the sum of pK_a and pK_b should be constant in the same molecule. The constant k was determined so that the equation (1) led to the observed light absorption spectra of triphenylmethane dyes and various aniline derivatives.

In the paper III⁹⁾, the author offered the treatment of the dissociation of naphthalene derivatives, naphthylamine and naphthol in their excited state on the basis of the molecular orbital treatment, where he assumed the same relation in the whole molecule because of the occurrence of the proton dissociation in the attached group. There were used 2 and 1 to the case of the excited and the ground state of the molecule in place of j and i respectively, i.e.

$$\alpha_2-\alpha_1=k(pK_{a_2}-pK_{a_1}). \qquad (2)$$

As indicated in the papers I and III, the Pariser-Parr approach in the S.C.F. treatment gives the coulomb integral of the atom r of molecule in the form,

$$\alpha_r=I_r+(q/2)(E_r-I_r), \qquad (3)$$

where I_r and E_r are the ionization potential and the electron affinity of the atom r in its valence state respectively and q is the π-electron density of the atom. Then the equation (2) is given by

$$\alpha_2-\alpha_1=(q_e-q_g)(E_r-I_r)/2, \qquad (4)$$

where q_e and q_g are the π-electron densities of the atom r in the excited and the ground state respectively. Combining the equation (2) with (4), we obtain the equation.

$$(q_e-q_g)(E_r-I_r)/2=k(pK_{a_2}-pK_{a_1}). \qquad (5)$$

Since the factor E_r-I_r of the left hand side of the equation is positive, the difference Δq of the π-electron density in the two states determines the sign of the right hand side of the equation. In other words, acids or bases can be classified into the following groups;

a) $\Delta q>0,\ pK_{a_2}>pK_{a_1}$
b) $\Delta q=0,\ pK_{a_2}=pK_{a_1}$
c) $\Delta q<0,\ pK_{a_2}<pK_{a_1}$.

Since pK_{a_2} is the acidic strength in the excited state, a) is the case in which the base becomes more basic after the first excitation; acridine, acridon and phenazine are known as examples of this case. In the case b), there occurs no change in the acid-base character by the first excitation; pyridine base is an example of this case. While c) is the case where the acid becomes more acidic after the excitation; examples are naphthylamines and naphthols with α- and β-substitution and were treated in the previous paper III. 3-Oxyacridine also belongs to this group.

In the present paper, it is intended to apply the equation (5) to the proton dissociation of some aromatic molecules belonging to the group a) and c).

§2. Proton Dissociation of Naphthyl Amine and Naphthol in Their Excited States

Though the basic concept appeared in the previous paper III is correct, there need some corrections on the data and discussion of the paper. As illustrated briefly in the paper, the concept of the proton dissociation is based on the result of the induction effect between σ- and π-electrons of the atom attaching the proton in the molecule. Therefore it will be convenient for us to discuss the effect rather in details about which the same situation has appeared in the hydrogen bond effect on the near ultraviolet absorption spectra of some aromatic molecules.¹⁰⁾ For example, let us consider a system composed from a molecule, a substituted group and a polar solvent. We know in some cases¹¹⁾ that substitution of the aromatic molecule B by an electron donating group AH causes the shift of the absorption spectra to the longer wave length, the origin of which is attributed to the stabilization of the energy levels of the electron partaking in the light absorption by B owing to the migration of the π-electron of AH. The formation of the hydrogen bond with the solvent molecule increases the distance between the atom A and the hydrogen atom H by about 0.03 A. Then the σ-electron sharing in the AH bond is more strongly localized to the atom A than without the hydrogen bond, which causes interaction between σ- and π-electron through the induction and drives the π-electrons of AH (nonbonding electrons) to the parent molecule B much more than without it. The stabilization energy ΔU due to the electron migration is given by the calculation based on the method of the electron migration theory¹¹⁾ used in the previous papers II and III. It is naturally expected that the interaction between AH and B depends upon the position of the substitution, e. g. α- and β-position of the naphthalene molecule. We should therefore use different constants of the induction for different positions. Fortunately one can evaluate the constants from one another using the data observed in the hydrogen bond effect in the following manner. For the system under consideration, four kinds of ΔU can be chosen; ΔU_e, ΔU_g, ΔU_{oe} and ΔU_{og}. The first two of these correspond to the case of hydrogen bond formation and the second two correspond to the case where no hydrogen bond is formed. The shift of the absorption spectra due to the hydrogen bond formation is given by

$$\Delta\tilde{\nu}_H=[(\Delta U_e-\Delta U_g)-(\Delta U_{oe}-\Delta U_{og})]/hc, \qquad (6)$$

where suffixes e and g indicate the excited and the ground state of B respectively. Integrals appeared in the terms ΔU's are indicated by the suffix o when there is no hydrogen bond formation. Among those, the resonance integrals and the coulomb integrals in the previous paper III are connected with each other by the relations

$$\rho_k-\rho_{ok}=\gamma_k=\gamma, \quad \chi-\chi_o=\alpha ,$$

and the energy levels for the vacant orbitals of B are connected by

$$\omega_k-\omega_{ok}=\beta_k=\beta ,$$

where $\alpha>0$, $\beta>0$ and $\gamma>0$ are assumed because of the increase of the electron donating character of AH due to the above induction. After the neglect of the terms higher than those of the second order, $\dfrac{\alpha-\beta}{\chi_o-\omega_{o1}}\ll 1$ and $\dfrac{\gamma-T\alpha}{\rho_{o1}-T\chi}\ll 1$, we obtain

$$\Delta\tilde{\nu}_H=\frac{\alpha-\beta}{\chi_o-\omega_{o2}}\left(\frac{\mu_{o,\,\mathrm{mig}}}{2\mathrm{x}e}\tilde{\nu}_o-\Delta\tilde{\nu}_o\right), \qquad (7)$$

where use has been made of the relations* $\chi_o<\omega_{o1}<\omega_{o2}<0$, and

$$\mathrm{hc}\,\tilde{\nu}_o=\omega_{o2}-\omega_{o1},\ \mathrm{hc}\,\Delta\tilde{\nu}_o=\Delta U_{oe}-\Delta U_{og} ,$$

$$\mu_{o,\,\mathrm{mig}}=2\mathrm{xe}\ \text{ and }\ \mathrm{x}=\int\psi_{o1}\,\psi_{o1}\,d\tau.$$

From these equations and (7), the relations $\tilde{\nu}_o>0$, $\Delta\tilde{\nu}_o<0$ and $\Delta\tilde{\nu}_{\mathrm{H}}<0$ are deduced, if the attached group has the electron donating character only. The quantity $\mu_{\mathrm{o,mig}}$ expresses the contribution of the migrating electron to the dipole moment and is estimated by the relation,

$$\mu_{o,\,\mathrm{mig}}=\mu_{\mathrm{obs}}-\mu_{\mathrm{AH}}+\mu_{\mathrm{CA}} , \qquad (8)$$

if we assume the validity of the bond additivity of the dipole moment. x denotes the length from the center of the gravity of the π-electron system of B to AH. The equation (7) was examined for the cases of aniline, phenol and *p*-aminoazobenzen by the author who gave

	aniline	phenol	p-aminoazobenzene	
$\Delta\nu_{\mathrm{H}}$	–646	–277	–1197	cm^{-1}
$\Delta\nu_{\mathrm{H,\,obs}}$	–610	–240	–1107	

respectively, assuming the value $\alpha-\beta=1.01$ eV for the first two cases and 1.75 eV for the last. The data necessary for some cases were given in the previous paper.[10)]

The deduction of the constant k_o in the previous paper III by the first order perturbation is not correct. Among the quantities in the equation (7), ν_o, ω_{o2}, x, e and χ_o can be assumed to be common for aniline and phenol and for α- and β-naphthol respectively.** Since the factor α–β can be assumed not to differ in the former because of the iso-electronic character of the π-electrons in the attached groups, the origin of the difference in the shift $\Delta\tilde{\nu}_H$ can be ascribed to the difference in $\mu_{\mathrm{o,o,mig}}$ and in $\Delta\tilde{\nu}_o$ for the former substances. On the other hand, there is no remarkable difference in $\mu_{\mathrm{o,mig}}$ and in $\Delta\tilde{\nu}_o$ for the latter (See Table I). The difference in the shift for these are, therefore, likely to come from the factor α–β. Since the values of $\mu_{\mathrm{o,mig}}$ are nearly equal for the former, the comparison of the shifts $\Delta\tilde{\nu}_H$'s in the paper III cannot give the difference in the constant of the induction for the latter, which may probably be given by the shifts in the latter. The value β in the equation (7) is considered to be much smaller in the latter than in the former because the π-electron system is much larger in naphthalene than in benzene. Then for the comparison of k values of two naphthols we may consider only α value which is the difference in the coulomb integral of AH due to the formation of the hydrogen bond with the solvent. Now we can estimate the constant k for β-naphthol by the following assumption that the same magnitude m of the localization of the σ-election in the attached group caused by the hydrogen bond formation corresponds to the same difference of pK value for both naphthols in the proton dissociation. Since the two quantities for α- and β-naphthol are represented by

---

* For the details of the deduction of the equation (7), see the previous paper[10)] by the author. T is the overlap integral between the π-orbitals of B and AH, ψ_{0_i} and ξ.

** Exactly speaking, χ_o's are different for $\mathrm{NH_2}$ and OH group.

$$\alpha_\alpha = k_\alpha \cdot m \quad \text{and} \quad \alpha_\beta = k_\beta \cdot m$$

respectively, the ratio of $\varDelta\tilde{\nu}_{\mathrm{H}}$ for each naphthol gives

$$k_\alpha \cdot 293 / k_\beta \cdot 403 = 140/410 \sim 280/590,$$

where use has been made of the data shown in the Tables I and II. If we choose $k_\alpha = 0.4375$ eV taking the mean value of those determined in the previous papers I and II, k_β is determined as 0.670～0.932 eV. Following the same procedure as in the paper III by taking the above values of k_α and k_β and the data of ionizations* into calculation, we obtain the resultant pK differences after and before the first excitation. These are listed in Table V. If the situation of the hydrogen bond effect for the two naphthylamines is the same as for the two naphthols, it would be necessary to use two different constant k_α and k_β for these two naphthylamines. Since data of the hydrogen bond effect suitable for this purpose are not available, the same value k is used for both of the two naphthylamines in the present calculation.

Table I. Data for two naphthols

	$\mu_{o,\mathrm{mig}}$	μ_{obs}	$\varDelta\nu_0$	$\varDelta\nu_{\mathrm{H,obs}}$
α–naphhtol	0.76D	1.43D[13]	–1050	–140,–280
β–naphthol	0.86	1.53	–1660cm^{-1}	–410,–590[12]cm^{-1}

As to the two values of $\varDelta\nu_{H,\mathrm{obs}}$, proton acceptor of the former and the latter is ethylether and triethylamine respectively. $\mu_{o,\mathrm{mig}}$'s were calculated by the equation (8) using $\mu_{\mathrm{CO}}=0.86$ D and $\mu_{\mathrm{OH}}=1.53$ D.[14]

Table II. Data for naphthalene

ω_{01}	ω_{02}	x	ν_0
–8.10 eV[15]	4.10 eV	2×1.39 A	32200 cm^{-1} [16]

Values of x are assumed to be the same for two naphthols and ω_{02} was estimated from ω_{01} and ν_0.

§3. Proton Dissociations of Acridon Cation and 3-Oxyacridine in Their Excited States

In this section, we shall discuss the molecules or ions belonging to the group a) or c).

i) *Acridon cation.*

Recently Kokubun[6] has reported about the acid-base character of acridon base. Based on the absorption and the fluorescent spectra observed by him, he pointed out that the acridon becomes stronger base after the first excitation. Without refering to the activity coefficient of the ion, he estimated $pK_{a_2}=1.26$ and $\varDelta pK_a=2.6$ from the frequency difference between the first absorption maxima by acridon and by its cation ; $\varDelta\tilde{\nu}=1200\,\mathrm{cm}^{-1}$.

Now let us examine the character of the excited acridon cation by the equation (5) on the basis of the molecular orbital treatment. The molecule of the acridon cation has the symmetry corresponding to the point group C_{2v}. If we choose the 15 π-orbitals as the bases of the representation, the characters for the operations of this group are as follows ;

Operation : R	E	C_2	σ_v	$\sigma_{v'}$
$\Gamma(C_{2v})$	15	–3	–15	3.

With the help of the character table of the irreducible representations, we get

$$\Gamma(\mathrm{C}_{2v}) = 9\mathrm{B}_2 + 4\mathrm{A}_2 + 2\mathrm{A}_2.^{**}$$

The orbitals belonging to each species are expressed as

$$\begin{aligned}\psi_{\alpha_2} = {} & c_1\phi_9 + c_2(\phi_{12}+\phi_{13}) + c_3(\phi_{11}+\phi_{14}) + c_4\phi_{10} \\ & + c_5(\phi_1+\phi_8) + c_6(\phi_7+\phi_2) + c_7(\phi_6+\phi_5) \\ & + c_8(\phi_5+\phi_4) + c_9\phi_{15}\,,\\ \psi_{\alpha_2} = {} & c_1(\phi_{13}-\phi_{12}) + c_2(\phi_{14}+\phi_1-\phi_{11}-\phi_8) \\ & + c_3(\phi_4+\phi_2-\phi_5-\phi_7) + c_4(\phi_3-\phi_6)\end{aligned}$$

and

$$\psi'_{\alpha_2} = c_1(\phi_1-\phi_8+\phi_{11}-\phi_{14}) + c_2(\phi_4-\phi_5+\phi_7-\phi_2),$$

---

* Ionization data used here, were taken from the works by Mulliken,[17] Dewar and Paoloni[18] which are

I_2: N^+ (sp^3, V_4) to N^{++} (sp^2, V_3) –28.76 eV,
I_1: N (sp^4, V_3) to N^+ (sp^3, V_4) –12.24 eV
for the ammonium like N atom and
I_2: O^+ (s^2p^3, V_3) to O^{++} (s^2p^2, V_0) –36.68 eV,
I_1: O (s^2p^4, V_2) to O^+ (s^2p^3, V_3) –14.73 eV
for the O atom in the hydroxy group respectively.

** The A_2 molecular orbitals, $\psi_{\alpha_2}=c_1(\phi_{13}-\phi_{12})+c_2(\phi_1-\phi_8)+c_3(\phi_{14}-\phi_{11})+c_4(\phi_4-\phi_5)+c_5(\phi_2-\phi_7)+c_6(\phi_3-\phi_6)$, can be approximated by two $\varPsi_{\alpha_2}$'s, because we see $c_2=\pm c_3$ and $c_4=\pm c_5$ (the double signs are to be read in the same order).

where ϕ_i is the $2p\pi$ orbitals of the ith atom (Fig. 1). The distribution of the π-electrons in the cation is determined by using the following approximations;

a) All the coulomb integrals of the carbon atoms except those for $i=9$, 15 12 and 13 are assumed to have the same value, i.e. $\alpha_i=\alpha$.

b) $\alpha_9=\alpha+3\beta$ is assumed for the protonated hetero nitrogen atom 9. This is slightly larger than $\alpha+2.4\,\beta$ deduced by Mataga.[19]

c) $\alpha_{15}=\alpha+1.4\,\beta$ is assumed for the oxygen atom 15 in OH.

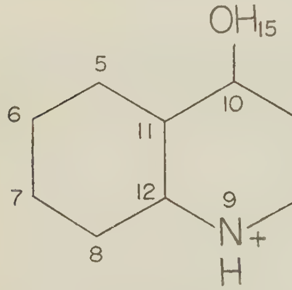

Fig. 1. Molecular figure of acridon cation.

d) $\alpha_{12}=\alpha_{13}=\alpha+0.5\beta$ is assumed because of the π-electron attraction by the protonated hetero nitrogen atom. Mataga gave a slightly smaller value $\alpha+0.4\,\beta$.

e) The resonance integrals between two adjacent atoms are assumed to have the same value β.

Solving the secular equations by using these approximations, we obtain the energy levels and the normalized coefficients of the atomic π-orbitals in each molecular orbital, a part of which is given in Table III. The first excited state is predicted to be obtained by promoting an electron in the highest occupied orbital ψ_{b_2} to the one with the same species. The transition from the ground state to it ($\psi_{b_2}\rightarrow\psi_{b_2}$) is shown to be an allowed one by the group theory and corresponds to the energy difference between $x=-0.891527$ and $x=0.256320$, where $x=(\alpha-\epsilon)/\beta$ with $\beta=-23000\,\text{cm}^{-1}$[20] and the energy ϵ of the molecular orbital. The dipole moment responsible for this transition has the direction pointing from the 9th to the 15th atom in Fig. 1, which coincides with that obtained by the spectral analysis. The first absorption spectrum of acridon cation is thus calculated as $26400\,\text{cm}^{-1}$. If we take account of the solvent effect which lowers the absorption energy by ca $1000\sim2000\,\text{cm}^{-1}$[21] even in the case of the non-polar solvent, the agreement of the above value with the observed one $23800\,\text{cm}^{-1}$ is quite satisfactory. For the oxygen atom of the OH group, the change Δq in the π-electron density due to the excitation is given by

$$\Delta q=\Delta c_9^2=0.099.$$

Then we obtain

$$\Delta pK_r=\frac{1}{2}\Delta q\frac{I_1-I_2}{k}=2.48\,,$$

which is in agreement with the value 2.6 deduced from the spectroscopic data by Kokubun.

Table III. c_i^2 values for the B_2 molecular orbitals ψ_{b_2}.

i	$x=-0.891527$	i	$x=0.256320$

9	0.013664	9	0.113125*

The coefficients c_i's corresponding to the c_i^2 values with asterisks should be taken negative.

ii) *3-Oxyacridine.*

Perkampus and Rössel[4] have reported that 3-oxyacridine shown in Fig. 2 increases its pK value after the first excitation and $\Delta pK=3.0$. We shall examine this by the equation (5). As denoted in the case of acridon cation, the oxygen atom should increase the π-electron density when it has a larger pK value after the first excitation (see Eq. (5)). As easily seen in Fig. 2, 3-oxyacridine has no symmetry axis in the molecular plane and we have to solve the secular equations of degree 15. The computing machine, E. T. L. Mark II, was used in the course of the calculations.

13	0.01123*	13	0.02394*
14	0.15644*	14	0.01661*
15	0.19658*	15	0.01617*

The coefficients c^i's corresponding to the c_1^2 values with asterisks should be taken negative.

The same approximations as used in the above was adopted except that $\alpha_9=\alpha+0.5\beta$ for the coulomb integral of the ring nitrogen atom, and $\alpha_{12}=\alpha_{13}=\alpha$ for those of the carbon atoms neighboring nearest to the ring nitrogen. A part of the energy levels and the normalized atomic orbital coefficients of each molecular orbital are given in Table IV. Those values are correct within the fourth decimal for the highest occupied level in the first excited state with $x=0.35772$. Those for the orbitalwith $x=-0.75988$, (the one in the ground state) are worse than those of the former in accuracy, though they give the π-electron density precisely enough in our approximation. The first absorption is obtained at 25300 cm^{-1} agreeing with the observation 24000 cm^{-1} within the limit of error caused by the solvent effect. The change in the π-electron density on the oxygen atom due to the first excitation is given by

$$\Delta q=\Delta c^2{}_{15}=-0.18,$$

and after using the equation (5), we have

$$\Delta pK_a=-4.52,$$

which indicates that 3-oxyacridine becomes more stronger acid after the first excitation contrary to the result by Perkampus and Rössel. Though we did not calculate about 3-oxyacridinium cation, the change in the π-electron density on the ring nitrogen atom due to the excitation, which is given from Table IV by

$$\Delta q=\Delta c_9{}^2=0.14\ ,$$

may be used to estimate the change in the basicity of the ring nitrogen due to the first excitation. From the comparison of two Δq's, it can be said that OH group becomes more acidic while the ring nitrogen becomes more basic in the first excited state respectively.

Therefore the first step of the proton dissociation of 3-oxyacridinium cation treated by Perkampus and Rössel will occur at OH group rather than at ring nitrogen atom as indicated by Weller.[5] Thus it is likely that the red shift of the first absorption maxima of 3-oxyacridine occurred in acidic region of pH, from 4200 A to 4600 A, corresponds to the dissociation of the proton of OH group and the blue shift of the absorption maxima, from 4600 A to 4300 A, occurred in alkaline region of pH corresponds to that of the ring nitrogen atom.

This conclusion can be in accordance with the result deduced from the consideration about the chemical kinetics by the author[22] who gave the equation,

$$hc(\tilde{\nu}_{\text{acid}}-\tilde{\nu}_{\text{alkali}})=-2.303RT\,(pK_{a_2}-pK_{a_1}), \qquad (9)$$

where $\tilde{\nu}_{\text{acid}}$ and $\tilde{\nu}_{\text{alkali}}$ are the absorption wave numbers of the ion or molecule in acidic and basic form respectively. Then our predicted value $\Delta pK_a=-4.52$ for 3-oxyacridine should be compared with that deducing from the first step of the dissociation of 3-oxyacridinium cation treated by Perkampus and Rössel, i.e., $\Delta pK=-5.27$. The situation is different in the case of acridon cation where, from Table III, Δq on the ring nitrogen atom is obtained as $\Delta q=-0.06$ denoting that though the first step of the proton dissociation occurs at OH group as indicated by Kokubun,[6] the basicity of the ring nitrogen atom is weakened slightly by the first excitation. In this connection, it is easily seen that the blue shift (from 23200 cm^{-1} to 24500 cm^{-1}) in the first step[6] corresponding to the dissociation of the proton of OH group and the red shift (from 24500 cm^{-1} to 23000 cm^{-1}) in the second step corresponding to that of the ring nitrogen are in agreement with the result of the equation (9) respectively.

§ 4. Results and Discussions

We set out the final results in Table V, where the first group is of the molecules belonging to c) group and the second one is of those belonging to a) group defined in §1. We see from Table V that the general agreement of the calculated values with those deduced from the spectroscopic data is good.

$\Delta\alpha$ is the change in the coulomb integral of the attached group due to the first excitation.

In the first group we used two k values according to the different positions of the substitution in two naphthols, the ratio of these values were estimated by using the equation (7) which expresses the absorption shift due to the hydrogen bond formation.* The equation is correct under the assumption $\frac{\alpha-\beta}{\chi_0-\omega_{01}} \ll 1$. Though this assumption is valid in the case where the parent molecule is benzene, it is not so good in the case where the parent molecule is naphthalene because of the smallness of the term $\chi_0-\omega_{01}$ as easily seen from the data shown in Table II and $\chi_0=-9.8$ eV (for NH_3) and –10.8 eV (for OH). Also it is noted that $\Delta\tilde{\nu}_{H}$ involves the term $\mu_{o,\text{mig}}$ and $\Delta\tilde{\nu}_0$ which are not equal for two naphthols, and the agreement is poor.

Among the hetero nitrogen cycles, acridine and phenazine are the typical bases which increase their basicity after the first excitation. Since these molecules have no attached groups, our treatment based on the effect of basic strength of the attached groups on light absorption spectra can not be applied to these molecules. However, if we determine by some way the constant of the induction on the ring nitrogen atom, equation (5) may be applied to those molecules where the constant k will have considerably small value. From the comparison of the predicted value with spectroscopic analysis, we conclude that the change in the acid-base character of the whole molecule or ion after and before the excitation can be estimated by the difference in the π-electron density of the special atom in the attached group after the first excitation.

The author wishes to thank to Prof. I. Oshida for his helpful discussion at the Institute and to Dr. Y. Komamiya and Mr. H. Toda for their services in driving the computing machine, E.T.L. Mark II, at the Electrotechnical Laboratory.

This work was supported by the Scientific Research Fund granted by the Ministry of Education.

---

* Observed pK_a values 9.37 and 9.49 for α- and β-naphthol indicate that α-naphthol is slightly more acidic than β-naphthol. This leads us to expect that the hydrogen bond is stronger for the former than the latter to the same polar solvent. But the observed values for $\Delta\tilde{\nu}_H$ indicate that $\Delta\tilde{\nu}_H$ is larger for β-naphthol than for α-naphthol in L_B band, while this is reverse for L_A band (in Platt's notation). Inspite of the pK_a observation prefering to $\Delta\tilde{\nu}_H$ of L_A band, we take that of L_B in the present case because of the first excited state. This may be a main reason of the disagreement in the case of β-naphthol. From the view point of the polarization direction, it is better to use $\Delta\tilde{\nu}_H$ of L_A for the comparison of two naphthols because the theoretical first absorption in naphthalene corresponds to the L_A band in polarization.

Spin-Spin Interaction in the Paramagnetic Salts

By Kō SUGIHARA

Physical Institute, Nagoya University, Nagoya

(Received April 30, 1959)

The spin-spin interaction via phonon exchange is proposed as a new mechanism of the so-called exchange interaction between the electron spins of the paramagnetic ions in crystal which has been overlooked hitherto. The interaction Hamiltonian derived by Van Vleck to account for the spin-lattice relaxation phenomenon is used for the numerical estimate. It is shown that the interaction through phonon exchange may have the same order of magnitude as the dipolar coupling in some of the paramagnetic salts.

This interaction is temperature independent and at large distances falls off as inverse cube power of the inter-atomic distance. In nickel Tutton salts, the magnitude of the interaction is about 10^{-3}cm^{-1} at the distance 12A which is comparable to that of the dipolar interaction.

§1. Introduction

Experimentally the exchange interaction in the paramagnetic salts can be estimated by the magnetic specific heat measurements.1) The exchange contribution to the specific heat can be found by subtraction of the single ion contribution which is estimated by using the magnetically diluted samples and the dipolar contribution.

However it is not conclusive that the exchange contribution comes only from the isotropic exchange interaction since the interaction H appears in the form $Tr(H^2)$. Further, informations on the exchange interaction are obtained from the line width of the magnetic resonance2) and the susceptibility measurement.3)

As magnetic ions in the paramagnetic salts are separated fairly well from each other by a distance of the order 6 or 7A, direct exchange may be negligibly small and the superexchange via the intervening nonmagnetic ions4) may be effective especially in the concentrated salts. But the origin of this indirect coupling still remains in an indistinct situation.

The exchange interaction between a pair of neighboring magnetic ions varies considerable from one salt to another and the fact that there appears to be particulary strong interaction between paramagnetic neighbors in the cyanides of 3*d* group and the complexes of the 4*d* and 5*d* groups*) suggests that the mechanism of exchange coupling between two magnetic ions involves the diamagnetic ions lying between them.5) In this paper we shall propose an interaction resulting from a phonon exchange between the magnetic ions. Important properties of the interaction are the long range character and the temperature-independence. In some salts, e.g. nickel Tutton salts the order of magnitude of the coupling is comparable to that of the dipolar coupling.

---

*) For these salts strong crystal field or covalent bonding exists.

§ 2. Level Splittings in Crystal Field

Here we shall consider the nickel Tutton salts as an easily calculable example. Nickel Tutton salts are monoclinic crystals and there are two Ni^{2+} in the unit cell. Each divalent cation is surrounded by a distorted octahedron (nearly regular octahedron) of six water molecules and each magnetic complex $Ni^{2+}(H_2O)_6$ has differently oriented principal axis. Griffiths and Owen[6] has investigated a number of nickel Tutton salts in the paramagnetic resonance experiments. The orbital level ^3F in a cubic field splits as shown in Fig. 1. Triply degenerate levels Γ_4 and Γ_5 are lifted by a tetragonal and rhombic field and the spin triplet in the ground state Γ_2 splits into three singlets W_1, W_2 and W_3.

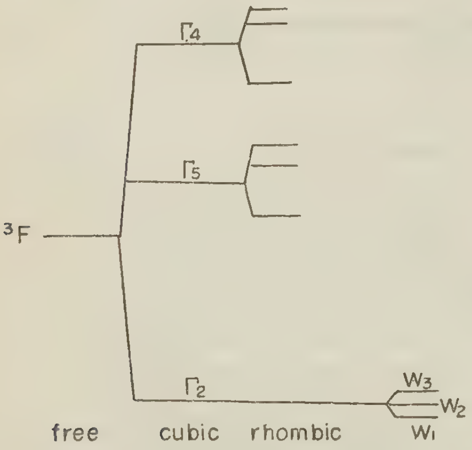

Fig. 1. Level splitting of Ni^{2+}

It is easily shown that

$$\Delta_{52} : \Delta_{45} = 5 : 4 , \tag{2.1}$$

where Δ_{52} and Δ_{45} are the energy gaps between $\Gamma_5-\Gamma_2$ and $\Gamma_4-\Gamma_5$ respectively. By combining the resonance data with the susceptibility measurements they obtain the spin–orbit coupling constant λ as about $-250\,\mathrm{cm}^{-1}$ which is 25% smaller than the free ion value and $g=2.25$ for all salts. From these data $\Delta_{52}=8000\,\mathrm{cm}^{-1}$ and $\Delta_{45}=6400\,\mathrm{cm}^{-1}$ are obtained. From the measurements of the optical absorption and g–value Owen[7] concludes $\lambda=-270\,\mathrm{cm}^{-1}$ and $\Delta_{52}=8400\,\mathrm{cm}^{-1}$ which are consistent with the resonance data.

Recently Low[8] investigated the paramagnetic and optical spectra of Ni–doped MgO crystal and obtained similar results.

§ 3. Spin–Spin Interaction through Phonon Exchange

Our eventual purpose in this work is to calculate the spin–dependent self–energy resulting from emission and absorption of one phonon between two magnetic ions i and j. We shall first define the Hamiltonian of the total system in the form

$$\mathscr{H} = H_O + H_L + \sum_j (H_{S.O}{}^{(j)} + H_{O.L}{}^{(j)}), \tag{3.1}$$

where H_O is the Stark energy of the orbit which will be assumed to be due to the point dipoles of the surrounding six water molecules and H_L is the energy of lattice vibrations. These two terms form the unperturbed Hamiltonian and the perturbation terms $H_{S.O}{}^{(j)}$ and $H_{O.L}{}^{(j)}$ denote the spin-orbit coupling and the distorted part of the crystalline field due to the lattice vibration of the j–th magnetic ion respectively. $H_{O.L}{}^{(j)}$ is the interaction introduced by Van Vleck[9] in his theory of the paramagnetic relaxation.

Here, we shall consider the process in which i–spin emitts (or absorbs) one phonon and j–spin absorbs (or emitts) it. According to the various combinations of $H_{S.O}$ and $H_{O.L}$ in the perturbational calculation, many processes will appear and the effective term among them has the following type

$$\begin{aligned}\mathscr{H}'_{ij} = \sum_{k,\nu} \sum_{p,q=i,j} \sum_{\delta=\pm1} &< N_{K\nu} | H_{S.L}{}^{(P)} | N_{K\nu}-\delta > \\ &< N_{K\nu}-\delta | H_{S.L}{}^{(q)} | N_{K\nu} > \\ &\times (\delta \hbar \omega_{K\nu})^{-1} ,\end{aligned} \tag{3.2}$$

where $N_{K\nu}$ is the phonon number with wave vector $\boldsymbol{K}$ and polarization ν. $H_{S.L}{}^{(i)}$ is the Hamiltonian of i–th ion inducing the spin–lattice relaxation and can be written as

$$\begin{aligned} H_{S.L}{}^{(i)} = \sum_{t.t'} \{ &< \Gamma_2 | H_{S.O}{}^{(i)} | \Gamma_{5t'} > \\ &< \Gamma_{5t'} | H_{S.O}{}^{(i)} | \Gamma_{4t} > < \Gamma_{4t} | H_{O.L}{}^{(i)} | \Gamma_2 > \\ &+ < \Gamma_2 | H_{O.L}{}^{(i)} | \Gamma_{4t} > < \Gamma_{4t} | H_{S.O}{}^{(i)} | \Gamma_{5t'} > \\ &< \Gamma_{5t'} | H_{S.O}{}^{(i)} | \Gamma_2 > \} (\Delta_{52} \Delta_{42})^{-1} \\ &+ < \Gamma_2 | H_{S.O}{}^{(i)} | \Gamma_{5t} > < \Gamma_{5t} | H_{O.L}{}^{(i)} | \Gamma_{5t'} > \\ &< \Gamma_{5t'} | H_{S.O}{}^{(i)} | \Gamma_2 > (\Delta_{52})^{-2} ,\end{aligned} \tag{3.3}$$

where Γ_{4t} and Γ_{5t} are the states which belong to Γ_4 and Γ_5 respectively. Since Ni^{++} and Cr^{+++} belong to the same orbital configuration and the difference of $3d$-electron numbers is five, so we can use the same expression for $H_{S.L}$*) as that for the chrome alum given by Van Vleck.10) Then

$$H_{S.L}=\mathcal{E}_1[Q_3(2S_z^2-S_x^2-S_y^2)$$
$$+\sqrt{3}\,Q_2(S_y^2-S_x^2)]$$
$$+\mathcal{E}_2[Q_4(S_xS_y+S_yS_x)+(S_zS_x+S_xS_z)$$
$$+Q_6(S_yS_z+S_zS_x)]\,, \tag{3.4}$$

with

$$\mathcal{E}_1=175\sqrt{3}\,\lambda^2\rho_2/(99\varDelta_{52}^2)\,,$$
$$\mathcal{E}_2=4\lambda^2[\rho_1+5\rho_2/33]/\varDelta_{52}^2+8\lambda \tag{3.5}$$
$$[\rho_1-5\rho_2/44]/(\varDelta_{52}\,\varDelta_{42})\,,$$
$$\rho_1=12e\mu<r^2>/7a^5\,,$$
$$\rho_2=-66e\mu<r^4>/7a^7\,. \tag{3.6}$$

Now the vibrations of a complex $M\cdot(H_2O)_6$ (M: magnetic ion) are specified by a set of normal coordinates Q_k which has been discussed in detail by Van Vleck.9)

$<r^2>$ and $<r^4>$ denote the mean square and fourth power radius of the $3d$-electron respectively, a the distance between the magnetic ion and any one of the water molecules and μ the dipole moment of a water molecule. Any other process than (3.2) are negligibly small since the ratio to (3.2) is the order $\hbar\omega_{K\nu}/\varDelta\ll1$. Hereafter, we shall restrict our calculation only to the term involving $\mathcal{E}_1$ which is the same order as $\mathcal{E}_2$. Displacement of a water molecules from the equilibrium position is expanded in Debye waves as follows

$$\xi(r)=\sqrt{\frac{\hbar}{2NM}}\sum_{K.\nu}\mathbf{e}_{K.\nu}(\omega_{K\nu})^{-1/2}(a_{K\nu}\exp(i\boldsymbol{Kr}).$$
$$+a_{K\nu}^*\exp(-i\boldsymbol{Kr})). \tag{3.7}$$

Since (3.7) is the expression commonly used, it may need no explanation. Using (3.7), we can express Q_2 and Q_3 as

$$Q_2^{(j)}=i\sqrt{\frac{\hbar}{2NM}}\sum_{K.\nu}(\omega_{K\nu})^{-1/2}(a_{K\nu}\exp(i\boldsymbol{Kr}_j)$$
$$-a_{K\nu}^*\exp(-i\boldsymbol{Kr}_j))$$
$$\times(e_{K\nu}^{(x)}\sin(\boldsymbol{KX})-e_{K\nu}^{(y)}\sin(\boldsymbol{KY}))\,,$$
$$Q_3^{(j)}=i\sqrt{\frac{\hbar}{6NM}}\sum_{K.\nu}(\omega_{K\nu})^{-1/2}(a_{K\nu}\exp(i\boldsymbol{Kr}_j)$$
$$-a_{K\nu}^*\exp(-i\boldsymbol{Kr}_j))$$
$$\times(e_{K\nu}^{(x)}\sin(\boldsymbol{KX})+e_{K\nu}^{(y)}\sin(\boldsymbol{KY}) \tag{3.8}$$
$$-2e_{K\nu}^{(z)}\sin(\boldsymbol{KZ}))\,,$$

where $\mathbf{r}_j$ is the coordinate of j-th magnetic ion and $X=(a,o,o)$, $\mathbf{Y}=(o,a,o)$, $\boldsymbol{Z}=(o,o,a)$. By inserting (3.4) and (3.8) into (3.2), it is easily shown that phonon number $N_{K\nu}$ cancels out, so that interaction turns out to be temperature independent. The effective spin Hamiltonian (3.2) becomes

$$\mathscr{H}'_{ij}=-\mathcal{E}_1^2\frac{V}{(2\pi)^3}\frac{1}{3NM}\sum_{\nu}v_\nu^{-2}\iiint\cos(\boldsymbol{K},\boldsymbol{r}_i-\boldsymbol{r}_j)$$
$$[F_{K\nu}(2S_{zi}^2-S_{xi}^2-S_{yi}^2)+3G_{K\nu}(S_{yi}-S_{xi}^2)]$$
$$[F_{K\nu}(2S_{zj}^2-S_{xj}^2-S_{yj}^2)+3G_{K\nu}(S_{yj}^2-S_{xj}^2)]$$
$$dKd\Omega_K\,, \tag{3.9}$$

where v_ν is the sound velocity for the polarization ν and

$$F_{K\nu}=e_{K\nu}^{(x)}\sin(\boldsymbol{KX})+e_{K\nu}^{(y)}\sin(\boldsymbol{KY})$$
$$-e_{K\nu}^{(z)}\sin(\boldsymbol{KZ})\,, \tag{3.10}$$
$$G_{K\nu}=e_{K\nu}^{(x)}\sin(\boldsymbol{KX})-e_{K\nu}^{(y)}\sin(\boldsymbol{KY})\,.$$

For simplicity, we have picked up the interaction between the equivalent ions and omitted the term between the inequivalent ones which can be easily written down.

It is very complicated to evaluate the integral (3.9) in general case, so we shall confine our consideration to the following special case :

$\boldsymbol{r}_i-\boldsymbol{r}_j=\boldsymbol{R}\|Z$ -axis, $R\gg a$ and $K_oR\gg1$ (K_o : cut off wave vector). Thus we obtain

$$\mathscr{H}'_{ij}=A\,(S_{yi}^2-S_{xi}^2)\,(S_{yj}^2-S_{xj}^2)+O(a^4/R^5), \tag{3.11}$$

$$A=-\frac{90}{\pi R^3v^2W}\left(\frac{\lambda^2}{\varDelta_{52}}\right)^2. \tag{3.12}$$

The coefficient A is the lowest order term ($\sim a^2/R^3$) in the expansion of a/R. In writing down (3.12), we have used the relation $\varDelta_{52}=25e\mu<r^4>/3a^6$ which is valid for the point dipole model. v is the effective common velocity for v_ν and W the density.

Using our simplified assumption, it is easily shown that the cross term such as $F_{K\nu}\,G_{K\nu}$ disappears rigorously and term containing $F_{K\nu}^2$ is negligibly small since the ratio to the term containing $G_{K\nu}^2$ is $\sim a^2/R^2$. In general cases, these terms may appear in the same order of magnitudes as that of $G_{K\nu}^2$. To evaluate (3.12) numerically, we use the following values of the constants

$$\lambda=-250\,\text{cm}^{-1}\,,\quad \varDelta_{52}=8000\text{cm}^{-1}\,,\quad W=2\,,$$
$$v=2.3\times10^5\text{cm/sec},^{**)}\quad R=12\text{Å} \tag{3.13}$$

---

*) For brevity, we shall omit the suffix specifying magnetic ion.

**) There are no available specific heat data of Tutton salts, so we take the value of v used Van Vleck for alums.

$R=12$Å[†] is the distance between a pair of equivalent magnetic ions satisfying the conditions $R \gg a$ and $K_0R \gg 1$ ($K_0=1.9\times10^8\mathrm{cm}^{-1}$). The value of A computed from (3.12) with the aid of (3.13) is

$$A=-1.5\times10^{-3}\mathrm{cm}^{-1}, \qquad (3.14)$$

and now it is remarkable that (3.14) is the same order as the dipolar coupling. It is easily shown that the oscillating terms proportional to $\cos(K_0R)/K_0R^2$ or $\sin(K_0R)/K_0R^2$ which are neglected in (3.11) are unimportant even if R is the distance between the nearest neighbor pair[*].

Our calculation is based on the two assumptions: i) the magnetic ion is purely ionic and ii) the water molecule can be regarded as point dipole. However the experimental observations that λ in salts is reduced considerably as compared with free ion value suggest our assumptions are oversimplified.

Nevertheless the final conclusion will not be altered drastically even if we treat the problem in more detail taking account of the charge transfer between the magnetic ion and the ligand.

§ 4. Conclusion

The discussion of the preceding section may be summarized in the following conclusions. In some paramagnetic salts, the spin—spin interaction via phonon exchange has a comparable order of magnitude to that of the dipolar coupling. This interaction falls off as inverse cube power of distance at the large distances and temperature-independent. In the diluted salts this interaction will be more important than the indirect coupling suggested by Kramers. Up to the present, informations on the mechanism of the spin coupling in the paramagnetic salts are quite incomplete, so it may be desirable to clarify the mechanisms from both experimental and theoretical investigations.

Measurement of Plasma Temperature and Electron Density

By Kiyoshi MURAKAWA and Shizuyo MIZUNO-HASHIMOTO

Aeronautical Research Institute, University of Tokyo, Komaba-machi Meguro-ku, Tokyo

(Received May 18, 1959)

This investigation aims at measuring the temperature of the plasma obtained by passing condensed discharge through a Geisler tube containing neon. The wave-length of Ne I $\lambda 5852$ emitted from condensed discharge was compared with that of the same line emitted from arc discharge, the comparison being made with a Fabry-Perot etalon. Red shift of the line by spark discharge was detected. From the amount of the shift the half-value width contributed by the ionic field and electrons was calculated by Lindholm's formula. Subtracting this (vectorially) from the observed half-value width, the width contributed by the Doppler effect alone was obtained, and then the plasma temperature was calculated. From the line profiles of $H\gamma$ and Ne I $\lambda 4715$ Holtsmark's so-called normal field strength F_n was obtained, and therefore the electron density could be deduced. In our present example the mean plasma temperature was $T=6\times 10^3$ K, and the mean electron density $N=1\times 10^{10}$ per cm.^{3}

§ 1. Introduction

For some time we are interested in measuring the temperature and the electron density in a plasma obtained by passing discharge through neon. As a first step toward this object condensed discharge through a Geisler tube was studied, because this is the easiest arrangement for spectroscopic determination of the above-mentioned quantities. A preliminary description of the result obtained was published1) in Japanese in 1958. Since then somewhat stronger spark discharge has been employed and somewhat higher temperature has been obtained.

Dynamic characteristics of the plasma in discharges through neon and argon was measured previously by Olsen and Huxford.2) The plasma seems to have been generated in a bulb similar to that of the present work, so their results will be referred to frequently in the present paper. Temperature of discharge in hydrogen (constant current) was measured by several investigators.3) In the case of hydrogen contribution of the ionic field and electrons to the width of spectral line is large compared with that of the Doppler effect, but in the case of neon, if adequate lines are selected, the latter effect is expected to be larger than the former, and can be used in calculating the plasma temperature. The primary purpose of the present investigation is to examine experimentally to what extent this expectation is satisfied.

§ 2. Experimental Arrangement

The plasma source was a discharge through a Geisler tube which was made of pyrex glass and whose capillary portion was about 3 mm in inner diameter. Neon of about 5 mm Hg pressure was filled in the tube. The electric circuit is shown schematically in Fig. 1. In order to get condensed discharge, a condenser with a capacity of $0.02\mu F$ was used and the current passed through a spark gap and the Geisler tube. This type of discharge will be denoted as spark discharge. In order to compare with this an ordinary a.c. discharge, discharge was passed by

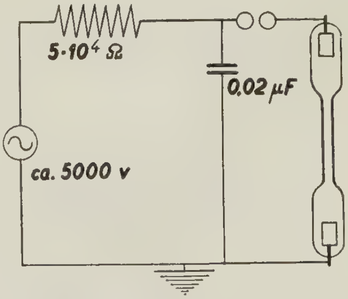

Fig. 1. Schematic diagram of the circuit for the condensed discharge in Geisler tube containing neon.

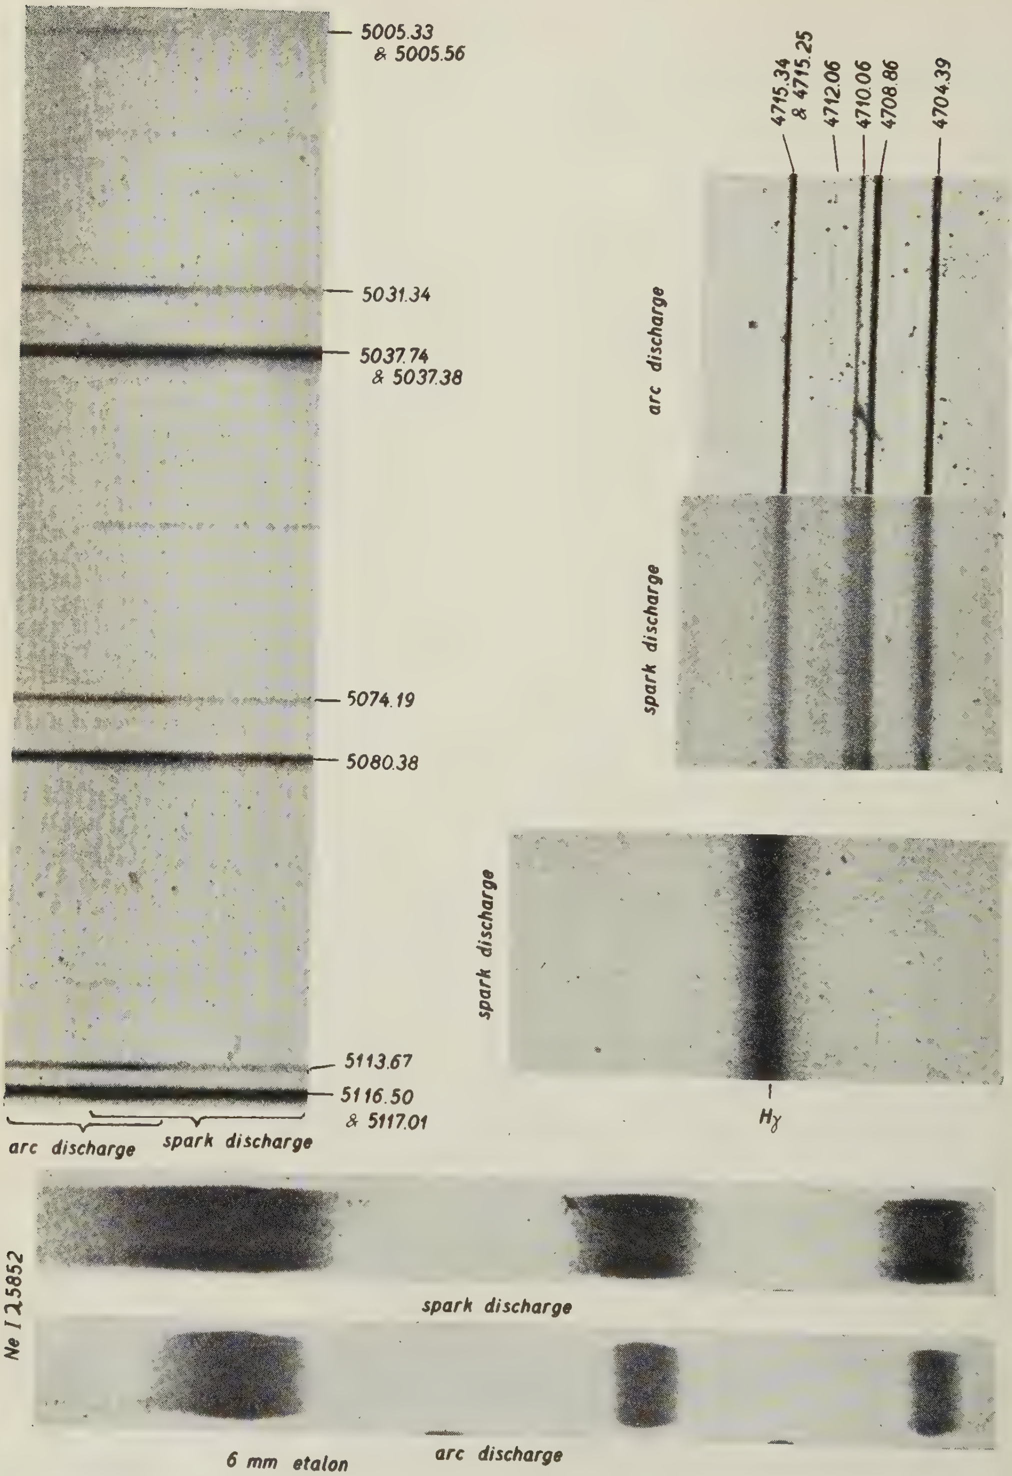

Fig. 2. Enlargement of some spectrograms. The four upper spectrograms were taken with a two-prism spectrograph. The two lower pictures were taken with a Fabry-Perot etalon.

displacing the condenser and the spark gap and lowering the output voltage of the transformer. This type of discharge will be called arc discharge.

For the purpose of spectroscopic observation, the light emitted from the capillary portion was viewed "side off". The spectrum was photographed by means of a two-prism spectrograph equipped with a camera-lens having 1.5 m focal length. When the displacement of a spectral line due to spark discharge had to be measured, a silvered or multi-layer coated etalon was employed. In order to get intensity marks, a step-filter having 30 steps with $\Delta D=0.15$ was used. Some of the spectrograms are reproduced in Fig. 2.

§ 3. Plasma Temperature

In order to determine the plasma temperature by means of Doppler effect, the line Ne I λ5852 was selected. First the interference pattern of λ5852 emitting from arc discharge was photographed and then, without touching the Geisler tube and the Fabry-Pérot etalon, that of λ5852 emitting from spark discharge was photographed. See Figs. 2 and 3. This method enables us to determine precisely the displacement of the line when the discharge condition is varied, and was adopted long ago by Ross and one of the authors.4) From the microphotometer trace of the interference patterns, the intensity distribution (line profile) was obtained, as shown in Fig. 4. In the analysis, it was assumed that natural neon consists of 10 parts of Ne^{20} and 1 part of Ne^{22} and that in Ne I λ5852 the Ne^{22}-component lies to the violet side of the Ne^{20}-component by the amount $\Delta\nu=0.072\ \mathrm{cm}^{-1}$ (according to Nagaoka and Mishima5)). In the following only the Ne^{20}-component (after making the correction due to Ne^{22}) is considered. Assuming that in arc discharge the line Ne I λ5852 undergoes no influence of the ionic field nor of the electrons, it was found that the spark discharge displaces the line to the red by the amount $\Delta\nu_{\parallel s}=-0.027\ \mathrm{cm}^{-1}$. It was also found that the half-value width of the line emitting from the spark discharge is $\Delta\nu_{h}=0.230\ \mathrm{cm}^{-1}$, in which the width due to the Fabry-Perot etalon is eliminated.

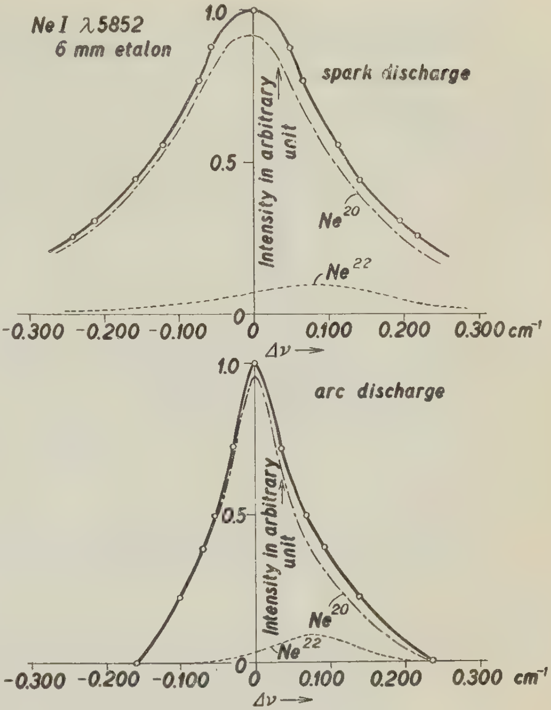

Fig. 4. Intensity distribution (profile) of the line Ne I λ5852 obtained with a 6 mm etalon.

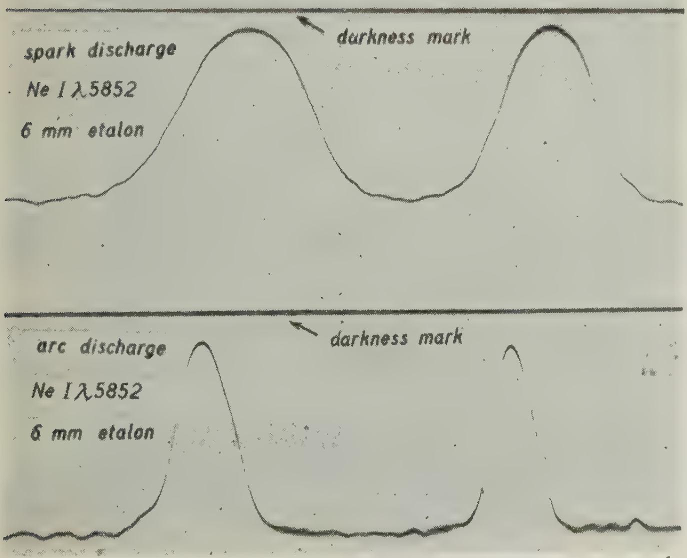

Fig. 3. Microphotometer trace of the interference patterns of the Fabry-Perot etalon (reduced about 1/3 from the original)

Ne I λ5852 was classified by Paschen as $1.5\,s_2-2\,p_1$. The initial level is $[2p\,3p]_0$, and the final level $[2p\,3s]_1$, in which $2p^5$ is abbreviated as $2p$. In the previous work¹⁾ it was shown that in Ne I the mixing of $2p\,3s$ and $2p\,3d$ is negligible, and that the Stark effect of λ5852 (in uniform electric field) is given by

$$\Delta\nu=-\gamma F^2\,,$$

$$\gamma=4.00\times10^{-12}\,,$$

in which F (electric field strength) is measured in volt/cm and $\Delta\nu$ in cm^{-1}, and it is assumed that F is adequately small. The value of γ was calculated by the method of Foster.⁷⁾

In the case of spark discharge the fluctuation of the ionic field and the collision damping by electrons give rise to broadening and displacement of spectral line.⁸⁾ In the case of a spectral line which exhibits quadratic Stark effect, Lindholm⁹⁾ showed that

$$\Delta\nu_h=0.0450\gamma^{\frac{2}{3}}v^{\frac{1}{3}}N/c\,,$$

$$\Delta\nu_{\rm dis}=0.0387\gamma^{\frac{2}{3}}v^{\frac{1}{3}}N/c\,,$$

in which γ is the Stark effect constant N the electron density (per cm³), and c is the velocity of light. The mean velocity of electron is denoted by v and is connected with the temperature by the relation

$$\frac{1}{2}m\,v^2=\frac{3}{2}k\,T.$$

From the formulas given by Lindholm, we get

$$\frac{\Delta\nu_h}{\Delta\nu_{\rm dis}}=\frac{0.0450}{0.0387}=1.16$$

In our case we got $\Delta\nu_{\rm dis}=-0.027$ cm^{-1}. Using the above-mentioned relation, we get $\Delta\nu_h=0.031$ cm^{-1}. This is the width contributed by the ion and electron alone and does not include the contribution of the Doppler effect.

The line profile $U(\Delta\nu)$ contributed by the ionic field alone can be calculated, using the probability function $W(F)$ introduced by Holtsmark.¹⁰⁾ The numerical calculation of $W(F)$ was published by Pannekoek and Verwey.¹¹⁾ Using their numerical values, the form of $U(\Delta\nu)$ was calculated, as shown in Fig. 5.

The line profile due to the electron alone can be assumed to be of dispersion type⁸⁾ and can be written as

$$I_{\rm el}=\frac{c}{(\Delta\nu-k)^2+\Delta\nu_h^2/4}\,.$$

The line profile contributed by the ionic field and the electron (neglecting the Doppler effect) can be expressed (as a first approximation) as

$$I(\Delta\nu)\,d\nu=d\nu\int_{-\infty}^{\infty}\frac{cU(x)\,dx}{(\Delta\nu-k-x)^2+\Delta\nu_h^2/4.}$$

On the other hand Doppler effect alone should give rise to a line profile of a gaussian type. The combination of the above-mentioned expression and gaussian distribution is much complicated and there is no simple way of deducing the Doppler width from the observed width.¹²⁾ We have therefore assumed that the Doppler width is the mean of the linear difference width and the square difference width, and obtained the Doppler half-value width $\Delta\nu_D=0.213$ cm^{-1}. It is connected with the absolute temperature T, the mass number M, and the wave.number ν (cm^{-1}) by the relation

$$\Delta\nu_{\rm D}=7.2\times10^{-7}\,\nu\sqrt{T/M}.$$

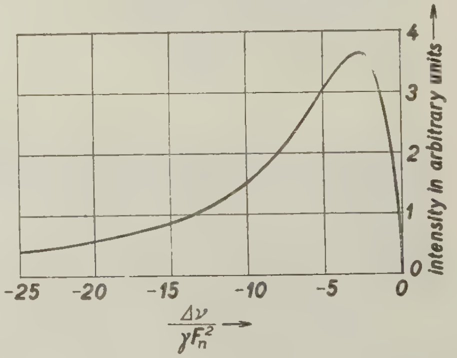

Fig. 5. Line profile of Ne I λ5852 calculated by means of Holtsmark's method and neglecting the influence of the electron and the Doppler effect.

Putting $\nu=17083$ cm^{-1}, $\Delta\nu_D=0.213$ cm^{-1}, $M=20$ in the formula, we get $T=6.0\times10^3$ K.

We shall see later that the value of F_n (Holtsmark's so-called normal field strength) is 1.7×10^4 volt/cm. Putting this value in Fig. 5 we see that the ionic field alone contributes 0.009 cm^{-1} to the half-value width and -0.003 cm^{-1} to the shift. It can be seen that in spark discharge the electron effect in Ne I λ5852 is larger than the ionic field effect in both half-value width and red shift.

§ 4. Electron Density in a Plasma

The electron density N can be deduced from the normal field strength F_n via the relation

$$F_n = 2.61\, N^{2/3} e\ ,$$

where e is the electron charge.

F_n can be determined from the profile of a line showing a linear Stark effect. Ne I λ4715 was selected for this purpose (the assumption of a linear effect is sufficient for our purpose, although this line suffers a quadratic effect in a small electric field). The hydrogen line can also be utilized, as was done by Olsen and Huxford.[2)] The Geisler tube used contained a trace of hydrogen, but no strong hydrogen line was obtained in the case of arc discharge. In the case of spark discharge, however, hydrogen lines (especially Hα, Hβ and Hγ) came out strongly. Microphotometer traces of the lines Ne I λ4715—4704 and the line Hγ are reproduced in Fig. 6.

From the microphotometer trace the line profile of Hγ was obtained, as shown in Fig. 7. It must be remarked that on the central part of Hγ two lines of Ne II are superposed. Using the theoretical profile curve for Hγ published by Olsen and Huxford, the value of F_n was determined so that the wing of the observed profile of Hγ would coincide with the wing of the theoretical profile (Holtsmark's classical theory applies only to the wing of the profile where the influence of the electron plays a minor role), and $F_n = 1.8 \times 10^4$ volt/cm was obtained.

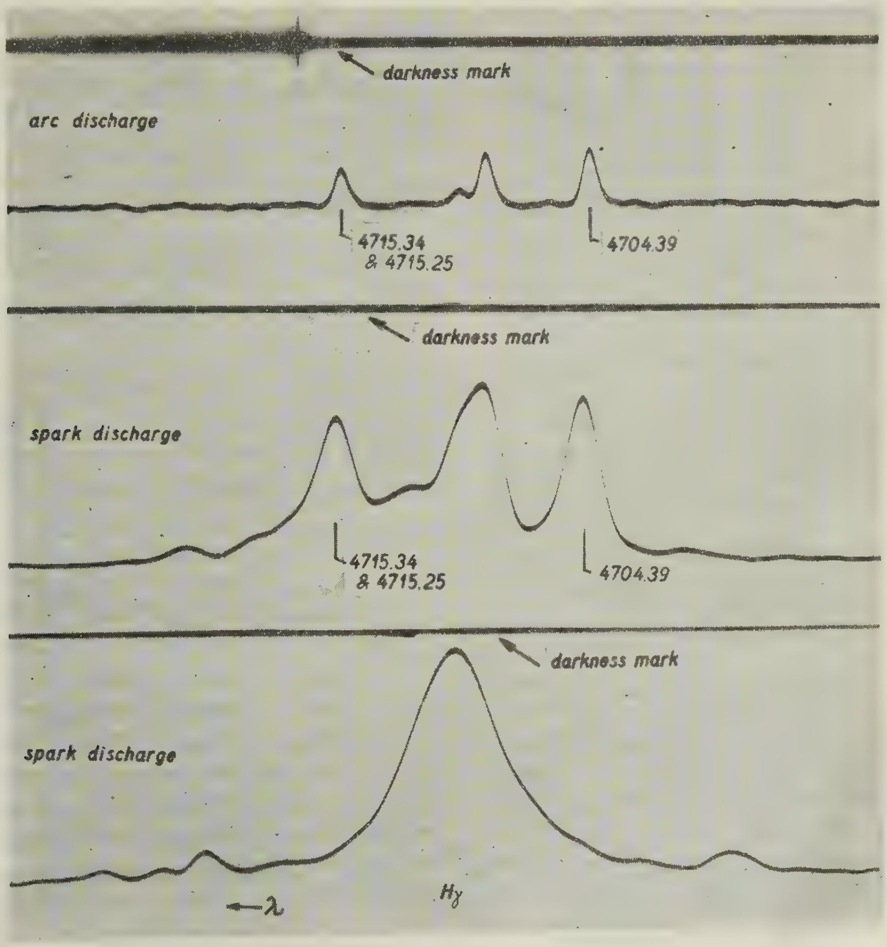

Fig. 6. Microphotometer trace of the lines Ne I λ4715-4704 and the line Hγ (reduced about 1/3 from the original).

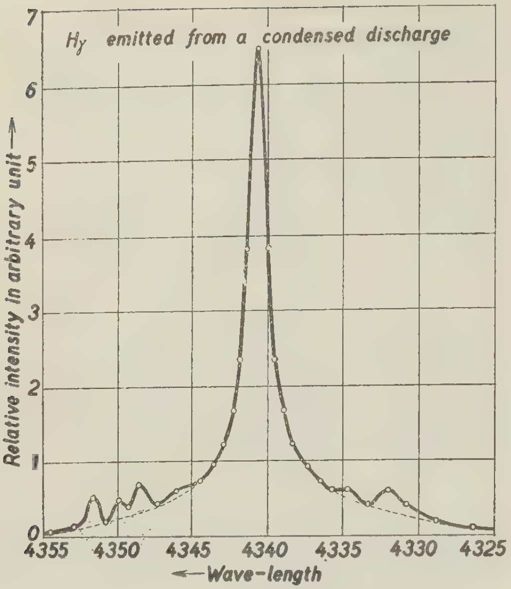

Fig. 7. Line profile or Hγ.

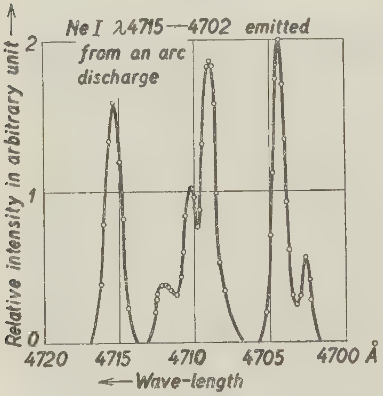

Fig. 8. Intensity distribution of the lines Ne I λ4715-4704 emitted from arc discharge.

The case of Ne I λ4715 is much more complicated, as shown in Figs. 8 and 9. The line λ4715 (in zero electric field) consists of a strong and a weak component, but Foster and Rowles[13] showed that in a sufficiently strong field they fuse together (Paschen-Back effect analog). The Stark effect for the line λ4715 is shown schematically in Fig. 10. The profile for λ4715 was calculated using the data published by Foster and Rowles and the method of Holtsmark. In Fig. 10 (and in Fig. 11) m_l of the optical electron is denoted as m_l for brevity. The experimental profile for λ4715 is such that the wing on the red side alone can be utilized, because the wing on the violet side is strongly disturbed by the wings of other lines. The wing on the red side of λ4715 is contributed mainly by (p_9)—$2p\,6d\,(d_4')$. The relative intensities of the components due to the transition) (p_9)—$2p\,6q$ were calculated by the method of Foster[7] in a rough way and the theoretical curve was calculated (Fig. 11), but the accuracy of calculation is such that it is sufficient for concluding that the

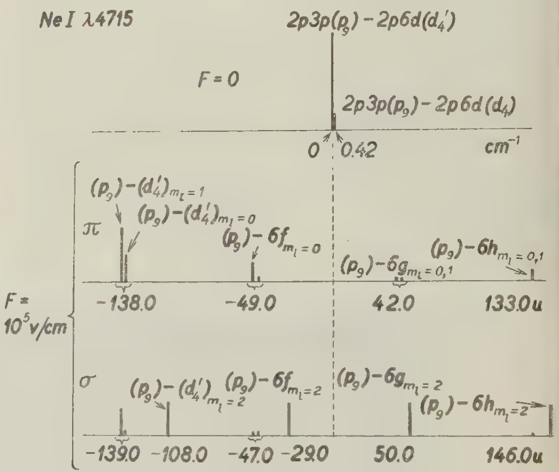

Fig. 10. Stark effect of the lines Ne I λ4715. The positions of the splitted components were taken from the article of Foster and Rowles. The relative intensities were calculated roughly by the authors. It was assumed that the lower level is not displaced by the electric field.

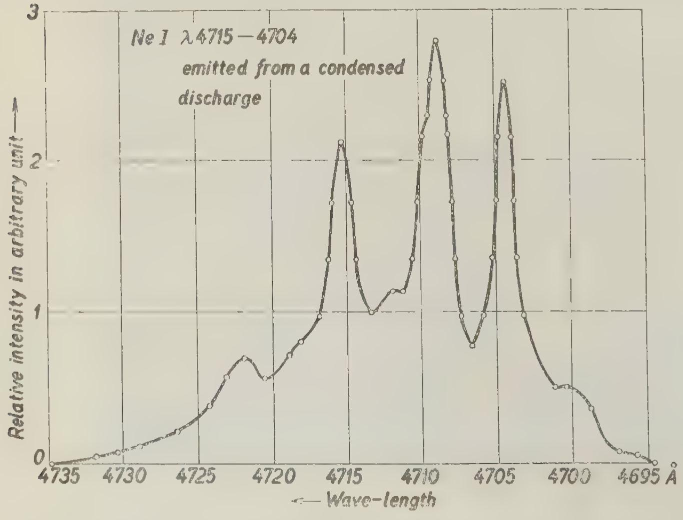

Fig. 9. Intensity distribution of the lines Ne I λ4715-4704 emitted from spark discharge.

effect of the transition $(p_9)-2p\,6f$ on the solid curve of Fig. 11 is negligible. It was found that the wing of λ4715 on the red side can be accounted for by putting $F_n=1.5\times10^4$ volt/cm. Since the conclusion from Hγ seems to have a somewhat better accuracy, the mean of F_n is taken to be $F_n=1.7\times10^4$ volt/cm. Putting this value in the above-mentioned formula, we get the electron density $N=1\times10^{16}$ (per cm³).

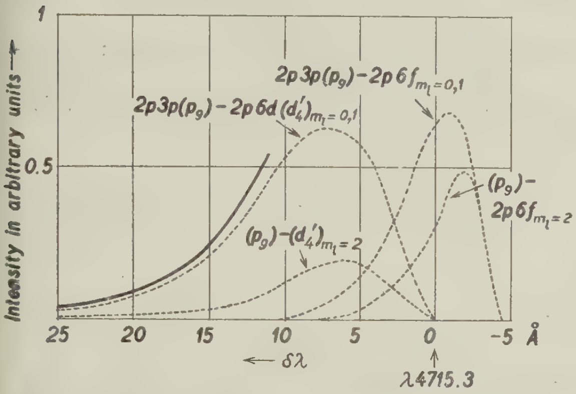

Fig. 11. Intensity distribution of the components $(p_9)-(d_4')$ and $(p_9)-6f$ of λ4715, calculated by Holtsmark method, neglecting the electron effect. It is assumed that $F_n=15$ kv/cm. The resultant intensity distribution that is useful for comparing with the experimental profile of the wing on the red side is shown by a solid curve. Paschen's notation for spectral term is in parentheses.

In the case of Ne I λ5037.7 $(2p\,3p-2p\,5d)$, the line profile for the spark discharge is degraded to the red (see Fig. 2), owing to the lack of $p-h$ component. The value of F_n deduced from this line is in agreement with the above-mentioned value of F_n, but in this case the accuracy is not so good.

§ 5. Physical Meaning of the Results Obtained

Since the current in the plasma varied with time, the physical meaning of the results obtained is somewhat more complicated than in the case of constant discharge current. The current and the potential were measured with a Tekronix c.r.o. and the wave forms are shown in Fig. 12. The main trend is similar to that of Olsen and Huxford,[2] so that it can be expected that also the time variation of the intensity of individual spectral line is similar. This was found indeed to be the case. The c.r.o. traces of the photomultiplier currents are reproduced in Fig. 13, but they are not new as compared with those published by Olsen and Huxford.[2]

Olsen and Huxford showed that although the discharge current reaches its maximum in a few μ sec and vanishes within 10 μ sec, the ion concentration keeps its approximately flat value for over 30 μ sec. We may therefore expect that once a high temperature is attained in the spark discharge, this will not decrease so rapidly as the discharge current.

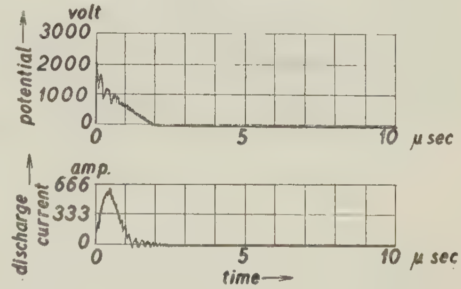

Fig. 12. Cathode-ray oscilloscope traces of the potential and the discharge current.

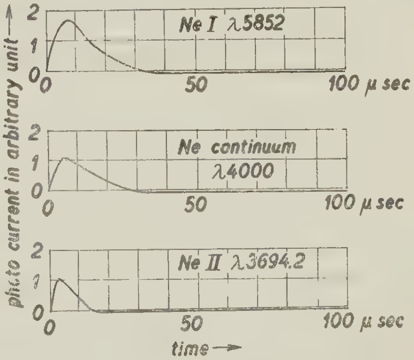

Fig. 13. Cathode-ray oscilloscope traces of the photo currents for individual spectral lines.

The line profiles of Ne I λ5852 and λ4715 and Hγ that were deduced in the present investigation are mean profiles, in which the mean is taken over the time, the intensity of the respective line at each instant being the weight. If we keep in mind the above-mentioned conclusion of Olsen and Huxford, we may assume that the mean plasma temperature deduced from the profile of Ne λ5852 (in the present work) would not be much lower than the maximum temperature.

Measurement of plasma temperature and

electron density will be continued, and it is hoped that by modifying the experimental set-up it would be possible to get a higher temperature than that reported here.

A Quantitative Study of the *M* Centre in KCl

By Tetsuhiko Tomiki
The Department of Physics,
The Faculty of Science,
Tohoku University, Sendai, Japan

(Received July 13, 1959)

As reported in the preceding short note1), two experimental results are obtained:

$$\Delta N_F/\Delta(f_M\cdot N_M)=2\ , \qquad (1)$$

$$2\eta_M=\eta_F=0.56,\ \text{above } 130°\text{C} \qquad (2)$$

where N_F and N_M are the concentration of the F and M centres, respectively, and are defined as follows:

$$N_F=1.31\cdot10^{16}H_F\cdot K_{F,\max}\ , \qquad (3)$$

$$f_MN_M=1.06\cdot10^{16}H_M\cdot K_{M,\max}\ . \qquad (4)$$

η is the quantum yield in the photochemical reaction $M+(\text{photon})_M\rightarrow F$, and defined by the next equations:

$$\left.\begin{aligned}\eta_M&=\partial(f_M\cdot N_M)/\partial q_M\ , &(5)\\ \eta_F&=\partial N_F/\partial q_M\ , &(6)\end{aligned}\right\}\ \text{for } q_M=0$$

where, q_M denotes the quanta absorbed in the M band. The result (2) shows that the M centre carries one electron at most. However, it is rather difficult to accept the relation $\eta_F=0.56$ without restriction, because the M centre decomposes thermally into the F centre above 130°C. Furthermore, the relation (1) indicates that f_M should be equal to 1.5, if the optical dipole-moment of the M centre is directed along the ⟨110⟩ of the host crystal, as is in the Seitz model.2) This is quite contradicted to the relation (2).

However, it is shown that the paradox is removed when the hypothesis by van Doorn3), the 2nd absorption band of the M centre hidden in the F band, is admitted. Then, the optically detected change ΔN_F should be multiplied with overlapping factor $\boldsymbol{p}$ in order to obtain the net variation of the number of F centre. $\boldsymbol{p}$ is obtainable under the requirement that the net quantum yield η_F^* should be unity:

$$\eta_F^*\equiv\partial(\boldsymbol{p}N_F)/\partial q_M=1.0\ . \qquad (7)$$

By using Eqs. (2) and (6), we have:

$$\boldsymbol{p}=1.8\ . \qquad (8)$$

If the oscillator strength of the 1st and 2nd bands of the M centre is denoted as f_{M1} and f_{M2}, respectively, then, the following equations are derived under the assumption that the dipole-moment of the M centre is directed to the ⟨110⟩:

$$\Delta(\boldsymbol{p}N_F)/\Delta(f_{M1}\cdot2N_0)=2\boldsymbol{p}\ ,$$

$$\Delta(\boldsymbol{p}N_F)=\Delta(6N_0)\ ,$$

where N_0 is the density of the M centre per cc whose dipole-moment is parallel to one of the ⟨110⟩. Thus,

$$f_{M1}=0.83\ ,\quad f_{M2}\cong1-f_{M1}=0.17\ . \qquad (9)$$

By using these constants we can estimate the net quantum yield η_M^* of the M centre above 130°C. From Eqs. (2) and (5) we have:

$$\eta_M=\partial(f_MN_M)/\partial q_M=\partial(2f_{M1}\cdot N_0)/\partial q_M\ ,$$

hence,

$$\begin{aligned}\eta_M^*&\equiv\partial(6N_0)/\partial q_M=3\eta_M/f_{M1}\\ &=3\times0.28/0.83=1.0\ . \qquad (10)\end{aligned}$$

Thus, the postulation (7) that requires $\eta_F^*=1.0$ leads to the conclusion that the quantum yield of the M centre η_M^* should also be equal to unity and, furthermore, $f_{M1}=0.83<1$. According to Eq. (10), it is possible to recalculate the quantum yield η_M^* using η_M. Then, η_M^* is expressed as follows:

$$\eta_M^*=1/\{1+1.40\cdot10^{-7}\exp(0.50/kT)\}\quad \text{for } kT \text{ in ev.} \qquad (11)$$

The obtained values, $A/B_0$4)$=1.40\cdot10^{-7}$ and $E=0.50$ ev, are also considered to be plausible. The simple calculation shows that the half width of the 2nd band of the M centre is the order of 0.08 ev at room temperature, if we assume that the absorption maximum is located at the peak of the F band. This result seems to be in concordance with the experimental fact that the half width of the F band is unaltered even when the "pure" M band exists on the red side of the F band1). The fact that the F band shows dichroism when it was illuminated with {110} polarized light in this band might reasonably be ascribed to the 2nd band of the M centre.

The author is very grateful to Prof. M. Ueta for his kind interest, and to Mr. Osaka for his discussions.

Antiferromagnetic Resonance in $CoCl_2 \cdot 6H_2O$

By Muneyuki DATE*

The Research Institute for Iron,
Steel and Other Metals,
Tōhoku University, Sendai

(Received June 4, 1959)

We observed the antiferromagnetic resonance of $CoCl_2 \cdot 6H_2O$ in the frequency range 9.5 to 38 GC/sec at liquid helium temperatures. The antiferromagnetic properties of the hydrated cobaltous chloride have been reported first by Haseda and Kanda¹⁾ from the measurements of the powder susceptibility. Recently, X-ray analysis of the crystal structure²⁾, specific heat³⁾, susceptibility of the single crystal,⁴⁾ and proton magnetic resonance of this salt⁵⁾ were investigated and it became clear that the easy direction is parallel to the c-axis.

Up to present, paramagnetic resonance experiments of this compound were attempted by Gerritsen (80° and 20°K)⁶⁾ and by the present author (4.2°K at 9 GC/sec),⁷⁾ but no resonance was observed and it has been considered that this may be due to the short spin lattice relaxation time of the Co^{++} ion. Recently we attempted to detect the paramagnetic resonance of this salt at 35 GC/sec region at 4.2°K and observed very broad absorption lines. T_1 is estimated to be about 4×10^{-12} sec at $T=4.2$°K and the principal g-values to be $g_a'=2.9$, $g_b=5.0$ and $g_c=4.0$, where the a'-axis inclines to the direction of the a-axis by about 32° because of the monoclinic structure ($\beta=122°12'$). It is interesting to note the results of the susceptibility measurements by Haseda.⁴⁾ He obtained $g\,'=2.7$, $g_b=4.9$ and $g_c=4.9$. Appreciable difference is seen in g_c. The cause of discrepancy may be considered as follows. From the results of our experiments, considerable amount of the antiferromagnetic state (short range order) seems to survive even near 4°K and this produces the shift of paramagnetic resonance line because the antiferromagnetic and paramagnetic resonance lines are not much separated in this direction. Pure antiferromagnetic resonance was observed below 2.1°K. Between 2.1°K and 4.2°K, very broad and unmeasurable lines exist. We observed the frequency, the angular and temperature dependences of the antiferromagnetic resonance lines. One of the experimental results is shown in Fig. 1. The critical frequency is measured as 34630 ± 50 MC/sec below which the resonance line describes a circle in the b-c plane just as in the a-b plane of $CuCl_2 \cdot 2H_2O$ at 9 GC/sec⁸⁾ and above which the resonance can be observed all directions in b-c plane. The critical field resonance is also seen. From this results, $c_2/c_1 \sim 2$ can be obtained by Nagamiya-Yosida theory⁹⁾ ¹⁰⁾ of antiferromagnetic resonance for the case of orthorhombic symmetry. The critical field is 7.2 kilo-oersted at 1.5°K. It must be noted, however, that the experimental results show slight but systematic deviations from Nagamiya-Yosida theory. The line width was also measured. Generaly speaking, the width is large compared with that of $CuCl_2 \cdot 2H_2O$. At 1.5°K, the narrowest one is of 100 Oe and the broadest one is of 2000 Oe. Detailed results and discussions will be published later.

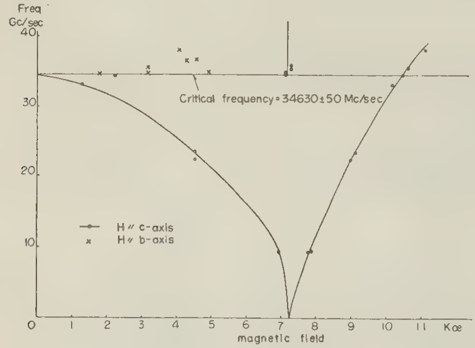

Fig. 1. Frequency-field diagram of antiferromagnetic resonance in $CoCl_2 \cdot 6H_2O$ at 1.5°K. Magnetic field is parallel to c-(easy) axis and b-axis.

Finally, the present author wishes to express his cordial thanks to Prof. Fukuroi for his continual encouragement during the course of present experiments. He is also indepted to Drs. Sugawara and Haseda for useful discussions on the present problem.

Crystalline Field Splitting in Ferrous Fluosilicate

By Taiichiro OHTSUKA

Research Institute for Iron,
Steel and Other Metals,
Tohoku University

(Received June 17, 1959)

When a large initial splitting of the spin state makes paramagnetic resonance unobservable, the splitting may be determined to a limited extent by measuring the susceptibility of single crystals at low temperatures. A rather large splitting of the lowest spin levels of $Fe^{2+}(^5D_4)$ in ferrous Tutton salt has been determined by this method.[1] Similar measurements have now been made on ferrous fluosilicate.

The isomorphous series of this crystal are known to have trigonal symmetry. The trigonal axis (c-axis) of the crystal coincides with the magnetic axis of the complex. Measurements were made parallel and perpendicular to the c-axis by the A. C. Hartsohn bridge method. The results are shown in Fig. 1.

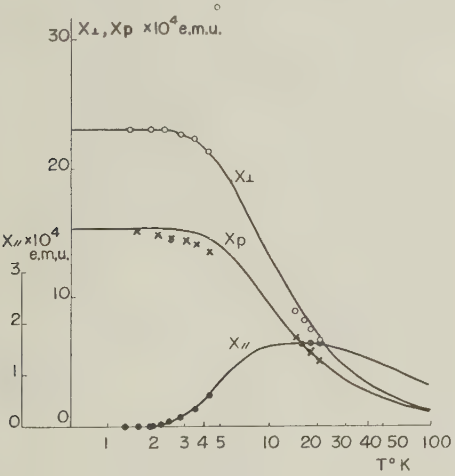

Fig. 1. $\chi_{//}$ (susceptibility parallel to c-axis) is plotted on an enlarged scale. χ_p is for a powder specimen. Solid lines are curves calculated using the values listed in Table I.

Table I.

	D	$g_{//}$	$g_\perp$
$FeSiF_6\cdot 6H_2O$	$-10.4\,cm^{-1}$	2.00	2.14
$Fe(SO_4)_2\cdot(NH_4)_2\cdot 6H_2O$*	$+14\,cm^{-1}$	2.32	2.06

* The ground spin doublet is split by an amount $6.4\,cm^{-1}$.

The pertinent parameters have been derived using the spin Hamiltonian $\mathscr{H}=-DS_z^2+g\beta\boldsymbol{H}\cdot\boldsymbol{S}$ with $S=2$. An expression for the susceptibilities for the case of axial symmetry may be readily derived and these have been used to fit the experimental results. The results may be expressed fairly well with a level scheme in which a spin singlet ($M=0$) lies lowest. The parameters derived are listed in Table I where the corresponding values for the ferrous Tutton salt have been listed for comparison. It is interesting to note that the sign of D and the anisotropy of g are opposite for the two salts. A similar change of sign seems to exist in the corresponding manganous salts.[2]

There is doubt as to the validity of the spin Hamiltonian for the Fe^{2+} case because the cubic field gives an orbital triplet lowest.[3] Our experiments are confined to low temperatures, however, and thus reflect only the splitting between the two lowest levels. The parameter D derived from our experiment corresponds to this splitting. It is probably incorrect to describe the scheme and the spacing of the excited levels with this D and the spin Hamiltonian. Measurements must be extended to higher temperatures in order to determine the details of the excited levels but the analysis will become progressively difficult because the splittings are then expected to become smaller than kT and one will get only an averaged out effect. There are reasons (the comparatively narrow line width of Mn^{2+} ions added as impurities)[1] to suspect that the excited spin doublets are split by rhombic distortion. Baker and Bleaney[4] report resonance at 20°K when the r.f. and external fields are directed along the c-axis. This could be due to transitions between the excited levels admixed by the rhombic field. If so the intensity should decrease when the temperature is lowered below about 14°K.

Proton resonance of the ligand water molecules have also been observed. With the external field perpendicular to the c-axis, 8 lines are observed with an overall splitting of 1 Mc/sec at 4.2°K. The splitting decreases and becomes very small as the field is rotated towards the direction parallel to the c-axis. This fact and the temperature dependence of the splittings are in close correspondence with the susceptibility results.

Acknowledgements are due to Prof. E. Kanda for his constant encouragement and to Assist. Profs. T. Haseda and T. Sugawara for various discussions.

Semiconducting Properties of Bi-Sb Alloys

By Seiichi TANUMA

The Research Institute for Iron,
Steel and Other Metals,
Tohoku University, Sendai

(Received June 24, 1959)

Bi and Sb crystallize with the same lattice structure, and the alloys between them become also solid solutions with the similar lattice structure in all composition.[1] It has been found that this alloy system, in spite of the crystallographic simpleness, shows anomalous electrical properties which can be explained by an assumption that the alloys of intermediate composition become intrinsic semiconductors. The resistivity, the Hall effect and the magneto-resistance of polycrystalline specimens which were prepared from zone refined constituent metals were measured in the temperature range from 4.2°K to 300°K. The plots of logarithmic resistivity versus reciprocal temperature are shown in Fig. 1. The similar plot for the Hall coefficient is also exemplified with the specimen #6 in the same figure. The sign of Hall coefficients was negative in all the present specimens. The concentration-dependence of both the resistivities and the Hall coefficients at 4.2°K and 200°K are shown in Fig. 2 (a) and (b). As shown in Fig. 1, the resistivity curves of the alloys containing Sb more than 4 atomic per cent seem to be non-metallic, or rather semiconductive. Fig. 2 proves that the alloys of intermediate compositions have high resistivities with the peak at around 10∼20 atomic per cent of Sb which is probably due to the depletion of carriers in them. The author regards that the positive gradients of the curves in Fig. 1 are due to the intrinsic semiconductivity. Then the maximum gradient in each alloy multiplied by twice the Boltzmann constant, $2k$, are plotted in Fig. 2 (c). This quantity may be regarded as a measure of the width of the forbidden energy band, even in the present case where the carriers are degenerate. Fig. 2 (c) suggests that the semiconductive range of the alloys spreads from 4 to about 50 atomic per cent of Sb. The increase of resistivity with the temperature rise which appears at high temperatures and which does not arise in the typical semiconductor, may be explained by the following assumption; the temperature variation of the carrier mobilities varies with temperature as T^{-p} with $p \gtrsim 2.5$ at higher temperatures instead of with $p=1\sim1.5$ which is in the case of the typical phonon scattering. This assumption is also supported by the temperature variation of the magneto-resistance observed. The occurrence of the semiconductive properties in this alloy system can be explained by examining the electronic structure of the Bi type crystal calculated by Mase.[2] The whole data and the detailed discussions will shortly be published.

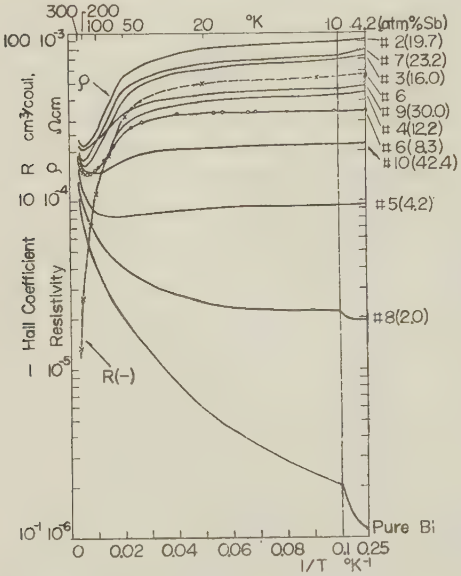

Fig 1. The logarithm of the resistivities and the Hall coefficient *versus* the reciprocal temperature.

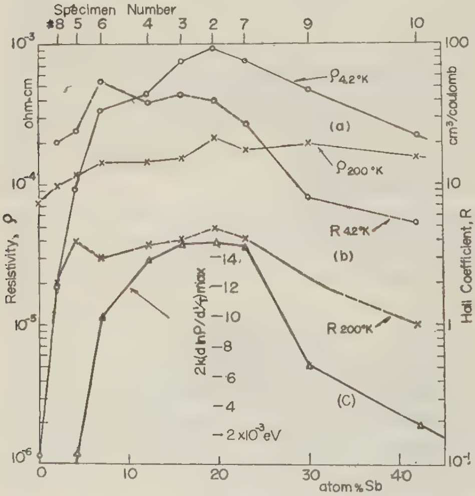

Fig. 2. The constitution dependencies of the resistivities (a), the Hall coefficients at 250 oersted (b), and $2k(\mathrm{d}\ln\rho/\mathrm{d}\,1/T)_{\max}$ (c).

The author wishes to express his sincere thanks to Prof. T. Fukuroi for his encouragements and to Mr. S. Mase of University of Nagoya for his stimulating discussions. A part of this study owes to the Research Fund from the Ministry of Education.

Curie Point in Thin Ni Films Determined by Electrical Method

By Kaizo KUWAHARA

Department of Physics, Faculty of Science, Hiroshima University

(Received July 13, 1959)

It is well known1)2) that the Curie point in thin films of ferromagnetics differs from that in bulk specimens. On the other hand, it is also well known3) that the electrical resistance of ferromagnetics shows an anomaly at the Curie point. Therefore, the electrical method has a possibility to determine the Curie point, and a few experiments along this line have been reported.4)5)

The present work is also based on the same idea as above. In this case, however, the reliability in the determination of Curie point would be much higher than the above experiments, because the decrease in resistance with applied magnetic field, which distinctly occurs near the Curie point, was utilized together with the resistance anomaly.

The experiment has been carried out with Ni films evaporated on slide glasses for microscope. To avoid oxidation, mechanical scratches and other troubles*, SiO_2 was coated upon the film surface. After over 10 hours of annealing at 420°C in vacuum, when the resistance of specimens ceased to drop, the resistance R and the longitudinal magnetoresistance $\Delta R/R$ (at 500 oe) were measured at various temperatures by means of potentiometer. In Fig. 1 an example is shown in the specimen of 576A. The kink in R and the minimum in $\Delta R/R$ occur at the same temperature, which gives the Curie point. In the case of such extremely thin films as 50A or below, there is no such appreciable kink in R as in thicker ones. It is not troublesome, however, to determine the Curie point, by referring to the minimum in $\Delta R/R$ in this case.

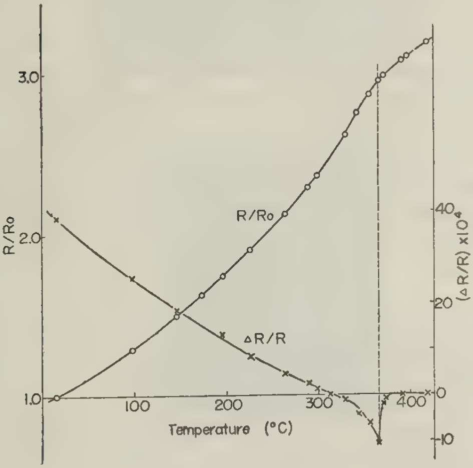

Fig. 1. Temperature dependence of R/R_0 and $\Delta R/R$, in the specimen of 576 A. R_0 is the resistance at 16°C. The minimum of $\Delta R/R$ coincides with the kink of R in temperature.

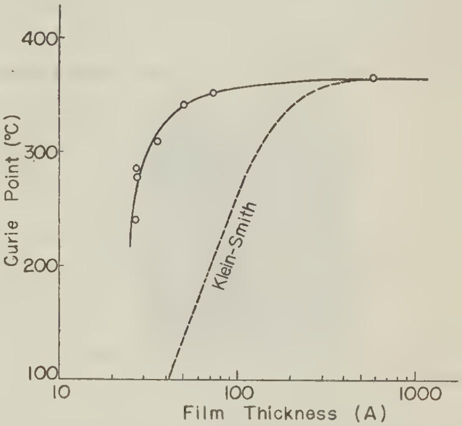

Fig. 2. Variation of Curie point with film thickness. The circles and the solid curve are obtained in this experiment. The dotted curve is derived by Klein and Smith theoretically.

The Curie point determined is plotted against film thickness in Fig. 2. As seen in this figure, the Curie point seems to fall effectively with the decrease in film thickness below 100A. Although this result coincides in tendency with the theory of Klein-Smith1) and the previous experiments,2)4)5) the details are considerably different from them, which might be a problem to be studied in the theory of spontaneous magnetization.

Proton Resonance in the Antiferromagnetic State of $NiCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 6H_2O$

By Tadashi SUGAWARA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received June 4, 1959)

In the previous short note on the proton resonance of nickel salts the author and Kim[1] reported that the resonance line in the paramagnetic $NiCl_2 6H_2O$ disappeared suddenly at about 8°K. However, it was found later that below 6°K the resonance consisted of a number of weak lines situated nearly symmetrically about the central frequency. The same behavior was observed also in $CoCl_2 \cdot 6H_2O$, which is isomorphous with $NiCl_2 \cdot 6H_2O$, at temperatures below 2.3°K.

As an example, the angular dependence of the low field spectrum in the *ac*-plane of $CoCl_2 \cdot 6H_2O$ at 2.08°K is shown in Fig. 1. Fig. 2 is a plot of the shift of a line in the spectrum as a function of temperature. The experimental points can be represented by a Brillouin function as shown in the Figure. These results are characteristics of the proton resonance in the antiferromagnetic state of a hydrated salt.[2] By extrapolating the curve in Fig. 2 to the ground line the Neél temperature was determined as 2.35 ± 0.05°K. The spectrum shown in Fig. 1 suggests that there are four inequivalent protons in a unit cell, of which two are located near the Co^{2+} ion and the other two are far from the ion. This proton arrangement seems to be consistent with the crystal structure reported by Mizuno *et al.*[3] From a preliminary analysis, based on the crystal structure, of the spectrum, it was found that the Co-spin is ordered parallel to the *c*-axis in agreement with the results of the susceptibility measurement[4] and the electron spin resonance.[5]

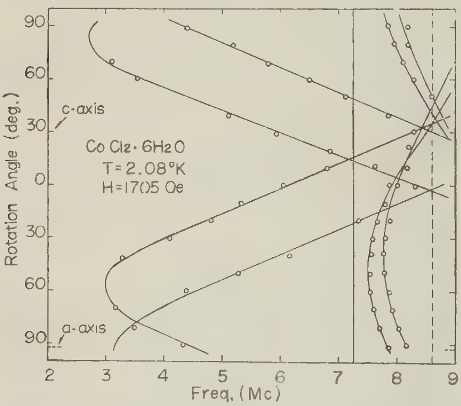

Fig. 1. Low frequency branch of the rotation spectrum in the *ac*-plane of $CoCl_2 \cdot 6H_2O$ at 2.08°K. The whole spectrum is nearly symmetrical about 8.6 MC. The resonance frequency for the undisplaced proton is 7.26 MC. There are some weak lines, not shown in the figure, of unknown origin.

The spectrum in $NiCl_2 \cdot 6H_2O$ was similar to that in $CoCl_2 \cdot 6H_2O$ except for the slightly different angular dependence and the smaller shift. In Fig. 2 is shown the temperature dependence of the shift of a line in this salt corresponding to that in $CoCl_2 \cdot 6H_2O$. By the same procedure described above the Neél temperature was determined as 5.8 ± 0.1°K. The observed spectrum can be explained qualitatively by assuming that the Ni-spin is ordered in the direction perpendicular to the *c*-axis. This fact seems not to be inconsistent with the result of the susceptibility measurement.[4]

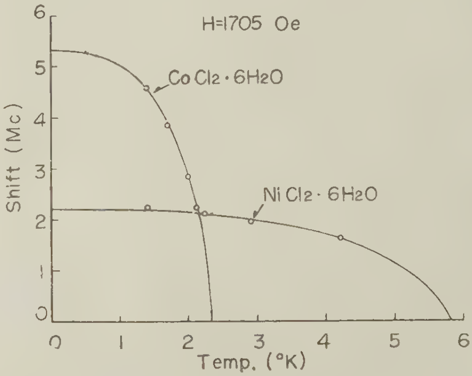

Fig. 2. Temperature dependence of the shift of a proton line. The external field is in the *ac*-plane and is nearly perpendicular to the *a*-axis.

The author wishes to thank Dr. Haseda for supplying good single crystals used in this work and also for communicating his unpublished magnetic data.

X-ray Observations of the Surfaces of Plastically Deformed LiF Crystals with the Berg-Barret Method

By Mitsuru YOSHIMATSU
Research Laboratory, Rigaku Denki Co., Ltd.
2627, Kichijoji, Musashino, Tokyo
and Kazutake KOHRA
Institute of Physics, College of General Education,
University of Tokyo, Komaba, Meguro, Tokyo

(Received July 11, 1959)

It has been recently shown that the Berg-Barret Method[1] of X-ray diffraction can reveal not only substructures of plastically deformed metals[2] but also individual dislocation lines.[3] With this method we observed the surfaces of LiF single crystals* plastically deformed by cleaving, thermal quenching and mechanical bending, by utilizing the (200) or (400) reflexion with CuKα.

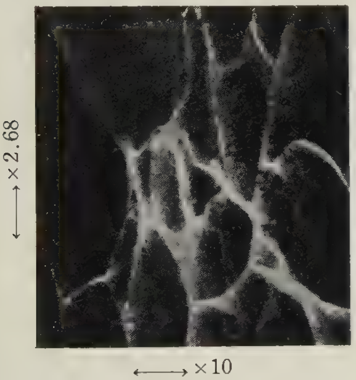

Fig. 1. Subgrain boundaries.

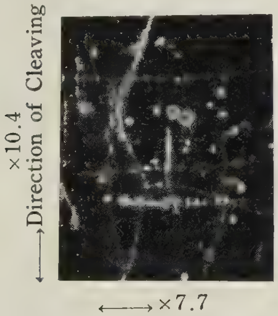

Fig. 2. Arrays of spots.

(i) The (200) reflexion photographs from cleaved surfaces vary highly sensitively with specimens, depending probably on the original properties of the crystal as well as the condition of cleaving. Few remarkable features are here described.

The lines corresponding to subgrain boundaries show almost always asymmetrical behaviour in intensity, being sharply defined at one side, while diffuse at another side (Fig. 1). In the optical micrographs of etched surface, surface[4], the grain boundary consists of the array of etch pits without any indication of asymmetry.

Arrays of spots are sometimes observed in X-ray photographs (Fig. 2). By comparison with the optical etch pit photographs, it is confirmed that each of individual spots corresponds to a dislocation cluster, which was called "Rosett" by Gilman and Johnston.[5]

Sometimes lines are observed running nearly parallel or perpendicular to the direction of cleaving (Fig. 3), which seem to correspond to the crack fronts and step lines, respectively.

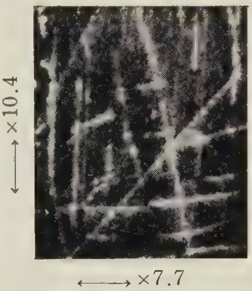

Fig. 3. Crack Fronts and Step Lines.

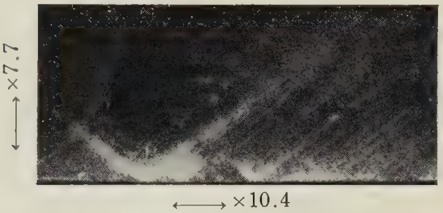

Fig. 4. Photograph of a bent crystal.

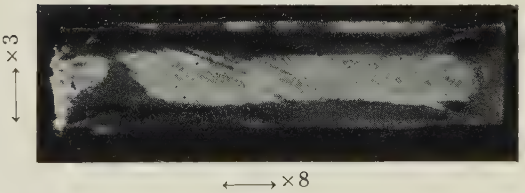

Fig. 5. Photograph of a quenched crystal.

(ii) Some crystals were bent with the radius of curvature 200 mm at room temperature and then annealed at 500°C for three hours. The (400) reflexion photograph from the side face is shown in Fig. 4. The slip lines appear densely in the vicinity of the point where the tools for bending contact the surface. Similar photographs were obtained also from the specimen not heat-treated, but the slip lines were not so distinct.

(iii) The (200) reflexion photographs of the crystal which was quenched from 400°C into water were taken. The features of the photographs were very different with specimens. One example is shown in Fig. 5. As a general tendency, the central part and the neighbourhood of the edge are intense, where slip lines run in the (110) direction.

---

* The crystals were purchased from Harshaw Chem. Co..

The authors should like to represent their sincere thanks to Prof. E. Fukushima and Prof. M. Sakamoto, Mr. K. Kobayashi and Mr. T. Arai for their valuable advices and discussions and to Mr. H. Nimura for his kind preparation of some etched surfaces.

X-ray Observation of the Strain Field in Germanium Single Crystals with the Use of the Anomalous Transmission

By Zensho ISHII

Electrotechnical Laboratory, Nagatacho, Tokyo

and Kazutake KOHRA

Institute of Physics, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo

(Received July 9, 1959)

The transmitted intensity of X-rays increases anomalously when the incident X-rays satisfy the Bragg-Laue condition on a net plane in a nearly perfect crystal with sufficient thickness. This phenomenon, being highly sensitive to the perfectness of the crystals, was applied for observing individual dislocation lines by Borrmann et al with the divergent beam method and, later, by Barth et al with the parallel beam method. With the latter method wider area of the crystal can be observed than with the former method.

With the parallel beam we observed the change of the X-ray transmission caused by the strain field in germanium single crystals when the (2$\bar{2}$0) reflexion takes place with CuK. The crystals were about 1 mm thick and the surface was parallel to the (111) plane.

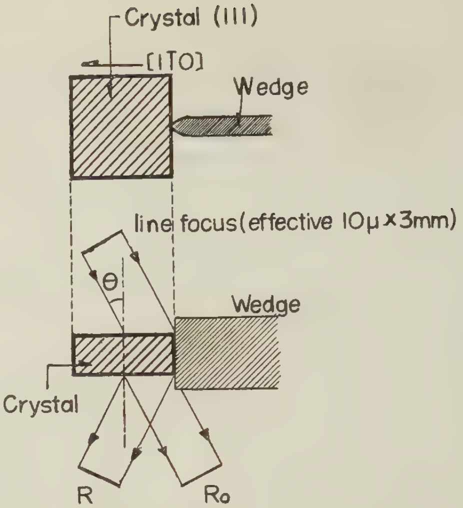

Fig. 1. Schematic diagram of the method to press the crystal.

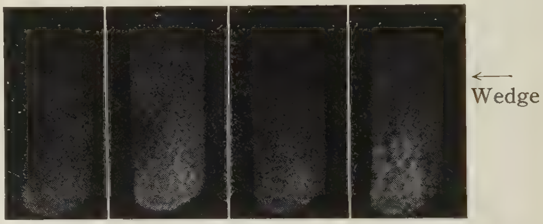

f=0, 40, 200, 320 gw

Fig. 2. Transmission photographs (R) of the pressed crystal.

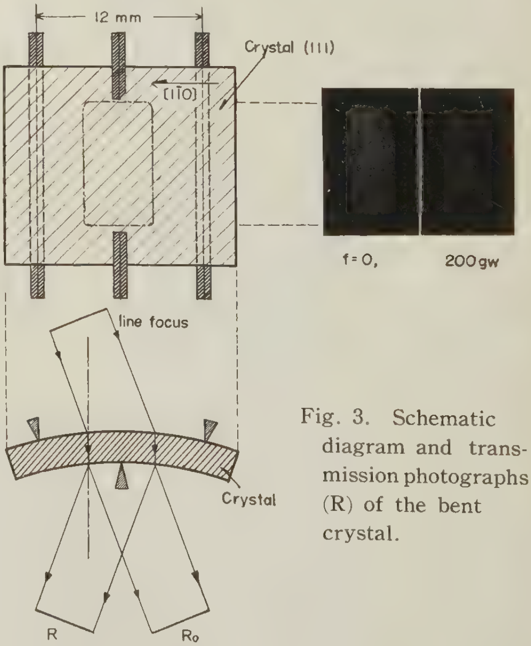

Fig. 3. Schematic diagram and transmission photographs (R) of the bent crystal.

(i) As shown in Fig. 1, the side face (1$\bar{1}$0) of the crystal was pressed with a wedge. The load was changed in the sequence of 0, 40, 200 and 320 g weight and then in the reversal sequence. A few examples of photographs are shown in Fig. 2.

It is seen that the transmission intensity is nearly zero in the vicinity of the wedge. This region is caused by the decrease of anomalous transmission owing to the imperfectness induced in the crystal structure, resulting from the strain field. The heavier is the load, the more extended is the region where the transmission is nearly zero. When the load was taken away, the pattern recovered the initial one.

(ii) A similar effect was observed when a crystal was bent. The photographs are shown in Fig. 3, where the load of 200 g weight was applied. The transmission decreases over the whole region and especially in the vicinity of the wedge.

The present method would be useful for studying the strain field in a nearly perfect crystal.

We should like to express our sincere thanks to Professor E. Fukushima and to Dr. M. Hatoyama for their kind interests and helpful discussions.

Alpha Excitation Functions of Iron-54

By Shigeo Tanaka, Michiaki Furukawa,
Masuo Yagi, Shiro Iwata and Hiroshi Amano
Institute for Nuclear Study, University of Tokyo, Tanashi, Tokyo

(Received June 20, 1959)

Excitation functions of the reactions, $Fe^{54}(\alpha, n)Ni^{57}$, $Fe^{54}(\alpha, p)Co^{57}$, $Fe^{54}(\alpha, 2n)Ni^{56}$, and $Fe^{54}(\alpha, pn)Co^{56}$ were measured by the activation method. Bombardments were made with monoenergetic beams of 32 MeV alpha-particles from the 63-inch INS (Tokyo) cyclotron. Energy dependence of the cross sections was measured by the stacked-foil technique in which thin iron foils (8μ thick and of natural isotopic abundance) were interspaced with aluminum absorbers. After bombardments cobalt, nickel and iron were chemically separated. The Co^{56} was counted with an NaI scintillation counter so biased as to cut gamma rays below 1 MeV. The absolute yield was calculated by comparing the samples with those of the calibrated Co^{56} standard. The absolute yield of Co^{57} was obtained by counting the photopeaks from 0.13 MeV gamma rays in a well type NaI scintillation counter, Compton tails from Co^{56} and Co^{58} being subtracted. The nickel fractions were allowed to decay to produce Co^{57} and Co^{56}, and nearly the same counting procedures were applied. Necessary corrections were made to all the counting data. Nuclear data used in this calculations of the absolute cross sections were obtained from "Table of Isotopes" of Seaborg et al.

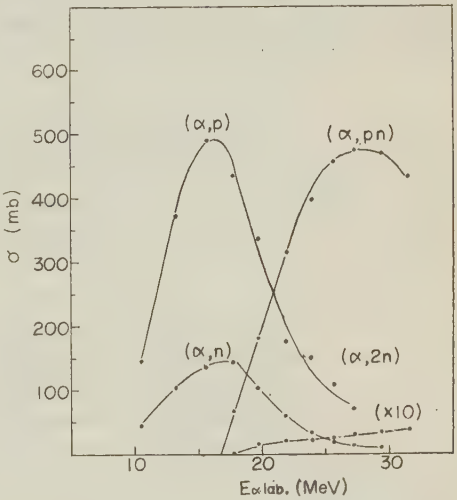

Fig. 1. Alpha excitation functions of Fe^{54}.

These results are shown in Fig. 1. $\sigma(\alpha, p)$ was generally a few times larger than $\sigma(\alpha, n)$. $\sigma(\alpha, pn)$ was larger than $\sigma(\alpha, 2n)$ by a factor of 10^2. Owing to the poor knowledge of decay scheme on Ni^{56}, the latter result is somewhat ambiguous. The results are at present analyzed on the basis of the statistical theory of nuclear reaction. The full reports on the alpha excitation functions including other types of reaction are to be published elsewhere in near future.

A Mechanism for Producing Extrusions and Intrusions during Fatigue

By Ryutaro Nagai
Department of Physics, Tokyo Gakugei University

(Received May 11, 1959)

Forsyth[1] and others[2][3] have observed small extrusions and intrusions on the surface of fatigued metals and ionic crystals e.g. aluminium 4% copper and silver chloride. Cottrell and Hull[2] have suggested that they are the result of slip on two intersecting slip planes and Mott[4] has suggested a mechanism in which a dislocation, which has a component of its Burgers vector normal to the surface, moves round a closed circuit by cross slip. The mechanism of Cottrell and Hull does not seem to explain the co-existence of the extrusion with the intrusion along a slip band, and the mechanism of Mott is not so far, it seems, applicable to intrusion.

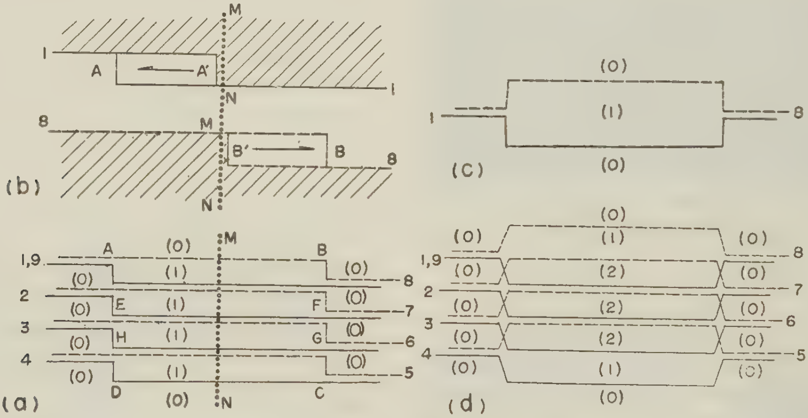

Fig. 1. (a) (c) (d): Slip lines produced on the surface. (Exchange of —— for ---- leads to exchange of extrusion for intrusion. —— Rising vertically to the surface, above this line. ---- Rising, below this line. $\overset{\text{——}}{\text{----}}$ Cancels each other. (0), (1), (2), ..., (−1), ... Height or depth vertical to the surface.) (b): Displacement of the jogs along the edge dislocation lines, in case of an excess of atoms. (Oblique lines indicate the extra plane of atoms.)

I would like to suggest another mechanism by which such extrusions and intrusions could occur, and by which the effect of a stress is not entirely cancelled by the reversed stress. Let a stress be applied to a crystal activating a Frank-Read source which with every rotation causes the new loop to expand on the adjacent parallel slip plane e.g. case (iii) of H. Suzuki[5], which may be a rare case, in which, the source is composed of elements of a hexagonal network, and the two pole dislocations are of the screw components of the opposite sign. Now let each edge dislocation 1, 2, 3, 4 with no jogs cut through a screw dislocation MN, so producing a jog in itself at MN. When the dislocations 1, 2, 3, 4 intersect the surface, they will produce the slip lines 1, 2, 3, 4 on the surface, each of which contains a step. If the stress is now reversed, the source will produce dislocations 5, 6, 7, 8 of the opposite sign which will also produce the slip lines 5, 6, 7, 8 each of which contains a step. The slip planes of 5 will coincide with the slip planes of 4. If, however, that jog is displaced along the dislocation line with respect to the first jog, Fig. 1(a) an extrusion ABCD will be formed after many cycles in case of an excess of atoms, and an intrusion in case of an excess of vacancies. In Fig. 1, the solid (dashed) line indicates the positive (negative) edge dislocation in the crystal and the positive (negative) slip line on the surface, at the same time. A probable reason why the first jog at MN should be displaced to A, E, H, D and to C, G, F, B along the pure edge dislocation line while the latter glides through the crystal towards the surface, can be seen if we consider Fig. 1(b). The jog A′ is produced first and the jog B′ on the reversed stress along the line of intersection with the screw dislocation MN. If these jogs pass through a region with an excess of atoms, such as interstitial atoms in metals (which have been worked or are being worked) or atoms in supersaturated alloys, the jog A′ moves to A, and B′ to B[6] (almost without the help of diffusion) and the result is an extrusion. If the region contained an excess of vacancies, they would move in the opposite direction with the result of an intrusion. At higher temperatures, the extrusion and the intrusion will become more complicated and irregular, because, if an edge dislocation passes through a region having an excess of atoms or vacancies, a row (or rows) of them may be added to the extra plane and grows. The row is also equivalent to the edge dislocation line between two jogs,[7] as shown in Fig. 1(c) (d) in case of an excess of atoms. In this case, the primary extrusion can be left on the reversed stress, even if the segments of the positive loops have not entirely got out of the crystal.

In order to explain the observed thickness of an extrusion of the alloy, $\sim 0.1\mu$, it would require 4×10^2 loops to be generated from the source per half cycle, and at least 3.5×10^3 cycles would be necessary so that the length of the extrusion may be 1μ, in case of Fig. 1(a).

A mechanism for growing a void which involves the interaction of a Frank-Read source with two screw dislocations of opposite sign will be published elsewhere.[7]

Another mechanism would be found if the straight slip lines without steps (jogs) e.g. 1, 2, 3→5, 6, 7→1, 2, 3→5, 6, 7, ··· appeared in turn, but it seems weak at present.

Time Decrease of Permeability in Silicon-Iron

By Kunirô TSUSHIMA, Mitsuru ASANUMA
and Syôhei MIYAHARA

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received June 29, 1959)

Snoek[1] showed that the existence of interstitial solutions of carbon and nitrogen is the cause of time decrease of initial permeability of iron and other body centered cubic ferromagnetic metals and alloys.

He assumed the decrease with respect to time should be represented as

$$r_t=r_0+r_a(1-e^{-t/\tau}),\quad \tau=\tau_0 e^{Q/RT} \qquad (1)$$

Here r_t : reluctivity at time t.

r_0, r_a: constant with respect to time.

Rathenau *et al.*[2] found for iron that by modifying (1) only one activation mechanism of elementary jumps of nitrogen atoms is involved in a restricted region where

$$g\left(\equiv\frac{r_t-r_0}{r_\infty-r_0}\right)=0\sim0.9\ ,$$

We performed similar experiment for 4% Si-Fe. Specimens were annealed in purified hydrogen at 850°C for a week to remove carbon and nitrogen as possible as we could.

Then the initial permeability μ was measured on a toroid, composed of 10 rings (2.5 cm external, 1.5 cm internal diameter, 0.02 cm thickness) of polycrystalline 4% Si-Fe. By determining selfinductance using alternating current bridge (1 Kc/sec), μ was measured with the measuring field of 1×10^{-4} oe.

Time decrease at each temperature is shown in Fig. 1. Assuming the relation (1), we plott $\ln t$ versus $1/T$ for some values of the parameter g, which is shown in Fig. 2. Up to g=0.3, straight line relationship is found and the slopes give the value of activation energy

$$Q=0.80\pm0.04\ \text{ev.}$$

Above value is in agreement with other data[3] of activation energy of diffusion of carbon in α-iron. For g larger than 0.3, this analysis cannot be applied.

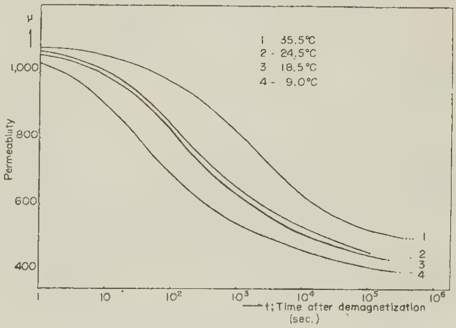

Fig. 1. Time decrease of μ in 4% Si-Fe after demagnetization at various temperatures.

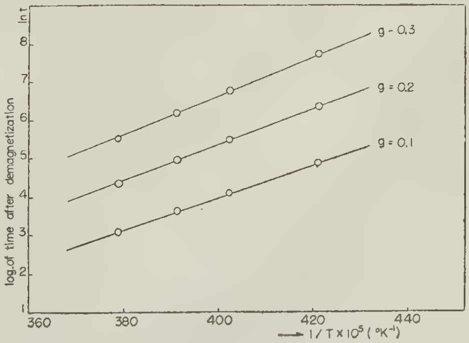

Fig. 2. Log. of time (sec.) *versus* inverse absolute temperature for g=0.1～0.3.

Changes of Coercivities by Heat Treatment and Cold-Rolling in Cu-Co Alloy

By Masayoshi SATŌ and Tadayasu MITUI

Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received June 25, 1959)

Magnetic properties on the Cu-Co alloys containing a few percent cobalt have been studied by many investigators[1~6]. Sucksmith *et al*[1,2] have measured changes of coercivities induced by heat treatment and cold-drawing. We also carried out the same study, but, as shown in followings, the results were remarkably different from his.

We studied the alloy containing ca. 2 wt % Co to clarify how the size, shape and the orientation of the precipitates affect magnetic properties. For this purpose the coercive force H_c and the reverse field H_r which is the field required to reduce the remanence to zero against the aging time at various temperatures were measured; the results are shown in Fig. 1. Though it is difficult to explain the great peak appeared in the curves for 600°C aging earlier than other peak, it might be due to eventual imperfections in the matrix.

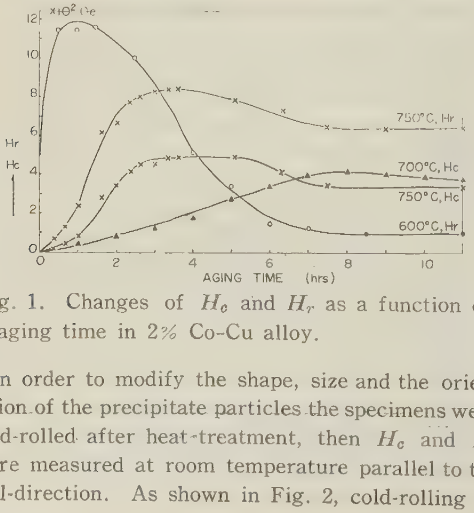

Fig. 1. Changes of H_c and H_r as a function of aging time in 2% Co-Cu alloy.

In order to modify the shape, size and the orientation of the precipitate particles the specimens were cold-rolled after heat-treatment, then H_c and H_r were measured at room temperature parallel to the roll-direction. As shown in Fig. 2, cold-rolling up to 70~80% reduction effects an increase of coercive force, further reduction causes coercive force to decrease. The value of H_r shows a similar behavior except for the earlier stage of reduction as shown in Fig. 3.

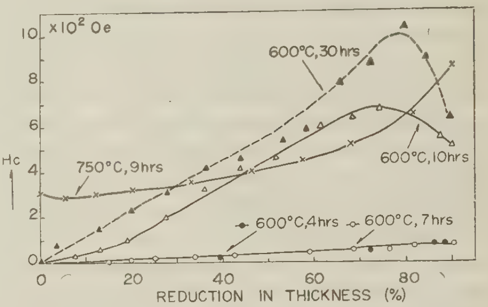

Fig. 2. Changes of H_c as a function of the roll reduction in thickness in 2% Co-Cu alloy.

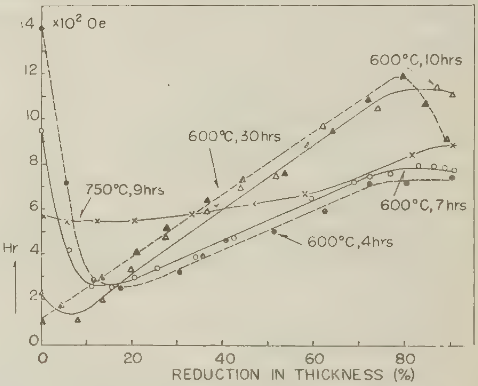

Fig. 3. Changes of H_r as a function of the roll reduction in thickness in 2% Co-Cu alloy.

The changes of H_c and H_r are not so simple to be explained by homogeneous deformation of the particles. Those might be explained in terms of shape effect taking not only the elongation of the particles but also the superparamagnetism induced by cutting-off into account. Moreover, the cutting-off effect was also found in the measurement of the magnetic anisotropy by one of the authors[7].

The detailed report will be published in this Journal.

Scattering of Protons by Silicon and Sulphur

By Yukiyasu ODA*, Minoru TAKEDA, Chuin HU and Shōhei KATO
Department of Physics, Osaka University, Osaka

(Received March 20, 1959)

The angular distributions of protons in elastic and inelastic scattering by Si and S have been studied, changing the bombarding energy from 4.95 Mev to 5.45 Mev with the interval of 100 Kev. The angular distributions of proton groups from the reaction $Si^{28}(p, p')Si^{28*}$ ($Q=-1.78$ Mev) are nearly symmetric about 90° for any bombarding energy and the total cross-section changes appreciably with the incident energy. On the other hand, the results for the reaction $S^{32}(p, p')S^{32*}$ ($Q=-2.24$ Mev) show large variation with the energy in both angular distribution and total cross-section. The energy dependence of the angular distribution of elastically scattered protons by silicon is found to be more remarkable than that by sulphur in the energy region studied.

§ 1. Introduction

Many experiments have been carried out on the elastic and inelastic scattering of protons on light even-even nuclei for various bombarding energies. In our laboratory, the angular distribution of inelastically scattered protons for the first excited states of Ne^{20},[1),2)] Mg^{24} [3)] and Si^{28} [4)] has been studied recently changing the energy of the proton beam from the 44-inches Osaka University Cyclotron. These results obtained in the energy region from 4.8 to 5.5 Mev show a remarkable energy dependences of differential cross section and angular distribution. In cases of these target nuclei, some resonance phenomena were found. Thus it is generally supposed that the inelastic scattering of protons proceeds mainly through the compound nucleus formation. On the other hand, in the elastic scatterings in neon, the angular distribution of protons changes rapidly with energies, supporting the existences of some resonance levels.

In the present study, the measurements of the angular distribution of protons elastically scattered from silicon and sulphur, and that of inelastically scattered proton groups corresponding to the first excited levels of Si^{28} and S^{32} have been performed in the energy region from 4.95 to 5.45 Mev. In order to facilitate the simultaneous measurement of angular distributions of the proton groups scattered elastically and inelastically by respective nucleus, we selected SiH_4 and SH_2 gases as targets.

§ 2. Methods and Results

The gas targets of SiH_4 and SH_2 were used for the purpose mentioned in § 1. SH_4 was produced by the reaction[5)]

$$SiCl_4+AlLiH_4=SiH_4+AlCl_3+LiCl$$

distillating by isopentan bath. SH_2 gas purified by distillating the commercial gas of 99% purity through the liquid air, has been used. These gases were filled usually at a pressure of 180 mmHg in the target cell.

We used NaI(Tl) scintillation counter as a detector, and pulse heights were analysed by the 20 channel pulse height analyser. The counter, scattering chamber and associated equipments were similar to those described in detail in the previous report[2)]. The definitions of scattering angles were made to the accuracy of about ±0.1° and the angular resolutions were ±1° in the range of laboratory scattering angles from 20° to 164°30′. The incident proton energies were reduced by aluminium absorbers in step of 100 kev.

The typical pulse height spectra of scat-

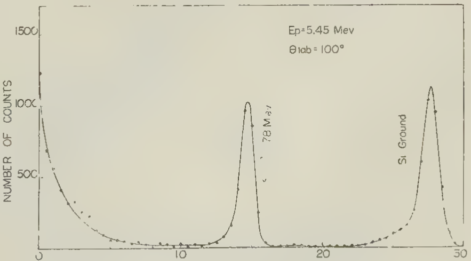

Fig. 1. The pulse height spectrum for protons scattered from silicon at the scattering angle of 100° with the incident energy of5.45 Mev.

---

* Now at Physics Department, Tokyo Institute of Technology, Oh-okayama, Tokyo.

tered protons by silicon at 100° and that by sulphur at 164°30′ in the laboratory system at the incident energy of 5.45 Mev are shown in Figs. 1 and 2, respectively. In the case of silicon, the inelastically scattered protons leaving Si^{29} (natural isotope abundance 4.68%) in the first excited state, were observed with low intensities and separated well from those of Si^{28}. Thus the inelastically scattered protons from Si^{29} would not disturb the measurement of the angular distributions of protons corresponding to the level of 1.78 Mev of Si^{28}. In the case of sulphur, the number of protons elastically scattered from nitrogen and oxygen (present as the contaminants) was small compared with that from sulphur, and their intensity was about 2% of that of protons elastically scattered from sulphur. The protons which excited the first level of S^{34} (the isotope abundance 4.22%) were not separated from these corresponding to the level of 2.24 Mev of S^{32}. The errors in the determinations of the differential cross sections for the inelastic scattering of protons by S^{32} would, however, be small since the isotope abundance of S^{34} is very low.

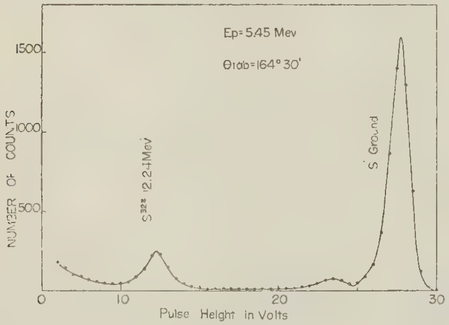

Fig. 2. The pulse height spectrum for protons scattered from sulphur at the scattering angle of 164°30′ with the incident energy of 5.45 Mev.

The angular distributions of elastically scattered protons by silicon and sulphur at various bombarding energies are illustrated in Figs. 3 and 4. Although the atomic numbers of target nuclei are now somewhat greater than that of neon studied in previous work, the curves in these figures show rather remarkable variations with the incident energy as in the case of neon. The resonance like anomaly found in the case of elastic scattering by silicon corresponds especially well to that found for the inelastic scattering. The discussions for these relations will be given later.

The observed angular distributions of the scattered protons which leave the nuclei Si^{28}

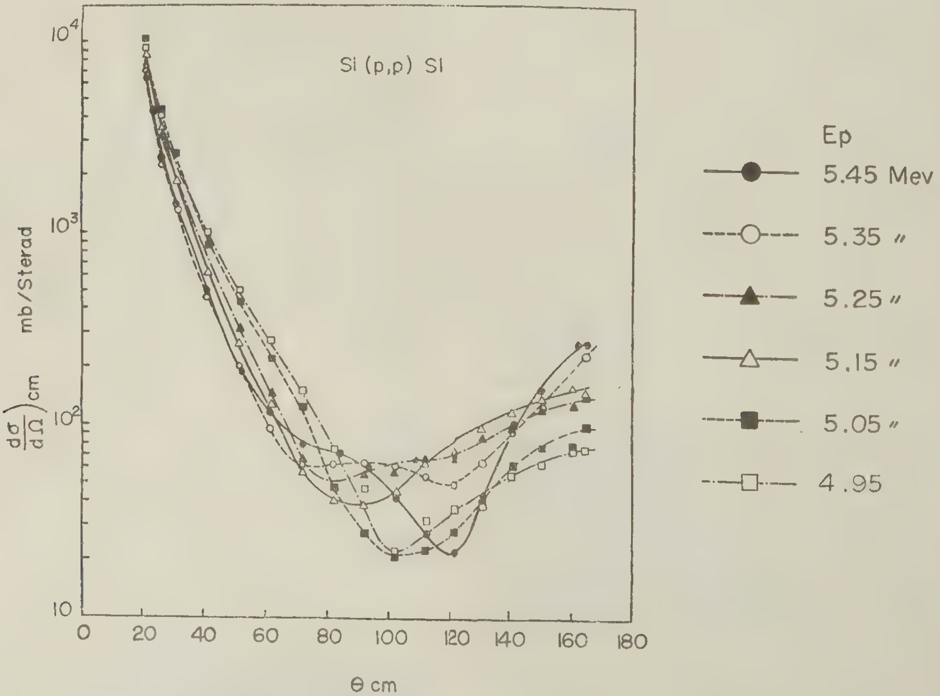

Fig. 3. The angular distributions of protons elastically scattered from silicon.

in their 1.78 Mev levels, and S^{32} in the 2.24 Mev level are shown in Figs. 5 and 6, respectively.

The angular distributions of inelastically scattered protons by Si^{28} show nearly symmetric about 90° for any bombarding energy. A resonance like anomaly is found at the energy of 5.45 Mev in the case of Si^{28}. These results agree with those obtained by Yamabe, et al.[4] in our laboratory in general features, except that our absolute values of cross sections are usually smaller than their values by about 10%. Both results are compatible in the position of the anomaly, the shapes of the angular distributions at corresponding energies and the feature of variation of cross sections with energy. It is possible that the discrepancy between these results might have been risen from the difference in bombarding energies, because the only little variation of the incident energy produce generally appreciable change in absolute cross section near the resonance.

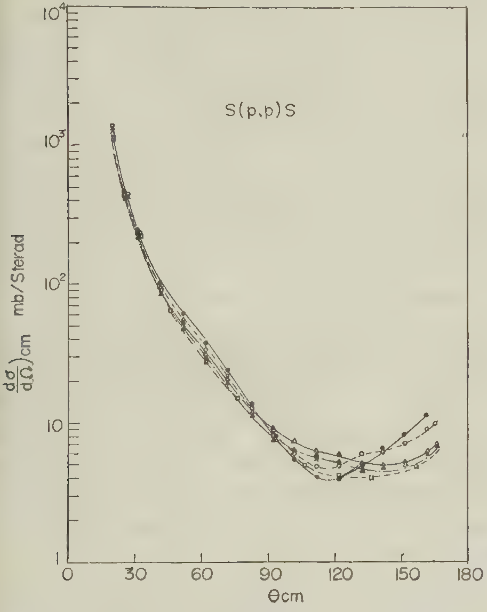

Fig. 4. The angular distributions of protons elastically scattered from sulphur. The curve indications of corresponding energies are given in Fig. 3.

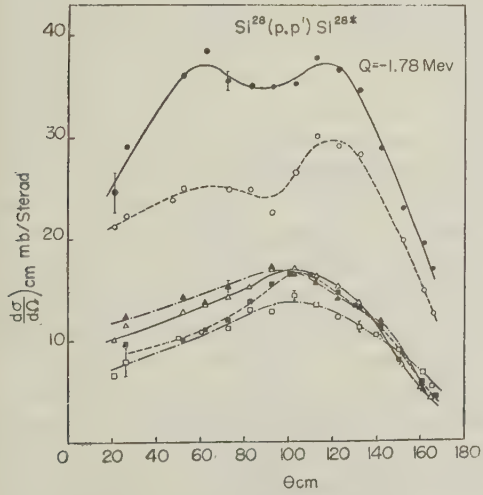

Fig. 5. The angular distributions of protons inelastically scattered from Si^{28}($Q = -1.78$ Mev). The curve indications of corresponding energies are given in Fig. 3.

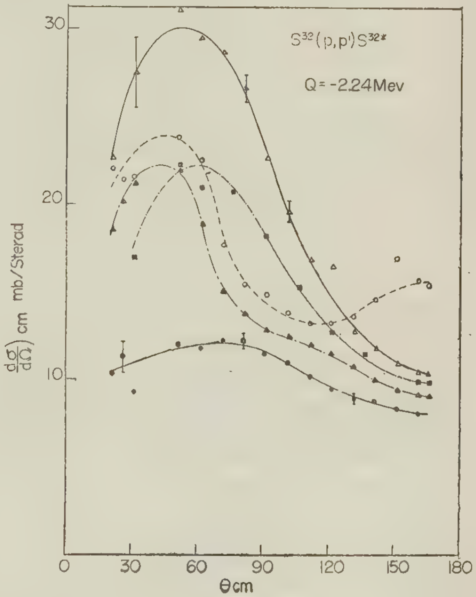

Fig. 6. The angular distributions of protons inelastically scattered from S^{32}($Q = -2.24$ Mev). The curve indications of corresponding energies are given in Fig. 3.

The angular distributions of inelastically scattered protons from S^{32}, on the other hand, show relatively larger asymmetry about 90° than those of neon and silicon, and are sensitive to the incident energy in the region from 4.95 to 5.45 Mev. The lack of the data of differential cross sections for the inelastic scattering in each nucleus at 40° in the laboratory system arises from the fact that the both proton groups from the H(p, p)H scattering and the inelastic scattering overlap with each other. The differential proton-proton scattering cross sections were measured at 40°, 50° and 60° in the center of mass system simultaneously with the inelastic scattering cross sections and are used to normalize the absolute values for elastic and inelastic scattering cross sections of these nuclei. In the case of inelastic scatterings, the main uncertainty in the final values of the cross sections is due to the subtraction of the background. The relative error of cross sections is generally about 5% for elastic and inelastic scattering and about 10% for forward angles for inelastic scattering. For the absolute cross sections, the over all errors do not exceed ±10%.

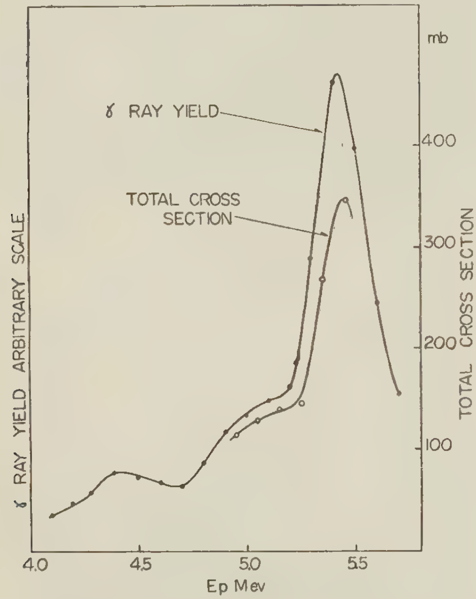

Fig. 7. The energy dependence of total cross sections and relative γ-ray yield for the reaction $Si^{28}(p, p')\ Si^{28*}(Q=-1.78$ Mev).

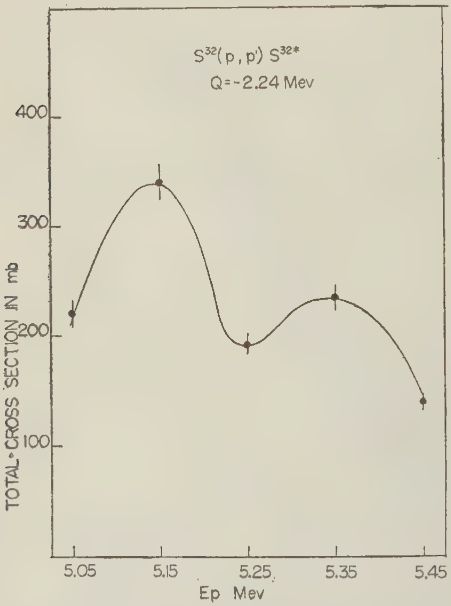

Fig. 8. The energy dependence of total cross sections for the reaction $S^{32}(p, p')\ S^{31*}(Q=-2.24$ Mev).

The energy dependences of total cross sections for inelastic scatterings from Si^{28} and S^{32} are shown in Figs. 7 and 8. Okada et al. in our laboratory have measured the excitation curves of gamma radiations resulting from the inelastic scatterings at 90° with respect to the proton beam[6),7)]. Resonances were found at 2.9, 3.5, 4.4, 5.0 and 5.4 Mev for silicon and at 4.8, 5.1, 5.3 and 5.6 Mev for sulphur. Their result is also illustrated in Fig. 7.

§ 3. Discussion

As have been stated, the observed angular distributions of inelastically scattered protons show large variations for small changes in bombarding energy. It would therefore be difficult to consider that the excitations are induced only through one of the direct processes which would not be so sensitive to the incident energy.

As will be stated below, however, it is easy to consider that the observed reactions are performed mainly through the formation of compound nucleus and its subsequent decay. Let both the continuum and statistical assumptions about the compound nucleus be violated in the experimental condition, then only a small number of compound nucleus levels concern with the reactions and the angular distributions would be expected to show a marked energy dependence. In our case, both assumptions would not be valid, since the compound nucleus P^{29} and Cl^{33} have relatively low excitation energies of ∼8 and 7 Mev respectively. On the basis of the experimental results obtained at lower energies[8)], the mean level spacing which is expected to hold in these energy regions seems to be about 200 kev and is probably larger than the beem energy spread. Therefore the angular distributions of the scattered protons resulting from the excitation of the particular level in compound nucleus would be expected to change their shape with proton energies. Now, the results for inelastic scattering represented in Figs. 5 and 6 and also those for elastic scattering shown in Figs. 3 and 4 show fairly marked variations with bombarding energy and suggest that the compound nucleus formations play predominant roles. For the case of silicon, C. Hu and others have observed further the angular distributions of the inelastically scattered protons at higher incident energies of 8.0, 11.0 and 14.0 Mev[9]. The inelastic angular distributions by silicon were also studied at 7.97, 8.55, 8.96, 9.28 and 9.45 Mev by Greenless et al.[10] and at 12.0 Mev by Conzett[11]. Fused quartz (SiO_2) was used as a target for these experiments. These distributions also change their shapes rapidly with proton energies. All these features seem thus to support that our reactions proceed mainly through the compound nucleus formations. The departures from 90° symmetry in the angular distributions would be caused by the interferences of the outgoing waves with different parities, although some parts of the asymmetry might be caused by the direct interaction process.

Here we discuss our present results in details. From the observed angular distribution of 1.78 Mev gamma rays from Si^{28} at the resonance energy of 5.4 Mev, Okada et al. assigned the spin and parity of the compound nucleus level of P^{29} at the excitation energy of 7.9 Mev as $5/2(+)$. Our experimental results seem also to support this assignment. First, the total cross section illustrated in Fig. 7 is about 400 mb at 5.4 Mev resonance. The magnitude is nearly in the limit of the maximum cross section $3\pi/k^2$ which is allowed by the theory assuming the reaction through single level. Next, we can reproduce the shape of the angular distributions at 5.45 Mev well postulating that the reaction proceeds through the compound nuclear state which has the assignment as above and decays to the final system of the channel spins $S'=3/2(l'=2)$ and $5/2(l'=0, 2)$ being mixed adequately. Here l' is the orbital angular momentum of outgoing protons.

The total cross sections for the inelastic scattering by S^{32} illustrated in Fig. 8 show that there are at least two resonances, one near 5.15 Mev and the other near 5.35 Mev, both of which have the width of about 100 kev. We suppose that the compound nucleus formation plays main role also in this case. We do not discuss here, however, the details of the possibilities for the theoretical interpretation of our experimental results of inelastic scattering, because other experimental knowledges about the nature of the compound states are not enough.

In order to investigate the results for the elastic scattering, we rearranged the data shown in Figs. 3 and 4 into the form of excitation curves at various scattering angles. Although we cannot find out any peculiar feature in the curves for sulphur thus obtained, we can find two anomalies in the case of silicon. Namely we find the one at 5.05 Mev, which is especially evident at angles $\theta \geq 100°$. It is worth while to note that in Fig. 7 one can observe an inelastic scattering anomaly at this point of energy. We can find another elastic scattering anomaly near 5.4 Mev only at the backward scattering angles $\theta \simeq 160°$. Although we observe an extremely sharp resonance behavior of inelastic scattering at this point of energy, we can find corresponding elastic scattering anomaly at only extremely backward angles.

These facts show somewhat complicated features of the conditions of the experiment studied with a beam of medium resolution as in our case. It seems that, beside the peculiar resonance levels recognized well in our experiments, there may be a certain number of levels which do not show marked resonance behaviors. Thus, except at the special resonance points of energy, our results would contain the contributions from those unresolved levels which are overlapping or neighboring to each other. These features will probably affect the variation of scattering phenomena with the change of incident energy, and further will stand for the relatively small asymmetries about 90° found in the results for the angular distribution of inelastically scattered protons.

Acknowledgements

The authors wish to thank Professor T. Wakatsuki for his interest in this work. They are indebted to the crew of the Osaka University Cyclotron for their supports throughout the experiments. They also acknowledge the guidance of Professor H. Kuroya for the production of silane.

Angular Distributions of Protons from the Reaction $^{12}C(\alpha, p)^{15}N$

By Itaru NONAKA, Hisashi YAMAGUCHI, Takashi MIKUMO, Iwao UMEDA*, Tatsuo TABATA* and Saburo HITAKA**

Institute for Nuclear Study, University of Tokyo,
Tanashi-Machi, Kitatama-Gun, Tokyo

(Received June 19, 1959)

Angular distributions of protons corresponding to the ground state transition from the reaction $^{12}C(\alpha, p)^{15}N$ have been measured at twelve energies of alpha particles between 25 and 39 MeV. Each angular distribution shows pronounced diffraction-like patterns, but there exists apparently a systematic shift in the shape and magnitude of angular distributions as the energy changes. At lower energies a sharp rise in the backward angles is observed, while at higher energies it is not observed.

Angular distributions of protons corresponding to some excited state transitions have also been measured at 34.6 MeV.

§ 1. Introduction

Recently, angular distributions of the proton group (P_0) corresponding to the ground state transition of the reaction $^{12}C(\alpha, p)^{15}N$ have been measured by R. Sherr and M. Rickey(1) at alpha particle energies of 30.5 MeV and 40.5 MeV, by C. E. Hunting and N. S. Wall(2) at 30.5 MeV, and by S. Yamabe, M. Kondo and T. Yamazaki(3) at 22.0 MeV. S. T. Butler(4) explained the result of C. E. Hunting and N. S. Wall as a typical evidence of direct interaction mechanism. This model, essentially like that of N. Austern, S. T. Butler and H. McManus(5), predicts that the differential cross section in the reaction $X(\alpha, p)Y$ is

$$d\sigma/d\omega \propto [\sum_l j_l(QR)]^2 F(\theta) ,$$

where $l\hbar$ is the orbital angular momentum transferred to the nucleus, Q the momentum transferred to the nucleus, R the nuclear radius, and $j_l(QR)$ is the spherical Bessel function of order l. Selection rules concerning the allowed l's are

$$|\boldsymbol{J}_X+\boldsymbol{J}_Y+\boldsymbol{i}|_{\min} \leq l \leq J_X+J_Y+i$$

where $\boldsymbol{J}_X, \boldsymbol{J}_Y, \boldsymbol{i}$ are, respectively, the spins of the target nucleus, of the residual nucleus and of the emitted proton.

All these angular distributions show sharp diffraction-like patterns, but they are quite different in shape at different energies.

---

** Kyushu University.

In order to study the reaction mechanism we have made the measurements of angular distributions of this reaction at alpha particle energies between 25.0 and 38.6 MeV. We have also made measurements of angular distributions of proton groups P_{12}, P_3 and P_{456} corresponding to the transitions leaving the residual ^{15}N nucleus at 5.28- and 5.31 MeV (P_{12}), 6.33 MeV (P_3), and 7.16-, 7.31- and 7.58 MeV (P_{456}) at $E_\alpha=34.6$ MeV.

§ 2. Experimental Procedure

At the Institute for Nuclear Study, University of Tokyo (I.N.S.J.), a 160 cm cyclotron[6] is now available for research. This cyclotron can be used in two ways, either as a fixed frequency (F–F) cyclotron or as a frequency modulated (F–M) cyclotron, by changing the oscillator-dee system. Moreover, when used as a F–F cyclotron one of the main advantages of this cyclotron is that it is of variable energy type; one can obtain beams of protons between 8 and 14 MeV, of deuterons between 13 and 21 MeV, and of alpha particles between 27 and 43 MeV. This machine is thus particularly suited for the investigations of the change of angular distributions as functions of bombarding energies.

Fig. 1 is a schematic diagram of the experimental arrangement. The general experimental methods are already described by K. Kikuchi, S. Kobayashi and K. Matsuda[7].

The alpha particle beam produced by the cyclotron was brought into a scattering chamber of 100 cm in diameter, after passing through a pair of quadrupole magnets and a sector-type focussing magnet, and through a concrete shield. The beam was collected in Faraday cup after passing through the target located at the centre of this chamber.

A system of beam collimating slits 5 mm in diameter, was inserted in front of the scattering chamber, and the intensity of the beam at the Faraday cup was about 0.1 μA. The beam energy spread was estimated to be within about 0.5% at the target.

For the experiments at $E_\alpha<27$ MeV, aluminium absorbers were inserted before the beam collimator. At $E_\alpha=25$ MeV the beam intensity was one order of magnitude less than that without absorbers.

(i) *Experiments at* $E_\alpha = 34.6$ MeV

At first (in spring, 1958) we measured the spectra and angular distributions of protons from this reaction at $E_\alpha = 34.6$ MeV as a "Test Experiment" of our cyclotron. At that time the protons emerging from the target were detected by a telescope of a proportional counter and a NaI(Tl)-scintillation counter set on the turn table in the scattering chamber. By inserting aluminium absorbers of suitable thickness between the target and the proportional counter, we could make all the outgoing alpha particles stop in the absorbers, while protons lost little energy.

The proportional counter contained about 30 cmHg of Argon-CO_2 mixture (5% CO_2). This counter was used to suppress the gamma-ray background especially in the backward angles. In front of the proportional counter a brass circular aperture of 8 mm in diameter was inserted to define the solid angle accepted by the counter system (order of 10^{-4} steradians).

After passing through the proportional counter, protons stopped in the NaI(Tl) crystal of 5 mm thick followed by a RCA 6342 photomultiplier. The energy resolution was about 3% (full width at half maximum). Signal pulses were sent, through a cathode-follower, to the counting room about 50 meters apart from the measuring room where the scattering chamber was set. And after being amplified by a linear amplifier they were fed into a 10-channel pulse height analyzer. This analyzer was gated by the pulses from the proportional counter, biased adequately in to separate protons from gamma-ray background.

We took the data with and without the proportional counter and found that as long as the ground state group (P_0) was concerned, it was sufficient to make the measurements without the proportional counter even at the largest angle (165°) by choosing the crystal as thin as possible.

As the target, we used a polystyrene film of 10 microns in nominal thickness* (measured thickness 2.94–3.11 mg/cm²). But, because of the large cross sections of $\alpha - p$ scattering, a great number of recoil protons produced by

the hydrogen atoms contained in the target masked the proton groups from the reaction $^{12}C(\alpha, p)^{15}N$ at forward angles. And there often happened pile-up of pulses in the amplifier and we were unable to measure the complete angular distributions even for the ground state group (P_0).

For the above reason, we used a soot target at small angles. About 0.5 mg/cm² of soots of benzene on a gold foil of 1 micron thick was used. But because of the difficulties in preparing homogeneous soot target, it was used only for measurements of relative values on differential cross sections.

(ii) *Experiments at other energies*

The main purpose of our present experiments was to investigate the change of angular distributions of the ground state proton group (P_0) with the alpha particle energy. For this aim, it was of interest to make measurements at extremely small and large angles, so we made use of small photomultipliers Du Mont 6467. Two NaI(Tl) scintillation counters making an angle of 180° from each other were placed on the turn table in the scattering chamber. The dimensions of the "forward" crystal were 2 cm×2 cm×0.5 cm, and those of the "backward" crystal were 2 cm×2 cm ×0.3 cm. The energy resolution (full width at half maximum) was about 5%. We chose the above photomultipliers at the sacrifice of the resolution, because of their small dimensions.

Thus we could take data at two angles at the same time ranging from 11° to 169°. Electronic circuits were essentially the same as in (i), except that 20-channel pulse height analysers were used in place of a 10-channel analyser.

The angle between the beam and the target was 45°, and the "forward" counter observed the "transmitted" particles and the "backward" counter the "reflected" ones. The schematic arrangement in the scattering chamber is shown in Fig. 2. The absolute values of the differential cross sections measured at 90° by both counters agreed very well in almost all the cases.

The beam current was measured by the Faraday cup and a beam current integrator, and furthermore monitored by a CsI(Tl) scintillation counter located at one of the side windows of the scattering chamber making an angle of 30° from the beam direction.

For the reason described in (i), we were obliged to prepare self supporting carbon targets by the following method[8]; we coated a glass plate by vinyl acetate dissolved in cyclohexanone*. After the evaporation of the solvent, we sprayed colloidal carbon onto this film. Carbon dispersion in water, "Hitasol" AF-1**, was particularly suitable for this purpose as it contained much less elements other than carbon (99.8% carbon) compared with ordinary carbon dispersion. We diluted this dispersion with water and sprayed it under a pressure of about 5 kg/cm².

After the sprayed carbon was dryed, the glass plate was immersed in a bath of cyclohexanone. As the vinyl acetate dissolved in cyclohexanone, a film of carbon peeled off from the glass plate and we scooped it on a target frame. After washing the carbon film in fresh cyclohexanone and drying it, we decomposed volatile substances, such as organic compounds and ammonia remained in colloidal carbon, by heating it over 500°C in vacuum.

By this method we could obtain a very homogeneous carbon foil of 2.37 mg/cm² which was used in the present experiments. With this carbon target we yet observed recoil protons in the forward angles, but its number was far smaller than in the case of polystyrene target and there were no such troubles as described in (i).

The errors indicated in the figures of angular distributions (Figs. 7) include those from two sources, the one being the errors in the estimation of background subtraction and the other the statistical one.

As the ground state proton group was far apart from the first and second excited state group, the background subtraction was generally easy and clear-cut except for extreme forward and backward angles where it happened more or less ambiguities in determing the background level under the peak. A smooth curve, generally a straight line, was drawn through the minima or through the extrapolated background level on both sides of the peak. But the errors from this source were estimated to be between 1 to 3% at most and were far smaller than those from the statistical source.

---

* Other organic solutions like polystyrene in benzene or collodion in amyl acetate were also suitable.

** Purchased from Hitachi Chemical Industry Co. Ltd.

As the cross sections of (α, p) reactions are generally small it was difficult to reduce the statistical errors, and they lay between 3 to 10%.

The estimated errors in the determination of mean target thickness were about 1%, arising chiefly from the measurements of target areas for both polystyrene and carbon foil targets. The errors estimated in the beam current integration were about 1%, and in the detector solid angles were 1%. Considering the inhomogeneities which may exist in the target, the absolute values of the differential cross sections indicated in the coordinates may have errors of about 20%.

§ 3. Results and Discussions

(i) *Experiments at* $E_\alpha=34.6$ MeV

Figs. 3 and 4 show typical histograms taken at $\Theta_{\rm lab}=50°$ and $\Theta_{\rm lab}=40°$ at $E_\alpha=34.6$ MeV (Lab.) with a polystyrene target. At extreme forward angles ($\Theta_{\rm lab}\leqq 40°$) a very strong proton group corresponding to recoil protons from

the $(CH)_n$ target masked the excited state groups P_{12}, P_3 and P_{456}.

The soot target with Au backing used for small angles might have poor homogeneity, so the data were taken only to obtain relative cross sections and weve normalized to the data taken at same angles with polystyrene target. At small angles, even with this soot target the recoil protons due to the water vapour adsorbed at the surface of target prevented the measurements of proton groups corresponding to higher excitations. Moreover, the P_3 group was so weak compared with either P_{12} or P_{456} groups, that it was quite difficult to obtain a complete angular distributions of this P_3 group. Fig. 5 shows the angular distribution of P_0 group and Fig. 6 shows those of P_{12}, P_3 and P_{456} groups at $E_\alpha=34.6$ MeV.

(ii) *Experiments at other energies*

As the groups corresponding to higher excitations were difficult to be investigated in the circumstances stated above, we decided to investigate the change of angular distributions of ground state group P_0 as functions of bombarding energies using the self supporting carbon target mentioned in § **2.** (ii).

We collected the angular distributions obtained at twelve bombarding energies in Fig. 7. The three dimensional view of $d\sigma/d\omega$ as functions of E and θ is shown in Fig. 8. Figs. 7, 8 include the results at $E_\alpha=34.6$ MeV

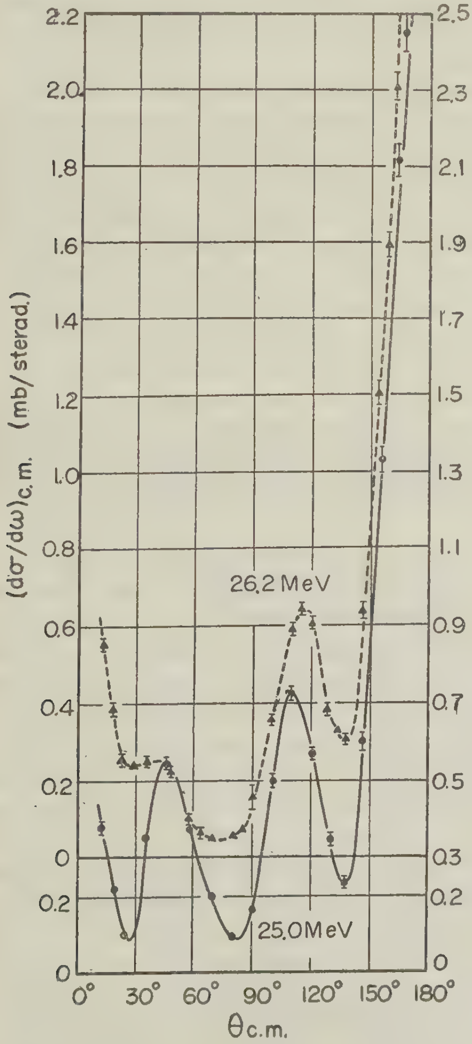

Fig. 7a. Change of angular distributions of ground state proton group P_0 between 25 and 26 MeV.

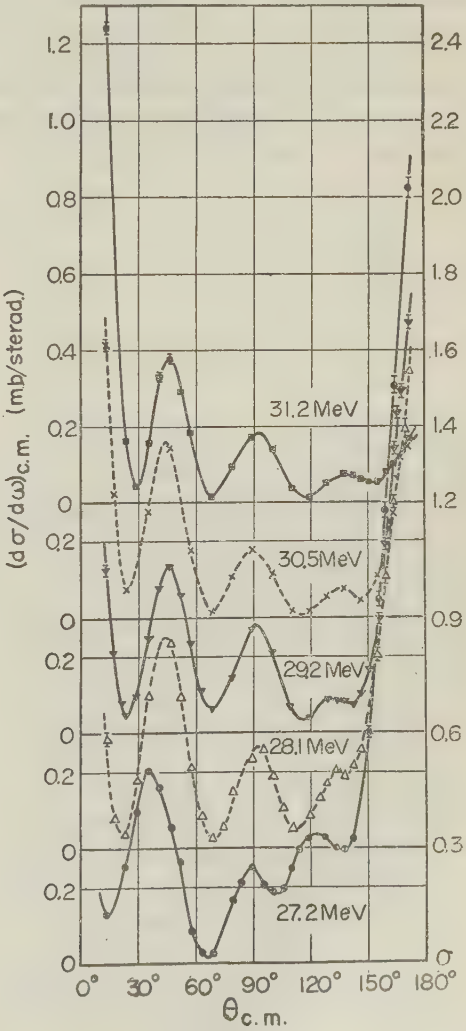

Fig. 7b. Change of angular distribution of ground state proton group P_0 between 27 and 31 MeV.

with polystyrene and soot targets. They are consistent with the results obtained with the carbon target, though the absolute values of the former are a little less. Present results are in reasonable agreement with those of R. Sherr and M. Rickey[1)] and of C. E. Hunting and N. S. Wall[2)] at neighbouring energies.

There are several remarkable features is the shape and magnitude of angular distributions.

(1) In the energy region between 25 and 26 MeV (Fig. 7a), angular distributions have two peaks and three valleys and there appear remarkable rises in the backward angles. These data were obtained, as mentioned above, by reducing the energies of alpha particles by introducing absorbers, and unfortunately we were unable to obtain beams of enough intensity with energies below 25 MeV. The preliminary results obtained by Osaka University group[3)] at $E_\alpha=22$ MeV hold qualitatively the features of those at 25 MeV; at 22 MeV the second peak approaches to the first one and the former becomes smaller than the latter.

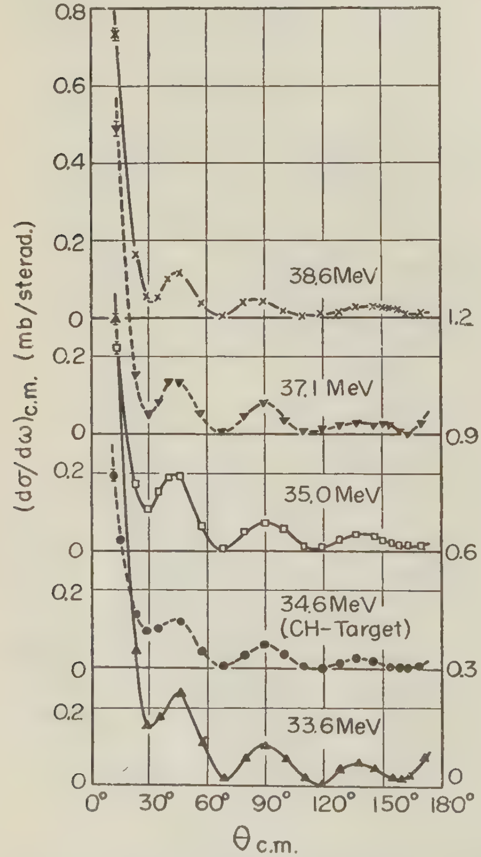

Fig. 7c. Change of angular distribution of ground state proton group P_0 between 33 and 39 MeV.

(2) In the energy region between 27 and 31 MeV (Fig. 7b), there appear three peaks and four valleys and their positions and magnitudes change systematically with energies. Particularly, the greater the beam energy becomes, the less the rise in the backward angles and the greater the rise in the forward angles.

(3) In the energy region between 33 and 39 MeV (Fig. 7c), there appears little rise of cross sections in the backward angles. The shapes of all these angular distributions resemble one another, the positions of peaks and valleys differ little, and the cross sections become smaller as the beam energies become higher.

(4) In Fig. 9, the differential cross sections at fixed laboratory angles are shown as functions of alpha particle energies. They show some resonance-like peaks and valleys, but this fact is considered to come from the changes of angular distributions with alpha particle energies and not necessarily from compound nucleus formation. In Fig. 10, the total cross section of P_0 group, σ_t, integrated from the angular distributions is shown as a function of alpha particle energies. The relative errors are estimated to be not greater than 10%, and it is sure that σ_t shows only a monotonously decreasing function of energies.

Detailed analyses have not yet been done, but we might conclude at least that any simple model of nuclear reaction is not sufficient to explain all our results. Concerning only to the angular region $\theta_{c.m.}<130°$, one might say that the reaction proceeds by either knock-on or stripping mechanism, as was described by S. T. Butler[4)]. But calculations by this model cannot fit the data very well at $E_\alpha=34.6$ MeV as is shown in Fig. 5, calculated values of $[j_1(QR)]^2$ for two nuclear radii $R=5.58\times10^{-13}$ cm and 3.67×10^{-13} cm normalized to the experimental value at the first maximum. Each first minimum calculated is too deep to fit the observed data. The second minimum and the second maximum are rather better fitted by $R=3.67\times10^{-13}$ cm than by $R=5.58\times10^{-13}$ cm, But the former value is too small as compared with the value gene-

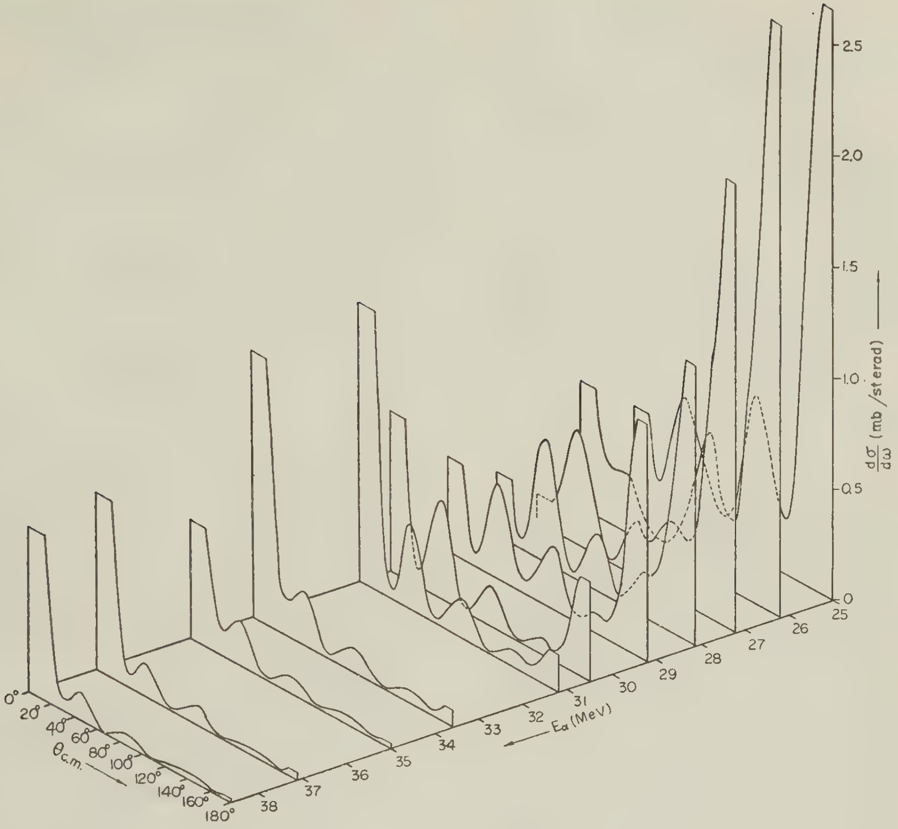

Fig. 8. $(d\sigma/d\omega)_{\mathrm{c.m.}}$ as functions of E_α and $\theta_{\mathrm{c.m.}}$

rally allowed in other experiments. One cannot fit the calculated values at all to the data in the backward region neither at E_α= 34.6 MeV nor at E_α=30.5 MeV.

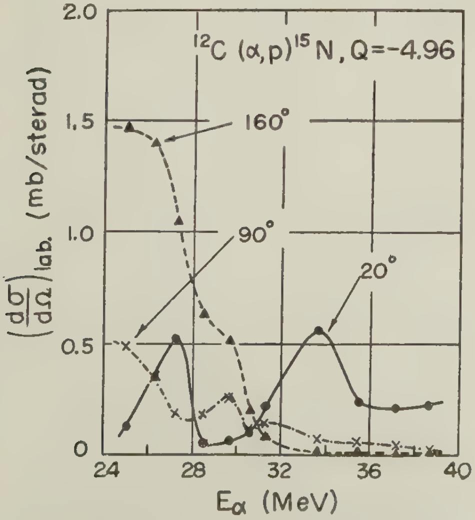

Fig. 9. Differential cross sections as functions of alpha particle energies at $\Theta_{\mathrm{lab}}=20°$ 90° and 160°.

The extraordinary rises of cross sections at large angles at alpha particle energies between 25 and 31 MeV might remind us some sort of heavy particle stripping suggested by G. E. Owen and L. Madansky[9]. But this model alone might not explain all the angular distributions. It may be that our results are ex-

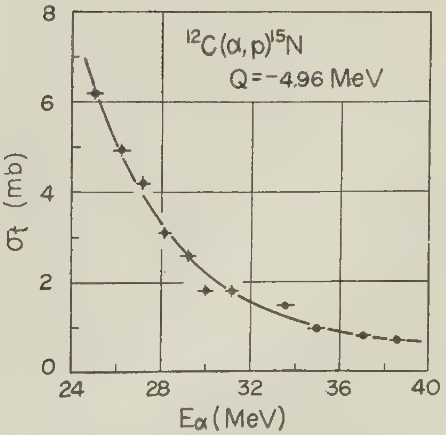

Fig. 10. Total cross section σ_t as a function of alpha particle energies.

plained by mixing the knock-on, stripping, heavy particle stripping and perhaps compound nucleus formation. Tne method of analyses used by G. F. Pieper and N. P. Heydenburg[10] for the reaction $^{19}F(\alpha, p)^{22}Ne$ at $E_\alpha = 6$ MeV may be helpful, and also the idea of semiclassical treatment of direct reactions by S. T. Butler et al.[11] may be useful.

At any rate, it is dangerous to ascribe the reaction mechanism to any model from an angular distribution obtained at a single energy and with a particular target. The accumulated data obtained here might be helpful to deduce something about the mechanism of the reaction $^{12}C(\alpha, p)^{15}N$.

Acknowledgement

The authors are very greatful to the devoted help by the cyclotron crew of I.N.S.; Messrs. T. Karasawa, A. Suzuki, H. Ogawa, T. Yamada, H. Adachi and Y. Miyazawa. The authors have also a distinct pleasure to thank the members of the Institute for their illuminating discussions.

The experiment at $E_\alpha = 34.6$ MeV was done as one of the " Test Experiments " of I.N.S. cyclotron and parts of the work were done by the temporal vising physicists from other universities; Drs. N. Ryu (Hiroshima University), Y. Nakano (Hokkaido Gakugei University) and Messrs. K. Takeshita (Kyushu University), T. Ishimatsu (Kyushu University), Y. Nakashima (University of Tokyo), and Ching Lin Wang (Kyoto University) and Miss. S. Mizuno (University of Tokyo).

The authors thank also Dr. N. S. Wall of M.I.T., Dr. M. Rickey of the University of Washington and the Osaka University group for sending us their preliminary data and for their helpful discussions. They express their cordial thanks to Prof. S. Kikuchi, Director of the Institute for his encouragement throughout these works.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 10, OCTOBER, 1959

Excitation Functions for (*p*, *n*) Reactions with Titanium, Vanadium, Chromium, Iron and Nickel up to Ep=14 MeV

By Shigeo TANAKA and Michiaki FURUKAWA

Institute for Nuclear Study, University of Tokyo, Tanashi, Tokyo

(Received June 20, 1959)

The absolute (p, n) cross sections on Ti^{47}, Ti^{48}, V^{51}, Cr^{52}, Fe^{56}, Fe^{57}, Ni^{61} and Ni^{64} were measured by the activation method at proton energies up to 14 MeV. The experimental results were compared with the predictions based on statistical model in terms of $\sigma(p, n)/\sigma_{total}$, and it was shown that the predictions based on this simple model are not necessarily in disagreement with the experiments.

§ 1. Introduction

The (p, n) cross sections were extensively measured by the Zurich group for the energies from the threshold of the (p, n) reaction to 6.7 MeV[1,2,3,4] According to Shapiro's calculation[5], agreement of the experimental values with the statistical theory was good for most nuclei so far as energy dependence was concerned. But the agreement was not always close and the assumption of a large variety of nuclear radii was necessary even for the nuclei of the same atomic number. Recently, Howe[6] extended the results of the Zurich group with copper and zinc into the energy region above the Coulomb barrier and confirmed that this variation, as far as compound model was assumed, is identified with the variation of the relative probability that the compound nucleus decays by neutron emission. He also suggested, as an alternative explanation, a picture of nuclear reactions in which a large fraction of events consist of direct proton-nucleon collisions at these low energies.

During the last several years, a growing number of experiments have thrown doubt on the validity of some of the assumptions and models on which the statistical theory of nuclear reaction is based[7,8,9]. However, it is obvious that quantitatively in this energy region the direct interactions are always relatively less important in comparison with the more probable statistical reaction[10,11,12].

Since few data[10,13] are available on the (p, n) cross section above 6.7 MeV, the excitation function measurements at higher energy region would give light on a more conclusive test for the validity of the statistical model of nuclear reaction.

§ 2. Experiments

The measurements of excitation functions were made for the (p, n) reactions of nuclides Ti^{47}, Ti^{48}, V^{51}, Cr^{52}, Fe^{56}, Fe^{57}, Ni^{61} and Ni^{64} for the proton energies up to about 14 MeV, above the thresholds of the competing reactions, (p, pn), $(p, 2n)$, etc. The target foils of natural isotopic abundance were activated with monoenergetic proton beams from 63-inch INS (Tokyo) cyclotron. All the bombardments were performed with extremely monochromatized external beams which were focussed by the quadrapole magnet and collimated successively by the narrow carbon slits only enough to obtain currents not less than about 0.5μA. The titanium, the iron and the nickel targets were rolled metal foils about 2 to 5 mg/cm² thick. The chromium targets were prepared by electrodeposition from bichromate solution onto thin copper plate, followed by dissolution of copper backing with nitric acid. The vanadium targets were prepared by spattering slurries of vanadium pentoxide in clear lacquer onto thin aluminum foils of known thickness. The 3 cm × 3 cm foils were used for the cyclotron bombardment when the section of the beam was about 0.5 cm². The foils were large enough to intercept all the protons including the scattered protons. The beam was collected by a Faraday cup. The signal from the cup was led to a 100% feedback type beam current integrator.

When it was difficult to distinguish the activity due to a (p, n) reaction from the interfering activities by means of a counting technique, chemical separation was performed.

For each target nucleus two kinds of cross section were measured: absolute (p, n) cross section measured with about 10 MeV protons which gave no second particle emission and relative cross section over the whole range of energies up to 14 MeV.

The absolute values of the cross sections were calculated from the formula $\sigma=\frac{A_0}{\lambda}\frac{1}{N}\frac{S}{A_t}$, where A_0/λ is the number of reaction product in the foil with A_t nuclei per area S by N protons. A_t/S was calculated from the measured weight and area of the foil, A_0/λ from the decay constant λ and the measured disintegration rate corrected for decay and N from the charge collected by the Faraday cup.

Table I lists the half-life and the probability of β^+ and β^- emission for the (p, n) reaction product used in the cross section calculation. These were obtained from the compilation of Seaborg et el[14]. and from the newer nuclear data in literature.

Energy dependence of the cross sections was measured by using the stacked-foil technique in which several target foils were interspaced with aluminum absorbers. In the most case of the bombardments, initial proton energies of 10 and 14 MeV were used. The energies of protons just entering and leaving each target foil were determined by calculating the energy loss in each foil in the stack. The energy loss in the aluminum absorber was calculated from the range-energy curve of Aron et al., and the dE/dx value in the other target foils was calculated in each case from the stopping power formula of Bethe et al[16]. The calculation leads to error onlv through the use of estimated mean excitation potential, I, in the stopping power formula and it can be shown that the error will be small over the range of proton energies used in this experiment for a variety of I.

The counting procedures were as follows.

Titanium targets: The disintegration rate of 16d-V^{48} was determined by a gamma-gamma coincidence counting after short-lived interfering activities had decayed. The relative yields of V^{48} were obtained by counting with an NaI scintillation counter set to count gamma rays above 0.6 MeV. Analysis of decay curves of 0.51 MeV gamma rays from positron annihilation gave the V^{47}/V^{48} ratios after subtraction of Compton tails from more energetic gamma rays. The yields of 31 m-V^{47} were given by applying these V^{47}/V^{48} ratios to the absolute yields of V^{48}.

Vanadium targets: Relative yields of 28d-Cr^{51} were given by counting with an NaI scintillation counter. To obtain the absolute yield of Cr^{51}, a source in a small volume was prepared from one of the targets and counted with an NaI scintillation counter in a defined geometry. The disintegration rate of Cr^{51} was thus determined by counting the photopeak from 0.32 MeV gamma ray.

Chromium targets: The Mn^{52m}/Mn^{52} ratios were given by analyzing decay curves of 1.45 MeV gamma ray from 21 m-Mn^{52m} and 5.7d-Mn^{52}. The disintegration rate of Mn^{52} was obtained by a gamma-gamma coincidence after short-lived activities had decayed. The relative yields of Mn^{52} were obtained by counting gamma rays above 0.6 MeV with an NaI scintillation counter.

Iron targets: After chemical separation, the cobalt fraction was made to a constant volume and a small portion was taken onto

Table I.

Reaction	Abundance in target	Half-life of product	Probability of β^+ and β^- emission
$Ti^{47}(p, n)V^{47}$	7.28%	31 m	97%
$Ti^{48}(p, n)V^{48}$	73.9	16.2 d	57
$V^{51}(p, n)Cr^{51}$	99.8	27.8 d	9*(0.32 MeV γ)
$Cr^{52}(p, n)Mn^{52m}$	83.8	21 m	99
$Cr^{52}(p, n)Mn^{52}$	83.8	5.7 d	33
$Fe^{56}(p, n)Co^{56}$	91.7	77 d	20
$Fe^{57}(p, n)Co^{57}$	2.19	270 d	100*(0.13 MeV γ)
$Ni^{61}(p, n)Cu^{61}$	1.19	3.3 h	66
$Ni^{64}(p, n)Cu^{64}$	1.08	12.8 h	57

a gold-spattered polyvinyl acetate film 50γ/cm^2 thick. After the source was dried in air, it was counted with a 4π methane proportional counter. The correction for the absorption loss in the foil was made. The relative yields of Co^{56} were obtained by counting with an NaI scintillation counter set to count gamma rays above 0.6 MeV. The absolute yields of Co^{57} were given by counting photo-peaks of the 0.13 MeV gamma rays in a well type NaI scintillation counter after subtraction of Compton tails from more energetic gamma rays.

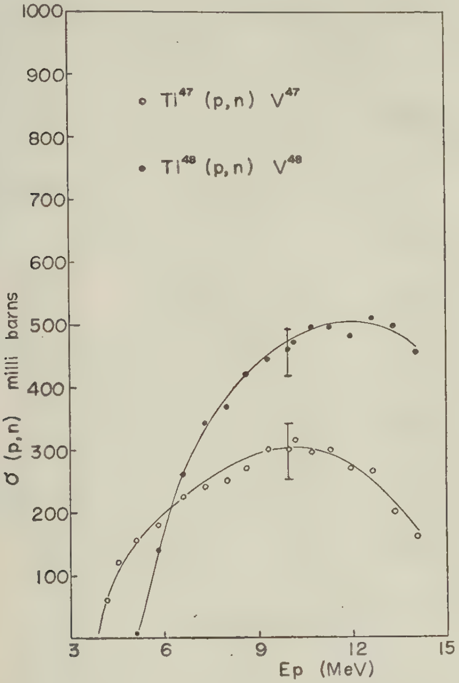

Fig. 1. The excitation functions for the reactions Ti^{47} (p, n)V^{47} and Ti^{48}(p, n)V^{48}.

Nickel targets: All the targets were chemically separated by means of anion exchange resin. Known portions of the copper fractions were evaporated to driness in counting dishes. These samples were counted with an end-window type Geiger Müller counter. The decay was followed for about 100 hours. Analysis of curves gave the Cu^{61}/Cu^{64} ratios after corrections for backscattering and absorption by air and the counter window. The disintegration rate of 12.8h-Cu^{64} was determined in the 4π beta proportional counter. The absolute yields of Cu^{61} were obtained from these Cu^{61}/Cu^{64} ratios and the disintegration rate of Cu^{64}.

§ 3. Results and Discussion

The absolute cross sections of the reactions studied are plotted as a function of the proton energy in Figures 1 to 5.

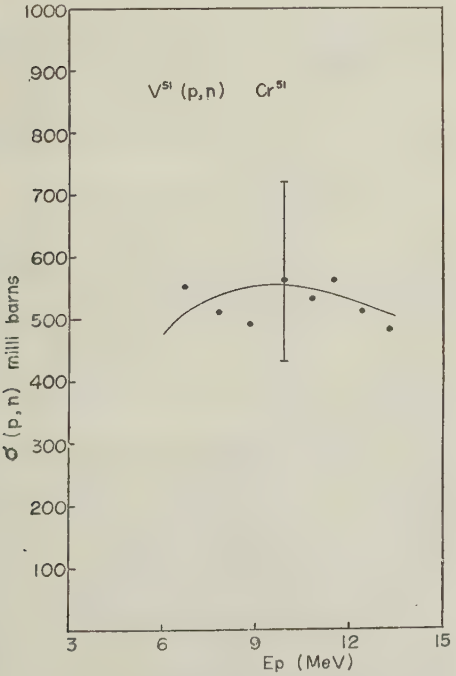

Fig. 2. The excitation function for the reaction V^{51}(p, n)Cr^{51}.

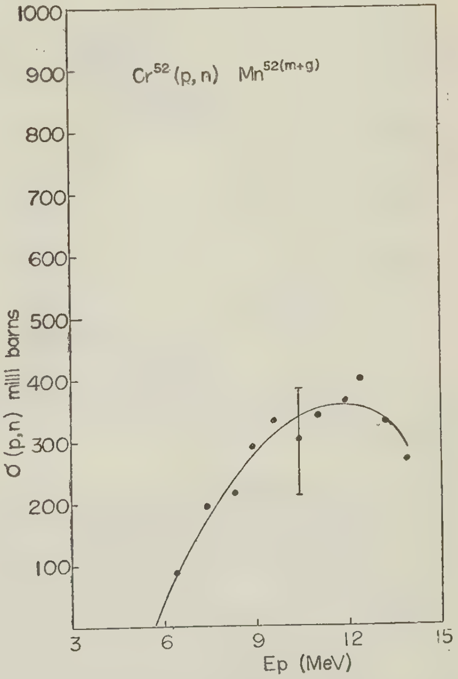

Fig. 3. The excitation function for the reaction Cr^{52}(p, n)Mn$^{52(m+g)}$.

The estimated standard error in the absolute cross sections, not including the uncertainty in the nuclear data, is shown in each figure. The curve in Figure 3 is the sum of σ_m and σ_g.

If the results of a measurement of the (p, n) cross section were analyzed in the light of the statistical theory assuming that the (p, n) cross section is the same as the total reaction cross section at this energy region, agreement with theory would be fairly good so far as energy dependence is concerned. Such an analysis, however, requires a large variation of assumed nuclear radii even from one isotope to another in a single element to fit the magnitude of cross section[5,6]. It appears as if the same could be said for the present results.

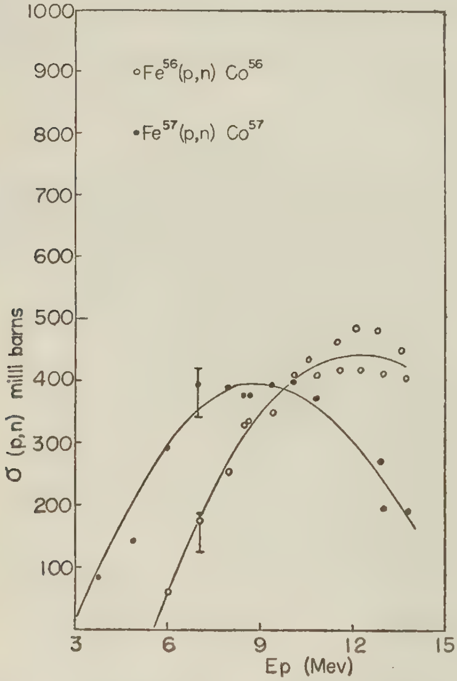

Fig. 4. The excitation functions for the reactions $Fe^{56}(p, n)Co^{56}$ and $Fe^{57}(p, n)Co^{57}$.

As far as the statistical model is assumed to be applicable, this discrepancy may be mainly due to the assumption which neglects the proton emission. When the proton binding energy of the compound nucleus is less than the neutron binding energy by a sufficient margin, it is obvious that the proton emission is not always negligible. This is especially the case when the fact is taken into account that the level densities in the two different residual nuclei may not be the same for the same exitation energy.

On this point of view, the full calculations about the emission probabilities of all the probable modes of decay of a compound nucleus were made as follows:

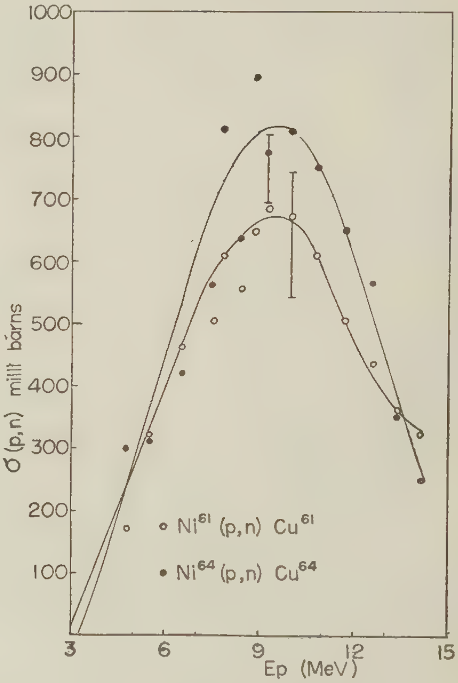

Fig. 5. The excitation functions for the reactions $Ni^{61}(p, n)Cu^{61}$ and $Ni^{64}(p, n)Cu^{64}$.

(a) The energy distribution of the emitted particle b is given by

$$N_b(\mathcal{E})\, d\mathcal{E} = \text{const. } \mathcal{E}\sigma_c(\mathcal{E})\omega(E)\, d\mathcal{E}\ .$$

Here $\mathcal{E}$ is the channel energy and E the excitation energy of the residual nucleus corresponding to the channel energy $\mathcal{E}$. Then $E = E_0 - Q_{cb} - \mathcal{E}$, where E_0 is the excitation energy of the compound nucleus and Q_{cb} is the binding energy of the particle b to the compound nucleus.

(b) σ_c is the capture cross section of evaporated particle on the residual nucleus and the values of σ_c were taken from Shapiro's calculation[5] for charged particles and $\sigma_c = \pi R^2$ for neutrons. (where the nuclear radii R is $r_0 \times A^{1/3}$) Here, the nuclear potential was conventionally assumed to be a square well, and the barrier was assumed to be independent of the excitation energy.

(c) The level density ω of the residual nucleus is based on a Fermi degenerate gas model and is given by $\omega(E)=c\exp[2(aE)^{1/2}]$, in which a and c are constants. It was assumed that a is the same for all residual nuclei studied, and the value of a chosen was 2, which is in agreement with many measurements of excitation functions with α-particles and with high-energy neutrons[17]. The dependence of the level density on the odd-even effect was taken into account on the basis of the work of Brown and Muirhead[18]

$$\omega_{0-0}/12 \sim \omega_{0-e}/5 \sim \omega_{e-e}/1 \ .$$

(d) Above the separation energy of a secondary proton emission γ-ray de-excitation may be considered more intensive than the proton emission until the excitation energy is 1~2 MeV above the separation energy owing to the Coulomb barrier. But unfortunately, the proper method for calculating γ-ray de-excitation is uncertain. In this paper, γ-ray de-excitation was allowed for by shifting the

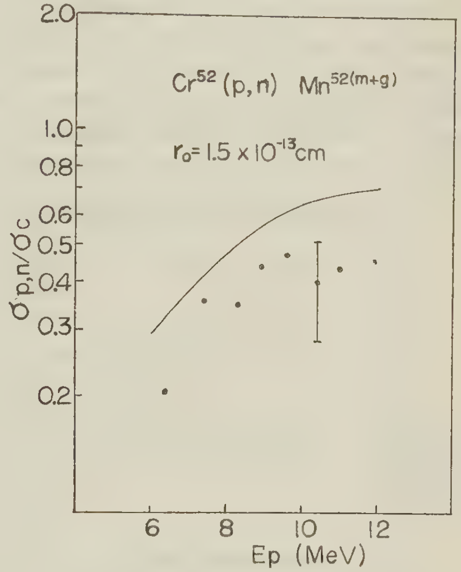

Fig. 8. The comparison of calculated and experimental values $\sigma(p, n)/\sigma_c$ for Cr^{52}.

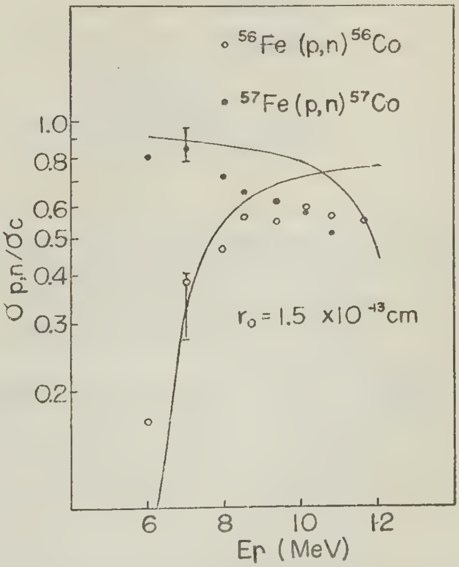

Fig. 9. The comparison of calculated and experimental values $\sigma(p, n)/\sigma_c$ for Fe^{56} and Fe^{57}.

threshold for the secondary proton emission 2 MeV upward.

(e) The emission probability calculations are very sensitive to the values of the binding energies of various particles. These values were obtained from the compilation of Way et al[19]. and they agree with those from recent mass measurements.

The experimental and theoretical values are compared through the values of $\sigma(p, n)/\sigma_c$. The solid curves in Figures 6 to 10 represent the calculated values of this quantity. The experimental points in Figures 6 to 10 are obtained from the observed (p, n) cross sections and the calculated total reaction cross section σ_c. The total reaction cross secton σ_c depends sensitively on the parameter r_0.

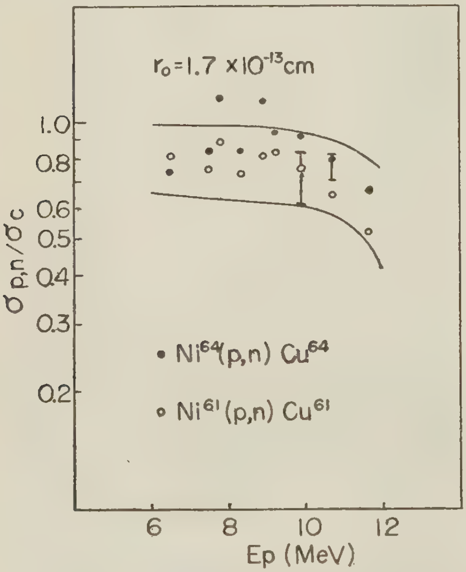

Fig. 10. The comparison of calculated and experimental values $\sigma(p, n)/\sigma_c$ for Ni^{61} and Ni^{64}.

Unfortunately, the same value of r_0 could not be taken consistently for all comparisons. The value $r_0=1.5\times10^{-13}$ cm was taken for all targets except for nickel, and 1.7×10^{-13} cm had to be chosen for nickel to fit the large (p, n) cross section.

It appears that the discrepancies between experimental and theoretical values do not exceed a factor of 1.5. This agreement, in view of the strong dependence of the calculations on some of the assumptions enumerated above, can not be claimed to be very meaningful. But the prediction of the statistical theory is not necessarily in disagreement with experiments. It may be profitable that, to discuss the validity of statistical theory, a review of some of the assumptions embodied in the present calculation is taken into account. The assumption of a square well potential in (b) may not be proper. It has been pointed out by K. Kikuchi[20] that the use of an exponential diffuse potential is more preferable to calculate the evaporation process. Besides, the assumption in (b) that the nuclear barrier is independent of excitation energy may not be valid. An increase in penetration with excitation would increase the emission of low-energy charged-particles. Indeed, it has been shown by Fulmer and Goodman[21] that the (p, α) cross sections agree with the assumption of a lowered Coulomb barrier for the excited compound nucleus.

Acknowledgements

This work was done with the aid of the visiting researchers from other universities: Drs. K. Otozai, S. Kume, S. Fukushima, S. Iwata (Osaka University), T. Shiokawa, M. Yagi (Shizuoka University) and Y. Kusaka (Konan University), to whom authors' thanks are due. Authors' thanks are also due to Drs. K. Kikuchi and T. Mikumo for their valuable discussion, and to Prof. I. Nonaka and the other staff of low energy division for their encouragement. We are also grateful to the cyclotron crew for their cyclotron operation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 10, OCTOBER, 1959

The Field Dependence of the Mobility of Electrons in *n*-Germanium

By Hisanao SATO
Department of Physics, University of Nagoya

(Received May 6, 1959)

The mobility of electrons in *n-Ge* at an arbitrary field strength is calculated by assuming the distribution function $f(\boldsymbol{p})$ in the form

$$f(\boldsymbol{p})=A\exp\left(-\frac{|\boldsymbol{p}+\boldsymbol{p}_0|^2}{2mkT}\right),$$

where T is the electron temperature and $\boldsymbol{p}_0$ represents the uniform displacement of the electron distribution in the direction of the electric field. Two parameters T and $\boldsymbol{p}_0$ are determined by the same way as Fröhlich and Paranjape did. Interaction constants between electrons and acoustical- and optical-modes of vibration are determined from the temperature dependence of the zero-field mobility. At room temperatures it is found that the electron temperature is determined almost by optical-mode scattering at low fields, but that the energy loss of electrons due to acoustical-mode scattering cannot be neglected at very high fields. Consequently the current density versus electric field relation becomes much different from Shockley's predictions. It seems that the agreement with the experimental results becomes more satisfactory.

§ 1. Introduction

The temperature dependence of the lattice-scattering mobility in *n*-type germanium was found to be $T^{-1.66}$[1]. This result is different from the theoretical prediction $T^{-1.5}$ which is derived by assuming that electrons are scattered by acoustical phonons[2]. Harrison[3] attributed this discrepancy to the scattering of electrons by optical phonons. He estimated the relative importance of acoustical-mode and optical-mode scattering by expanding the matrix elements for scattering in powers of the electron wave number and studying the first non-vanishing terms. He concluded that in *n*-type germanium the matrix elements for scattering by optical modes are large compared to those for scattering by acoustical modes. Although the amplitude of optical modes are small, their contribution to the mobility must become comparable to that of acoustical modes at about 300°K (we assume a characteristic temperature of optical phonons is equal to it).

It has been reported that at high electric field the current deviates from Ohm's law and become proportional to the square root of the field strength[4]. Shockley[5] analyzed this current versus field relation theoretically, assuming that steady-state conditions are realized by the processes in which electrons lose their momentum and energy to acoustical vibrations. It has been remarked that his theory is not in agreement with experiments quantitatively. Yamashita and Watanabe[6] solved the Boltzmann equation by assuming the distribution function in the from

$$f(\boldsymbol{p})=f_0(p)+\mathrm{P}_1(\cos\theta)f_1(p)\,, \qquad (1)$$

where $\mathrm{P}_n(\cos\theta)$ is the Legendre polynomials of degree n, the polar axis being chosen in the direction of the electric field. But the quantitative discrepancy between theory and experiment was not explained.

Sodha and Agrawal[7] calculated the low field mobility, taking optical modes into consideration. At low fields we can write the mobility μ in the form

$$\mu=\mu_0(1-\nu F^2)\,, \qquad (2)$$

where μ_0 is the zero-field mobility and F the field strength. If we consider the scattering by acoustical modes only, the theoretical magnitude of ν becomes about a hundred times as large as the experimental value. Sodha and Agrawal concluded that their calculation could not remove this discrepancy. Yamashita[8] evaluated ν also, taking account of the scattering by both acoustical and optical modes and solving the Boltzmann equation on the assumption (1). He showed that theoretical ν was in agreement with the experimental one very nicely.

At high fields the average energy of electrons increases and the mobility decreases since relaxation times are approximately inversely proportional to the velocity of electrons. Under steady-state conditions, the distribution function of electrons is so determined that the rates of gain and loss of energy (or momentum) balance each other. If we consider the scattering by acoustical modes only, electrons become hot even in a weak field because the energy loss of electrons by the emission of acoustical phonons is small. On the contrary, the energy of optical phonons emitted by electrons is so large that the optical modes play an essential role in determing the energy exchange between electrons and lattice vibrations except at very low temperatures.

The purpose of this paper is to remove the discrepancy between Shockley's theory and experiments in the hot electron problem and to study the scattering mechanism of electrons by lattice vibrations in n-type germanium. To solve the Boltzmann equation we assume the distribution function in the form

$$f(\boldsymbol{p})=A\exp\left(-\frac{|\boldsymbol{p}+\boldsymbol{p}_0|^2}{2mkT}\right), \qquad (3)$$

supposing that the exchange of energy and momentum between electrons is so fast that they are in internal equilibrium. In (3) T is the temperature of electrons and $\boldsymbol{p}_0/m$ is their drift velocity. Estimating the contribution of optical modes to the mobility from the experimental zero-field mobility μ_0, we calculate the low field mobility, (2), and the mobility of hot electrons. In § 3 it is shown that the rate of the energy loss of electrons is determined almost by the optical-mode scattering at room temperatures. But at very high fields (§ 5), where the average energy of electrons become high, it appears that one cannot neglect the acoustical-mode scattering since high energy electrons can emitt a high energy phonon.

§ 2. The Boltzmann Equation

When a static electric field F is in the z direction, the Boltzmann equation is

$$eF\frac{\partial f}{\partial p_z}+\left(\frac{\partial f}{\partial t}\right)_L+\left(\frac{\partial f}{\partial t}\right)_e=0\,, \qquad (4)$$

where $(\partial f/\partial t)_L$ and $(\partial f/\partial t)_e$ are the rate of change of f due to collisions with phonons and between electrons, respectively. We assume that the energy of electrons E is a parabolic function of momentum p; $E=p^2/2m$, m being the effective mass.

Now we shall write the explicit from of $(\partial f/\partial t)_L$. According to Harrison[3], the matrix element of the perturbing potential H' is of first order in powers of the phonon wave number $(q/\hbar)$ for scattering by acoustical modes, whereas for scattering by optical modes the zero order term remains nonvanishing. Thus we have

$$|H'|^2=\frac{C^2q^2}{2N_0M\hbar\omega_q}\begin{Bmatrix}n_q\\ n_q+1\end{Bmatrix} \qquad (5)$$

for acoustical-mode scattering, and

$$|H'|^2=\frac{C'^2q_L^2}{2N_0M\hbar\omega}\begin{Bmatrix}n_0\\ n_0+1\end{Bmatrix} \qquad (6)$$

for optical-mode scattering, where $q_L/\hbar$ is equal to inverse atomic distance. C and C' are constants of the same order of magnitude.

As usual, the energy of an optical phonon, $\hbar\omega$, is assumed to be constant, while for an acoustical phonon

$$\hbar\omega_q = sq\ , \tag{7}$$

where s is the sound velocity. Then we have for acoustical-mode and optical-mode scattering respectively

$$\left(\frac{\partial f}{\partial t}\right)_{ac} = \frac{2\pi B_a}{\hbar q_L} \sum_{\boldsymbol{q}} q n_q [\{f(\boldsymbol{p}+\boldsymbol{q})e^x - f(\boldsymbol{p})\}\delta(E_{\boldsymbol{p}+\boldsymbol{q}} - E_{\boldsymbol{p}} - \hbar\omega_q)$$

$$+\{f(\boldsymbol{p}-\boldsymbol{q}) - f(\boldsymbol{p})e^x\}\delta(E_{\boldsymbol{p}-\boldsymbol{q}} - E_{\boldsymbol{p}} + \hbar\omega_q)]\ , \tag{8}$$

$$\left(\frac{\partial f}{\partial t}\right)_{op} = \frac{2\pi B_0}{\hbar} n_0 \sum_{\boldsymbol{q}} [\{f(\boldsymbol{p}+\boldsymbol{q})e^u - f(\boldsymbol{p})\}\delta(E_{\boldsymbol{p}+\boldsymbol{q}} - E_{\boldsymbol{p}} - \hbar\omega)$$

$$+\Delta(E)\{f(\boldsymbol{p}-\boldsymbol{q}) - f(\boldsymbol{p})e^u\}\delta(E_{\boldsymbol{p}-\boldsymbol{q}} - E_{\boldsymbol{p}} + \hbar\omega)]\ , \tag{9}$$

where for simplicity we have used following notations:

$$(B_a/q_L) = (C^2/2N_0Ms),\quad B_0 = (C'^2 q_L^2/2N_0M\hbar\omega),\quad x = (sq/kT_0),\quad u = (\hbar\omega/kT_0),$$

$$n_q = (e^x - 1)^{-1},\quad n_0 = (e^u - 1)^{-1},\quad \Delta(E) = 1 \quad \text{for } E \geq \hbar\omega$$

$$0 \quad \text{for } E < \hbar\omega\ .$$

T_0 is the lattice temperature.

In n-type germanium, similarly to other semiconductors, the energy of most electrons satisfies

$$E \ll q_D^2/8m \tag{10}$$

even in hot electron states, where $q_D/\hbar$ is the Debye cut off wave number. Accordingly the energy of acoustical phonons interacting with electrons is small enough to apply classical statistics;

$$n_q = \frac{kT_0}{sq}\ . \tag{11}$$

§ 3. The Low-Field Mobility

We assume (3) and expand it in powers of $\boldsymbol{p}_0$, which has only z-component in an isotropic case:

$$f = f_0 + f_1 + f_2 + f_3\ , \tag{12}$$

where

$$f_0 = A\exp\left(-\frac{E}{kT}\right),\qquad f_1 = -\frac{p_0 p_z}{mkT} f_0\ ,$$

$$f_2 = \left(\frac{p_0^2}{2mkT}\right)\left(\frac{p_z^2}{mkT} - 1\right) f_0\ ,\qquad f_3 = \frac{p_0^3 p_z}{2(mkT)^2} f_0 - \left(\frac{p_0 p_z}{mkT}\right)^3 f_0\ .$$

A is determined by $\sum f = \sum f_0 = N$, where N is the number of conduction electrons. We need to consider terms f_2 and f_3 to calculate ν in (2), since p_0 is proportional to F in lowest order and p_0^3 to F^3

Following Fröhlich and Paranjape[7] we shall determine T and p_0 by the conditions that in stationary states the rate of gain of energy and momentum furnished by the field is equal to the rate of dissipation to the lattice vibrations. Multiplying the Boltzmann equation (4) by p_z or E and summing over the momentum space, we obtain

$$NeF = \sum_{\boldsymbol{p}} p_z \left(\frac{\partial f}{\partial t}\right)_L, \tag{13}$$

$$Fj = -\sum_{\boldsymbol{p}} E \left(\frac{\partial f}{\partial t}\right)_L, \tag{14}$$

since both energy and momentum are conserved in the case of the electron-electron collisions;

$$\sum_p p_z\left(\frac{\partial f}{\partial t}\right)_e = \sum_q E\left(\frac{\partial f}{\partial t}\right)_e = 0\,. \tag{15}$$

In (14) j is the current density and from (3)

$$j = -\frac{e}{m}\sum_q p_z f = \frac{Nep_0}{m}. \tag{16}$$

i) the calculation of collision terms

To calculate (13) and (14) we substitute (12) into $(\partial f/\partial t)_L$. Then it may be written as the expansion in powers of p_0;

$$\left(\frac{\partial f}{\partial t}\right)_L = \left(\frac{\partial f}{\partial t}\right)_L^0 + \left(\frac{\partial f}{\partial t}\right)_L^1 + \left(\frac{\partial f}{\partial t}\right)_L^2 + \left(\frac{\partial f}{\partial t}\right)_L^3. \tag{17}$$

Details of the calculation of these terms are given in Appendix.

By expanding the right-hand side of (A10) and (A17), in powers of the temperature difference and retaining first order terms, we obtain

$$\left(\frac{\partial f}{\partial t}\right)_{ac}^0 = \Gamma\left(\frac{4ms^2}{kT_0}\right)\gamma E^{1/2}\left(1-\frac{E}{2kT_0}\right)f_0(T_0)\,, \tag{18}$$

$$\left(\frac{\partial f}{\partial t}\right)_{op}^0 = \Gamma a n_0 \gamma u^2(\sqrt{E+\hbar\omega} - \Delta(E)e^u\sqrt{E-\hbar\omega})f_0(T_0)\,, \tag{19}$$

where

$$\gamma = (T-T_0)/T_0\,. \tag{20}$$

$$a = (B_0/B_a)(sq_L/2\hbar\omega)\,, \tag{21}$$

and Γ is a constant defined by (A7). $f_0(T_0)$ is the thermal equilibrium distribution;

$$f_0(T_0) = A_0\exp\left(-\frac{E}{kT_0}\right)\,, \tag{22}$$

where A_0 is determined by the number N. an_0 represents the ratio of the effects of optical-mode scattering to that of acoustical-mode scattering.

$(\partial f/\partial t)_L{}^1$ is given by (A13) and (A17), which can be used for hot electrons. In this section $f_1(T)$ may be expanded as follows;

$$f_1(T) = -\frac{p_0p_z}{mkT}f_0(T) = -\frac{p_0p_z}{mkT_0}\left(1-\frac{5}{2}\gamma+\gamma\frac{E}{kT_0}\right)A_0\,e^{-E/kT_0} = f_1(T_0)\left(1-\frac{5}{2}\gamma+\gamma\frac{E}{kT_0}\right). \tag{23}$$

Then we get

$$\left(\frac{\partial f}{\partial t}\right)_L^1 = -\Gamma\{\sqrt{E} + an_0u(\sqrt{E+\hbar\omega}+\Delta(E)e^u\sqrt{E-\hbar\omega})\}f_1(T_0)\left(1-\frac{5}{2}\gamma+\gamma\frac{E}{kT_0}\right). \tag{24}$$

In order to calculate the current correctly to terms of order F^3, we may put $T=T_0$ in f_2 and f_3. Then, as shown in appendix B, we have except for terms proportional to $P_2(\cos\theta)$

$$\left(\frac{\partial f}{\partial t}\right)_{ac}^2 = \left(\frac{p_0^2}{2mkT_0}\right)\Gamma\left(\frac{8ms^2}{kT_0}\right)\cos^2\theta\cdot\sqrt{E}\left(1-\frac{E}{2kT_0}\right)f_0(T_0)\,, \tag{25}$$

$$\left(\frac{\partial f}{\partial t}\right)_{op}^2 = \left(\frac{p_0^2}{2mkT_0}\right)\Gamma an_0(2u^2)\cos^2\theta(\sqrt{E+\hbar\omega} - \Delta(E)e^u\sqrt{E-\hbar\omega})f_0(T_0)\,, \tag{26}$$

$$\left(\frac{\partial f}{\partial t}\right)_L^3=-\Gamma\{\sqrt{E}+an_0u(\sqrt{E+\hbar\omega}+\Delta(E)e^u\sqrt{E-\hbar\omega})\}f_3(T_0)\,. \tag{27}$$

ii) the calculation of p_0

p_0 is determined from (13), the right-hand side of which is a function of the electron temperature T or γ. We have to calculate it correctly to linear terms in γ, since γ is of order F^2. From (24) we obtain

$$\sum_P p_z\left(\frac{\partial f}{\partial t}\right)_L^1=N\left(\frac{p_0}{m}\right)\left(\frac{8m}{3}\right)\left(\frac{kT_0}{\pi}\right)^{1/2}\Gamma\mathrm{G}\left\{1+\gamma\left(\frac{\mathrm{H}}{\mathrm{G}}-\frac{5}{2}\right)\right\}, \tag{28}$$

where

$$\mathrm{G}=1+an_0u(u/2)^2e^{u/2}K_2(u/2)\,, \tag{29}$$

$$\mathrm{H}=3+an_0u(u/2)^2e^{u/2}\{3K_2(u/2)+uK_1(u/2)\}\,, \tag{30}$$

in which K_n is the modified Bessel function of the second kind.[10]

The zero-field mobility μ_0 is given by substituting $\gamma=0$ and $p_0=m\mu_0F$ in (28) which on the other hand, is equal to NeF:

$$\mu_0=e\left[\frac{8m}{3}\left(\frac{kT_0}{\pi}\right)^{1/2}\Gamma\mathrm{G}\right]^{-1}. \tag{31}$$

This is different from the ordinary definition of the mobility obtained by neglecting electron-electron collisions.[11]

From (27), puting $p_0=m\mu_0F$ in $f_3(T_0)$, we have

$$\sum_P p_z\left(\frac{\partial f}{\partial t}\right)_L^3=NeF\left(\frac{\mu_0F}{v_T}\right)^2\left(\frac{2\mathrm{H}}{5\mathrm{G}}-1\right), \tag{32}$$

where $v_T=(2kT_0/m)^{1/2}$ means the thermal velocity of electrons. Substituting (28) and (32) into (13), we obtain finally

$$\frac{p_0}{m}=\mu_0F\left[1-\left(\frac{\mathrm{H}}{\mathrm{G}}-\frac{5}{2}\right)\left\{\gamma+\frac{2}{5}\left(\frac{\mu_0F}{v_T}\right)^2\right\}\right]. \tag{33}$$

iii) the calculation of γ

It follows from (18) and (19) that

$$\sum_P E\left(\frac{\partial f}{\partial t}\right)_L^0=-\gamma Ne(3s^2\mathrm{I}/\mu_0\mathrm{G})\,, \tag{34}$$

and from (25) and (26)

$$\sum_P E\left(\frac{\partial f}{\partial t}\right)_L^2=-Ne(2s^2\mathrm{I}/\mu_0\mathrm{G})(\mu_0F/v_T)^2\,, \tag{35}$$

where

$$\mathrm{I}=1+an_0\left(\frac{v_T}{s}\right)^2\left(\frac{u}{2}\right)^4e^{u/2}K_1(u/2)\,. \tag{36}$$

Then we get from (14), using the approximate relation $Fj=Ne\mu_0F^2$,

$$\gamma=\frac{(\mu_0F)^2\mathrm{G}}{3s^2\mathrm{I}}-\frac{2}{3}\left(\frac{\mu_0F}{v_T}\right)^2. \tag{37}$$

iv) numerical results

The current density j can now be calculated from (16), (33) and (37) as follows:

$$j=\frac{Ne\,p_0}{m}=Ne\mu_0F\left[1-\left(\frac{\mathrm{H}}{\mathrm{G}}-\frac{5}{2}\right)\left\{\frac{(\mu_0F)^2G}{3s^2\mathrm{I}}-\frac{4}{15}\left(\frac{\mu_0F}{v_T}\right)^2\right\}\right]. \tag{38}$$

Provided that the scattering by optical modes is negligible or $a=0$, ν in (2) becomes from (38)

$$\nu=\nu_0=\frac{\mu_0^2}{6s^2}\left(1-\frac{4s^2}{5v_T^2}\right)\simeq\frac{\mu_0^2}{6s^2}\,. \tag{39}$$

In order to estimate the magnitude of a, we make use of the experimental results of the zero-field mobility. By fitting the theoretical μ_0 to the data, it is found that a becomes 0.22. This value seems reasonable from the theoretical point of view.

Choosing $(\hbar\omega/k)=300°\mathrm{K}$, $s=5.4\times10^5$ cm/sec, and $m=m_0/4$[11], m_0 being the free electron mass, we find that the value of I is determined almost by optical modes at ordinary temperatures; $\mathrm{I}\gg1$. This is easily seen from the definition of G and I. In G the term due to optical modes will be of order unity. On the other hand, in I the term caused by the optical-mode scattering has a factor $(v_T/s)^2$, which is of order 10^3. Further due to the small value of a it appears that $s^2(\mathrm{I/G})$ becomes far smaller than v_T^2 and therefore f_2 and f_3 have negligible effects on ν. Thus in our case ν can be written as

$$\nu=\left(\frac{\mathrm{H}}{\mathrm{G}}-\frac{5}{2}\right)\frac{\mathrm{G}}{3s^2\mathrm{I}}\mu_0^2\,. \tag{40}$$

From the fact that I is determined by optical modes, it follows that electrons exchange their energy mainly with optical modes. This is in agreement with Yamashita's result.[8]

Table I. The variation of ν/ν_0 with temperature and a.

	ν/ν_0	
T°K	$a=0.2$	$a=0.3$
100	0.060	0.049
200	0.055	0.035
300	0.059	0.047

Table I gives the variation of ν/ν_0 with temperature and a, where we take $m=m_0/4$, ignoring the anisotropy of the energy band and the intervalley effects. Since I is nearly proportional to m^{-1}, ν/ν_0 is nearly proportional to m.

§4. Field Independent Drift Velocity due to Optical-mode Scattering

The drift velocity becomes constant and independent of the electric field under the conditions that the average energy of electrons is much larger than the energy of optical phonons, but still so small that the acoustical-mode scattering can be ignored as regards the energy exchange between electrons and lattice vibrations.

We assume the electron distribution centered about $\boldsymbol{p}=\boldsymbol{p}_0$ in momentum space:

$$f=f_0(|\boldsymbol{p}+\boldsymbol{p}_0|)=f_0+f_1=f_0(E)+\frac{p_0p_z}{m}\frac{\partial f_0}{\partial E}\,, \tag{41}$$

neglecting higher order terms since the average energy of electrons becomes large at high fields. We need not assume a paticular functional from of f_0 in this section.

Substituting f_0 into (8) we obtain

$$\left(\frac{\partial f}{\partial t}\right)^0_{ac}=\Gamma\left(\frac{4ms^2}{kT_0}\right)\sqrt{E}\left\{\left(f_0+kT_0\frac{\partial f_0}{\partial E}\right)+\frac{E}{2}\left(\frac{\partial f_0}{\partial E}+kT_0\frac{\partial^2 f_0}{\partial E^2}\right)\right\}, \tag{42}$$

which was given by Yamashita and Watanabe[6]. Substituting f_0 into (9) and expanding $f_0\,(E\pm\hbar\omega)$, we have

$$\left(\frac{\partial f}{\partial t}\right)^0_{op}=\Gamma au\hbar\omega\left(\frac{f_0}{\sqrt{E}}+\sqrt{E}\frac{\partial f_0}{\partial E}\right). \tag{43}$$

For $E\gg\hbar\omega$, it follows from (A13) and (A19) that

$$\left(\frac{\partial f}{\partial t}\right)^1_L=-\Gamma\{1+au(1+2n_0)\}\sqrt{E}\,f_1\,, \tag{44}$$

from which the condition (13) becomes

$$\sum_p p_z\left(\frac{\partial f}{\partial t}\right)_L=\frac{4}{3}p_0\Gamma\{1+au(1+2n_0)\}N\langle E^{1/2}\rangle=NeF\,, \tag{45}$$

where

$$N\langle E^{1/2}\rangle = \sum E^{1/2} f_0 \,.$$

Next, from (42) and (43), we compute the rate of the energy loss as follows:

$$-\sum_p E\left(\frac{\partial f}{\partial t}\right)_L = N\Gamma\left[au\hbar\omega\langle E^{1/2}\rangle + \left(\frac{2ms^2}{kT_0}\right)\{\langle E^{3/2}\rangle - 2kT_0\langle E^{1/2}\rangle\}\right]. \tag{46}$$

(46) suggests that the rate of the energy loss is determined only by optical modes, provided that the average energy satisfies

$$\langle E\rangle \ll au\hbar\omega\left(\frac{kT_0}{2ms^2}\right) = a\hbar\omega\left(\frac{\hbar\omega}{2ms^2}\right). \tag{47}$$

Using the values of constants obtained in § 3, (47) becomes

$$\langle E\rangle \ll 70\hbar\omega \tag{47'}$$

which is compatible with the assumption $E \gg \hbar\omega$.

Neglecting the terms corresponding to the acoustical-mode scattering in (46), we have

$$-\sum E\left(\frac{\partial f}{\partial t}\right)_L = N\Gamma au\hbar\omega\langle E^{1/2}\rangle = NFe(p_0/m)\,. \tag{48}$$

Eliminating $\langle E^{1/2}\rangle$ from (45) and (48), we obtain the drift velocity p_0/m as

$$\frac{p_0}{m} = \left(\frac{\hbar\omega}{m}\right)^{1/2}\left[\frac{4}{3}\{(au)^{-1}+1+2n_0\}\right]^{-1/2}. \tag{49}$$

The calculated drift velocity, shown in Table II, is somewhat smaller than Ryder's data.

Table II. Field independent drift velocity for $(\hbar\omega/k)=300°\text{K}$, $m=m_0/4$, $a=0.22$.

T°K	p_0/m (cm/sec)
300	4.5×10^6
200	5.6×10^6
100	7.3×10^6

§ 5. The Mobility of Hot Electrons

(47′) shows that electrons lose their energy mainly through the interactions with optical modes, unless the electron temperature becomes about $2\cdot10^4$°K. If it is accepted as true, the current is not proportional to $F^{1/2}$ at any field strength in n-type germanium, since this dependence is a consequence of taking account of the acoustical-mode scattering only.

As it has been seen in § 3 that the contributions of f_2 and f_3 are quite small to the determination of the field dependent mobility even in a weak field, here

$$f = f_0 + f_1\,, \qquad f_0 = A\exp(-E/kT)\,, \qquad f_1 = -\frac{p_0 p_z}{mkT} f_0\,. \tag{50}$$

Then the following equations are easily obtained; from (A10) and (A17)

$$-\sum_p E\left(\frac{\partial f}{\partial t}\right)_L = N\Gamma\left(\frac{8m}{3}\right)\left(\frac{kT}{\pi}\right)^{1/2}(3s^2)\mathrm{I}(\alpha) = F\cdot j\,, \tag{51}$$

where

$$\mathrm{I}(\alpha) = \frac{1-\alpha}{\alpha} + an_0\left(\frac{v_T}{s}\right)^2\frac{\alpha u^3}{16}(e^{u(1-\alpha)}-1)e^{\alpha u/2}K_1(\alpha u/2)\,, \tag{52}$$

and from (A14) and (A16)

$$\sum_p p_z\left(\frac{\partial f}{\partial t}\right)_L = \left(\frac{p_0}{m}\right)N\Gamma\left(\frac{8m}{3}\right)\left(\frac{kT}{\pi}\right)^{1/2}\mathrm{G}(\alpha) = NeF\,, \tag{53}$$

where

$$\mathrm{G}(\alpha) = 1 + an_0\left(\frac{u}{2}\right)\left(\frac{\alpha u}{2}\right)^2\{(e^{u(1-\alpha)}+1)K_2(\alpha u/2) + (e^{u(1-\alpha)}-1)K_1(\alpha u/2)\}\,, \tag{54}$$

and $\alpha=(T_0/T)$. From (51), (53) and (31) we get the drift velocity as a function of the electron temperature,

$$\frac{p_0}{m}=\mu_0 F\sqrt{\alpha}\,[\mathrm{G}(1)/\mathrm{G}(\alpha)]\,, \tag{55}$$

and the electron temperature as a function of the electric field,

$$(\mu_0 F)^2=\frac{3s^2\mathrm{I}(\alpha)\mathrm{G}(\alpha)}{\alpha[\mathrm{G}(1)]^2}. \tag{56}$$

We have calculated the drift velocity numerically in Fig. 1 from (55) and (56), taking the values of constants; $\mu_0=3800\,\mathrm{cm}^2/\mathrm{volt\ sec}$ at $T_0=300°\mathrm{K}$, $a=0.22$, and $m=m_0/4$, neglecting the anisotropy of the band and the intervalley effects as in § 3. The theoretical curve in Fig. 1 is in fairly agreement with Ryder's data at 298°K (circles). Concerning this calculations, we should remark that the contributions of the acoustical mode to $\mathrm{I}(\alpha)$ are not negligiblly small for $\alpha\lesssim 0.1$, or $T\gtrsim 3000°\mathrm{K}$. Consequently the drift velocity does not become flat, but increases gradually. For instance, $p_0/m=5.4\times10^6$ cm at $F=4.7\times10^3$ volts/cm and 5.6×10^6 cm at 7.8×10^3 volts/cm, which are considerably larger than that obtained in § 4.

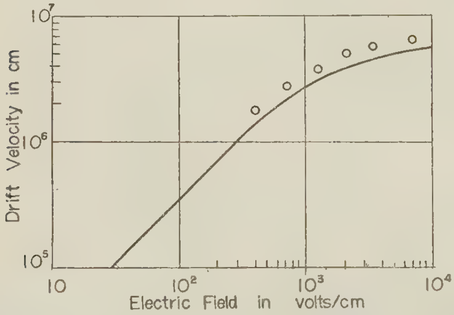

Fig. 1. Drift velocity as a function of electric field at 300°K in n-Ge. Circles are taken from Ryder's paper.

§ 6. Concluding Remarks

We have calculated the mobility of electrons by the method of Fröhlich and Paranjape. If we suppose that the electron-electron collisions are effective enough, it seems resonable to determine T and p_0 in (3) from the conditions (13) and (14) that the rates of change of momentum and energy summed over all electrons balance. The reason why the results of Sodha and Agrawal are so different from ours is not clear. But it is certain that the rate of the energy loss of electrons is determined by the collisions with optical modes at low fields. The conclusion is derived from the value of I in § 3, and since $\mathrm{I}\gg 1$, ν/ν_0 becomes very small compared to unity.

In cases where the electron density is so low that the interactions between them may be neglected, the assumption (3) is in general not good. Although the zero-field mobility given by (31) is not correct in that case, it can be interpreted as the first approximation of the variation method, if we write as usual

$$f=f_0+p_z c(E)\frac{\partial f_0}{\partial E},$$

and

$$c(E)=\sum_{r=0}^{\infty} c_r E^r$$

where f_0 is the thermal equilibrium distribution[12]. We shall discuss the application of the variation principle to the mobility at an arbitrary field strength in the following paper where the relations between the method of this paper and Yamashita's one will become clear.

Lastly, we note the effect of f_2 and f_3 in (12) on the low field mobility. In n-type germanium we concluded that they play no role because of the smallness of a. From (38) ν can be written as

$$\nu=\frac{\mathrm{G}}{3s^2\mathrm{I}}\left(\frac{\mathrm{H}}{\mathrm{G}}-\frac{5}{2}\right)\mu_0^2(1-\xi)\,,$$

where $\xi=(4\mathrm{I}/5\mathrm{G})(s/v_T)^2$ indicates the term due to f_2 and f_3. At the temperatures for which $u\leq 1$, ξ is very small compared to unity for all values of the parameter a. However, it may not always be negligibly small at low temperatures; for example, $\xi\simeq 0.14$ for $a=1$ and $u=3$.

The author would like to express his thanks to Prof. K. Ariyama and Dr. S. Nakajima for reading and commenting on this paper.

Appendix A

We expand $f(\boldsymbol{p}\pm\boldsymbol{q})$ in powers of p_0 similar to (12). Then by energy conservation the zeroth order term can be written as

$$f_0(\boldsymbol{p}\pm\boldsymbol{q})=f_0(p)e^{\mp\alpha x} \tag{A1}$$

for acoustical-mode scattering, and

$$f_0(\boldsymbol{p}\pm\boldsymbol{q})=f_0(p)e^{\mp\alpha u} \tag{A2}$$

for optical-mode scattering, where $\alpha = T_0/T$. For f_1, f_2, and f_3 we must put $p_z \pm q_z$ in place of p_z;

$$f_1(\boldsymbol{p}\pm\boldsymbol{q}) = -\frac{p_0(p_z\pm q_z)}{mkT} f_0(\boldsymbol{p}\pm\boldsymbol{q}) \,, \tag{A3}$$

$$f_2(\boldsymbol{p}\pm\boldsymbol{q}) = \left(\frac{p_0^2}{2mkT}\right)\left(\frac{(p_z\pm q_z)^2}{mkT} - 1\right) f_0(\boldsymbol{p}\pm\boldsymbol{q}) \,, \tag{A4}$$

$$f_3(\boldsymbol{p}\pm\boldsymbol{q}) = \left[\frac{p_0^3(p_z\pm q_z)}{2(mkT)^2} - \frac{1}{6}\left(\frac{p_0(p_z\pm q_z)}{mkT}\right)^3\right] f_0(\boldsymbol{p}\pm\boldsymbol{q}) \,. \tag{A5}$$

Substituting (11) and (A1), or (A3), into (8), we get

$$\left(\frac{\partial f}{\partial t}\right)^0_{ac} = \left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right) \sum_{\boldsymbol{q}} [\{e^{x(1-\alpha)}-1\}\delta_+ + \{e^{\alpha x}-e^x\}\delta_-] f_0(p) \,, \tag{A6}$$

$$\left(\frac{\partial f}{\partial t}\right)^1_{ac} = -\frac{p_0 f_0(p)}{mkT}\left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right) \sum_{\boldsymbol{q}} [\{(p_z+q_z)e^{x(1-\alpha)}-p_z\}\delta_+ + \{(p_z-q_z)e^{\alpha x}-p_z e^x\}\delta_-] \,, \tag{A7}$$

where sufficis + and − mean the terms corresponding to the emission and to the absorption of phonons, respectively. The integrals in the $\boldsymbol{q}$ space are carried out by introducing polar coordinates q, β, ψ, the polar axis being in the direction of p:

$$\sum_{\boldsymbol{q}} \to \frac{V}{(2\pi)^3\hbar^3}\iiint q^2 dq d\cos\beta d\psi \,.$$

Integration over β can be used to eliminate the δ-functions.

From (10) and the energy conservation, we have

$$\cos\beta_\pm = \frac{1}{2p}(\mp q + 2ms) \,, \tag{A8}$$

$$0 \le q \le 2p \pm 2ms \,. \tag{A9}$$

Since $x \ll 1$ and $\alpha \le 1$, we can expand $e^{x(1-\alpha)}$, $e^{\alpha x}$, and e^x, and then (A6) becomes

$$\begin{aligned}\left(\frac{\partial f}{\partial t}\right)^0_{ac} &= \left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right)\frac{Vmf_0(p)}{(2\pi)^2\hbar^3 p}\left[(1-\alpha)\left\{\int_0^{2p+2ms} xq\,dq - \int_0^{2p-2ms} xq\,dq\right\} - \alpha(1-\alpha)\int_0^{2p} x^2 q dq\right] \\ &= \Gamma\left(\frac{4ms^2}{kT_0}\right)(1-\alpha)\sqrt{E}\left(1-\frac{E}{2kT}\right) f_0(p) \,,\end{aligned} \tag{A10}$$

where

$$\Gamma = \left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right)\frac{V(4m)(2m)^{1/2}}{(2\pi)^2\hbar^3} \,. \tag{A11}$$

Making use of the relation

$$\int_0^{2\pi}(q_z)_\pm d\psi = \int_0^{2\pi} q\{\cos\theta\cos\beta_\pm + \sin\theta\sin\beta_\pm\cos\psi\}d\psi = 2\pi q\cos\theta\cos\beta_\pm \,, \tag{A12}$$

we obtain from (A7)

$$\left(\frac{\partial f}{\partial t}\right)^1_{ac} = -\frac{p_0 f_0(p)}{mkT}\left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right)\sum_{\boldsymbol{q}} [q_z\delta_+ - q_z\delta_-] = -\Gamma\sqrt{E}\, f_1(\boldsymbol{p}) \,. \tag{A13}$$

For optical-scattering, the energy conservation leads to

$$\cos\beta_\pm = \frac{1}{2pq}(q_0^2 \mp q^2) \,, \tag{A14}$$

$$\mp p \pm \sqrt{p^2 \pm q_0^2} \leq q \leq p + \sqrt{p^2 \pm q_0^2}\,, \tag{A15}$$

where

$$q_0^2/2m = \hbar\omega\,. \tag{A16}$$

From (9)

$$\begin{aligned}\left(\frac{\partial f}{\partial t}\right)_{op}^{0} &= \left(\frac{2\pi B_0}{\hbar}\right) n_0 f_0(p)\Big[(e^{u(1-\alpha)}-1)\sum_{q}\delta_{+} + \Delta(E)(e^{\alpha u}-e^{u})\sum_{q}\delta_{-}\Big]\\ &= \Gamma a n_0 u\Big[(e^{u(1-\alpha)}-1)\sqrt{E+\hbar\omega} + \Delta(E)(e^{\alpha u}-e^{u})\sqrt{E-\hbar\omega}\Big] f_0(p)\,,\end{aligned} \tag{A17}$$

where

$$a = (B_0/B_a)(sq_L/2\hbar\omega)\,.$$

We can easily verify the following relation from (A12), (A14) and (A15)

$$\sum_{q}(p_z \pm q_z)\delta_{\pm} = 0\,. \tag{A18}$$

Then it follows that

$$\begin{aligned}\left(\frac{\partial f}{\partial t}\right)_{op}^{1} &= \left(-\frac{p_0 f_0(p)}{mkT}\right)\left(\frac{2\pi B_0 n_0}{\hbar}\right)\sum_{q}\Big[\{(p_z+q_z)e^{u(1-\alpha)}-p_z\}\delta_{+} + \Delta(E)\{(p_z-q_z)e^{\alpha u}-p_z e^{u}\}\delta_{-}\Big]\\ &= -\Gamma a n_0 u\left(\sqrt{E+\hbar\omega} + \Delta(E)e^{u}\sqrt{E-\hbar\omega}\right) f_1(p)\,.\end{aligned} \tag{A19}$$

Appendix B

To calculate the current to terms of order F^3, we can put $T=T_0$ in f_2 and f_3. Substituting $f_2(T_0)$ into (8) and (9), we have

$$\left(\frac{\partial f}{\partial t}\right)_{ac}^{2} = \frac{p_0^2 f_0(T_0)}{2(mkT_0)^2}\left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq}\right)\sum_{q}\Big[\{(p_z+q_z)^2-p_z^2\}\delta_{+} + \{(p_z-q_z)^2-p_z^2\}e^{x}\delta_{-}\Big]\,, \tag{B1}$$

$$\left(\frac{\partial f}{\partial t}\right)_{op}^{2} = \frac{p_0^2 f_0(T_0)}{2(mkT_0)^2}\left(\frac{2\pi B_0}{\hbar}\right) n_0 \sum_{q}\Big[\{(p_z+q_z)^2-p_z^2\}\delta_{+} + \Delta(E)\{(p_z-q_z)^2-p_z^2\}e^{u}\delta_{-}\Big]\,. \tag{B2}$$

The integration over ψ gives

$$\begin{aligned}\frac{1}{2\pi}\int_0^{2\pi}(\pm 2p_z q_z + q_z^2)_{\pm}\,d\psi &= \pm 2pq\cos^2\theta\cos\beta_{\pm} + q^2\left(\cos^2\theta\cos^2\beta_{\pm} + \frac{1}{2}\sin^2\theta\sin^2\beta_{\pm}\right)\\ &= \frac{1}{2}q^2\left[\cos^2\theta\left(3\cos^2\beta_{\pm} \pm \frac{4p}{q}\cos\beta_{\pm} - 1\right) + (1-\cos^2\beta_{\pm})\right],\end{aligned}$$

which becomes for acoustical-mode scattering from (A8)

$$\frac{1}{2}q^2(1-\cos^2\beta_{\pm})(1-3\cos^2\theta) \pm 2msq\cos^2\theta\,, \tag{B3}$$

and for optical-mode scattering from (A14)

$$\frac{1}{2}q^2(1-\cos^2\beta_{\pm})(1-3\cos^2\theta) \pm q_0^2\cos^2\theta\,. \tag{B4}$$

Terms proportional to $(1-3\cos^2\theta)$ play no role in our calculations since their contributions to (13) and (14) are vanishing. Therefore we take only the last terms of (B3) and (B4), which come from the change of the energy of electrons by collisions. Then

$$\begin{aligned}\left(\frac{\partial f}{\partial t}\right)_{ac}^{2} &= \frac{p_0^2 f_0(T_0)}{2(mkT_0)^2}\left(\frac{2\pi B_a}{\hbar}\right)\left(\frac{kT_0}{sq_L}\right)\sum_{q}\Big[2ms\cos^2\theta\, q\{\delta_{+}-\delta_{-}\} - 2ms\cos^2\theta\, qx\delta_{-}\Big]\\ &= \left(\frac{p_0^2}{2mkT_0}\right)\Gamma\left(\frac{8ms^2}{kT_0}\right)\cos^2\theta\sqrt{E}\left(1-\frac{E}{2kT_0}\right) f_0(T_0)\,.\end{aligned} \tag{B5}$$

$$\left(\frac{\partial f}{\theta t}\right)_{op}^{2}=\frac{p_0^2 f_0(T_0)}{2(mkT_0)^2}\left(\frac{2\pi B_0}{\hbar}\right)n_0 q_0^2\cos^2\theta\sum_{\boldsymbol{q}}[\delta_+-\Delta(E)e^u\delta_-]$$

$$=\left(\frac{p_0^2}{2mkT_0}\right)\Gamma a n_0(2u^2)\cos^2\theta(\sqrt{E+\hbar\omega}-\Delta(E)e^u\sqrt{E-\hbar\omega})f_0(T_0)\,. \tag{B6}$$

To compute $(\partial f/\partial t)_L{}^3$ we put $T=T_0$ in $f_3(\boldsymbol{p})$ and $f_3(\boldsymbol{p}\pm\boldsymbol{q})$. Now we can show

$$\sum_{\boldsymbol{q}}(p_z\pm q_z)^3\delta_\pm=0\,, \tag{B7}$$

which is exact for optical-mode scattering, and for acoustical-mode scattering it holds approximately by the neglect of $2ms$ in (A8) and (A9). Accordingly we obtain in the same way as $(\partial f/\partial t)_L{}^1$

$$\left(\frac{\partial f}{\partial t}\right)_{L}^{3}=-\Gamma\{\sqrt{E}+a n_0 u(\sqrt{E+\hbar\omega}+\Delta(E)e^u\sqrt{E-\hbar\omega})\}f_3(T_0)\,, \tag{B8}$$

where

$$f_3(T_0)=\frac{p_0^3 p_z}{2(mkT_0)^2}f_0(T_0)-\frac{1}{6}\left(\frac{p_0 p_z}{mkT_0}\right)^3 f_0(T_0)\,. \tag{B9}$$

A Few Quarternary Systems of Perovskite Type $A^{2+}B^{4+}O_3$ Solid Solutions

By Takuro IKEDA

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received May 6, 1959)

The properties of the quarternary systems (Sr–Pb)(Ti–Zr)O_3 and (Ba–Pb)(Ti–Sn)O_3 are studied. The shift of transition points with composition is measured by the temperature variation of the dielectric constant of the ceramic sample, and the phase diagrams at room temperature are determined with help of X-ray measurement.

The phase diagram of (Sr–Pb)(Ti–Zr)O_3 includes two ferroelectric phases F_α (rhombohedral) and F_β (tetragonal), two antiferroelectric ones A_α (pseudotetragonal) and A_β (tetragonal) and a paraelectric one P. A_β occupies larger area than expected. The diagram of (Ba–Pb)(Ti–Sn)O_3 resembles that of (Ba–Pb)(Ti–Zr)O_3 previously reported by the author and consists of F_1, F_2 (the same as the low temperature phases in $BaTiO_3$), F_α, F_β and P, although the immiscible region is found in the composition containing smaller amounts of Ba and Ti.

Roth early classified graphically the perovskite ABO_3 compounds on the basis of electronic polarizability of A ion and ionic radius of B ion. The present author advances this line experimentally by taking up a factor of A ion and one of B ion, using many data already published as well as the present results. The arrangement of A ions nearly agrees with that in terms of the electronic polarizability. Concerning the disposition of B ions, however, the ordering of Ti–Zr–Hf–Sn is adopted, and in addition, Sn and Hf ions are arranged near Zr ion. This diagram may be rather successfully applied to the classification of perovskite $A^{2+}B^{4+}O_3$ solid solutions.

Furthermore, the possibilities for dielectric and piezoelectric use of the ceramic materials belonging to these systems are examined. Larger dielectric constants are found with certain compositions in (Ba–Pb)(Ti–Sn)O_3, but a striking improvement for PZT ceramics may be rather questionable in both systems.

§ 1. Introduction

In order to find the origin of ferroelectricity and antiferroelectricity of the perovskite type $A^{2+}B^{4+}O_3$ compounds, many reports have already been published concerning the families with various A^{2+} ions and B^{4+} ions. Of all, several earlier studies performed by the workers in our country have brought many informations on their properties; for instance, (Pb–Ba)TiO_3 by Shirane *et al*[1], Pb(Ti–Zr)O_3 by Sawaguchi[2], (Pb–Ba)ZrO_3 and (Pb–Sr)ZrO_3 by Shirane *et al*[3][4], and (Pb–Sr)TiO_3 by Nomura and Sawada[5], etc. As shown by the effect of addition of Pb^{2+} ion, the ionic radius was not found to be only a factor, but the polarizability had to be considered. Taking account of such circumstances, some studies have been attempted to classify these $A^{2+}B^{4+}O_3$ compounds by certain appropriate factors. Wood[6] classified various perovskite type crystals graphically in terms of ionic radii of A and B ions, and found the unsatisfactory positions of some ions, e.g. Sn^{4+} aud Ce^{4+}. Roth[7] extended more elaborate studies, and the electronic polarizability of A ion was taken up as a factor in addition to the ionic radii of A and B ions. One of his results is shown in Fig. 1, where the ordinate indicates the electronic polarizability of A^{2+} ion and the abscissa the ionic radius of B^{4+} ion. In that case, the position of Sn^{4+} ion is not still adequate, mainly because of the immiscibility of PbO and SnO_2. In order to advance these attempts, rather more studies on the systems (A–A′)(B–B′)O_3 will be desired. The previous work of the author on the system (Ba–Pb) (Ti–Zr)O_3 gave a datum along these lines. In the present paper, some effects of Sr^{2+} and Sn^{4+} ions are examined. Such classification in terms of a factor of A^{2+} ion and one of B^{4+} ion will be experimentally devised here, and may be expected to give further informations on the roles of A^{2+} and B^{4+} ions.

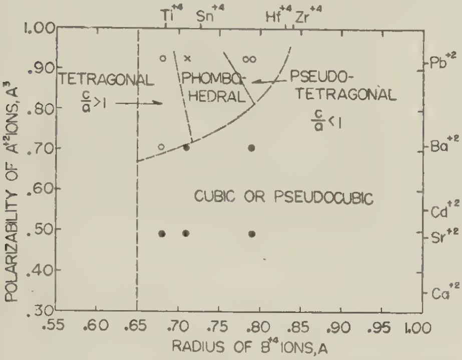

Fig. 1. Classification of $A^{2+}B^{4+}O_3$ compounds (Roth)

Concerning the effects of Sr^{2+} and Sn^{4+} ions, several binary systems have been studied. Substituting Pb of $PbTiO_3$ by Sr, the Curie point falls monotonously with concentration and the tetragonal F_β phase changes to the paraelectric phase, as shown by Nomura and Sawada.[5] The antiferroelectricity of (Pb–Sr)ZrO_3 system was examined in detail by Shirane *et al*[3]; two antiferroelectric phases, A_α and A_β, are seen, where A_α belongs to the orthorhombic crystal class, the same as that of $PbZrO_3$ (pseudotetragonal with the axial ratio smaller than one) and A_β the tetragonal one. In the system Pb(Ti–Zr)O_3, a ferroelectric F_α phase (rhombohedral) appears together with F_β and A_α, and the boundary between F_α and F_β is hardly removed with varying temperature, as shown by the elegant studies of Sawaguchi.[2] The properties of Pb(Ti–Sn)O_3 and Ba(Ti–Sn)O_3 systems have been studied by several authors. Jaffe *et al*[9] reported the phase diagram of Pb(Ti–Sn)O_3 including F_β and other ferroelectric phase, and the dissociation region of the specimens containing more than 75 mole percent of Sn. The crystal form of the latter phase was not exactly known and was only described as pseudocubic. The effect of substituting Ti of $BaTiO_3$ partly by Sn has been known; namely, it is similar to that of Zr ion, but the shift of the transition points is faster than in the case of Zr.[10] The dielectric properties of (Pb–Ba)SnO_3 were reported,[11] but the phase relations were not clearly studied, except the ferroelectricity of (Pb70–Ba30)SnO_3 at −120°C.

Some ceramics of $BaTiO_3$ and its families are important for industrial purposes. The ceramics of $BaTiO_3$ containing more or less amounts of $PbTiO_3$ or $CaTiO_3$ have been fairly used for the electromechanical transducers. Many improvements of their qualities have been attempted. Jaffe *et al*) reported the excellent properties of Pb(Ti–Zr)O_3 ceramics of compositions near the boundary between F_α and F_β (PZT). It was shown by the present author[8] that some ceramics belonging to the system (Ba–Pb) (Ti–Zr)O_3 offer better materials in a few points. For obtaining better dielectric materials, on the other hand, much efforts has always been made. For instance, Coffeen[12] studied some influences of adding $PbSnO_3$, $Bi_2(SnO_3)_3$ (less than 50%) and others to $BaTiO_3$. A few studies on the quarternary systems by the author may be believed to provide several improvements along these lines.

§ 2. (Sr-Pb)(Ti-Zr)O_3

(a) *Preparation of samples*

$SrCO_3$, PbO, TiO_2 and ZrO_2 were mixed in proper mole ratio, calcined and sintered. TiO_2 used here is especially produced from $TiCl_4$ and has purity of 99.57%. $SrCO_3$ and ZrO_2 are of reagent grade, and PbO of c. p. grade. The volatilization of PbO was prevented as well as possible by firing in PbO atmosphere, and the inner parts of the specimen were used for electric and x-ray measurements. They were not chemically analyzed after firing, but their positions in the phase diagram are indicated by the mixing composition. The Curie point of each sample prepared twice or more agrees within a few degrees at worst.

(b) *Dielectric constant versus temperature*

The dielectric constant of small square plates with various compositions was measured at 550 Kc by the tuning method, with increasing temperature above room temperature. Most of the curves show peaks, which correspond to Curie points. Some of them containing less amount of Ti have humps below Curie points. These occur at other transition points. With varying composition, any shifts of these points are examined and shown as various sections in Fig. 2.

In comparison with other data on the binary systems, A_α phase is determined, which is believed to have the same structure as that of $PbZrO_3$.

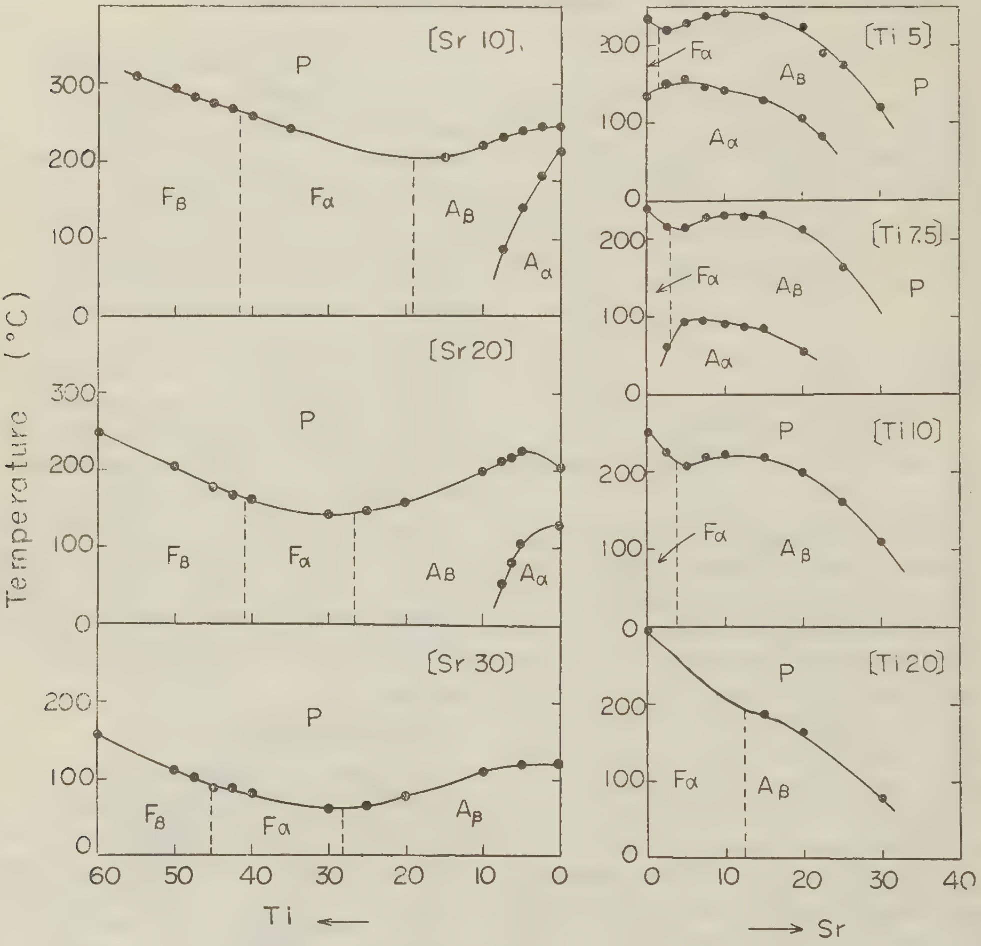

Fig. 2. Transition point in (Sr–Pb) (Ti–Zr)O_3

(c) *Dielectric hysteresis and thermal expansion*

F_α and F_β phases appearing in $Pb(Ti\text{–}Zr)O_3$ system could not be located in above experiment. In order to know how A_β phase spreads over and where the boundary between A_β and F_α is situated, dielectric hysterese are at first observed at 50 c/s by the Sawyer-Tower method.

Some specimens show clear ferroelectric hysterese, and others only straight lines. In those with intermediate composition, however, are observed narrow ferroelectric-like hysterese or double-hysteresis-like (stranguiated) patterns, and it is not possible to decide to which phase they belong.

In the case of the thermal expansion experiment in $Pb(Ti\text{–}Zr)O_3$[13] and $(Pb\text{–}Sr)ZrO_3$[3] systems, it has been shown that an abnormal contraction occurs at transition point from a ferroelectric to a paraelectric phase and a rapid expansion from an antiferroelectric to another phase. Providing that these facts hold also in the present case, the thermal expansion measurements are to give further means of the determination.

Some results on the observations of dielectric hysterese and the thermal expansion measurements are listed in Table I; where E: expansion, C: contraction (at the transition point with increasing temperature), F: ferroelectric hysteresis, D: double hysteresis, N: narrow hysteresis and L: straight line. In addition, the crystal structures are examined by the X-ray powder method, as described in the next section, and are indicated as well; R shows the rhombohedral class, and T the pseudotetragonal with the axial ratio c/a smaller than one.

Table I.

Composition Ti	Sr	Crystal From	Thermal Expansion	Dielectric Hysteresis	Phase Change
5	2.5		E E	N	$A_\alpha \to A_\beta \to P$
	5		E E	N	
	15			L	
	20	T			
	30			L	$A_\beta \to P$
7.5	2.5	T	E C	F-like	$A_\alpha \to F_\alpha \to P$
	5		E E	N	$A_\alpha \to A_\beta \to P$
	15			L	
	20	T			
10	2.9	R	C	F	$F_\alpha \to P$
	5		E	F-like	$A_\beta \to P$
	10	T	E	N	
	15			L	
	20	T		L	
15	5	R	C	F	$F_\alpha \to P$
	10	T	E	F-like	$A_\beta \to P$
	15			L	
20	15	T		F-like	$A_\beta \to P$
	20	T	E	D	
	30			L

	30			L	
30	20	R		F	$F_\alpha \to P$
	30	R		F	

With varying temperature, the boundary between A_β and F_α phases may probably be rather vertical to the composition axis, for any hump corresponding to the transition between these phases is not found so far as the present specimens are concerned. Thus determined are the phase changes of the samples and the boundaries between F_α and A_β phases, as indicated in Table I. and by dotted lines in Fig. 2.

The determination of the phases by the results of the thermal expansion agrees with those of the x-ray measurement. The samples, being considered to belong to A_β and lie near the border to F_α, show apparent ferroelectric-like hysterese. As for the reason, the following possibilities may be considered; one is that the samples become ferroelectric under the high electric field and remain in the same state in more or less time after removal of the field, and another that they are mostly antiferroelectric in one direction and slightly ferroelectric in other directions. But further examinations will be desired, especially by using single crystals.

(d) *X-ray measurement*

The lattice parameters of the powdered specimens are measured by the diffractometer, using CuKα radiation. The samples on the Ti rich side near $PbTiO_3$ must belong to F_β after Nomura *et al.*[5] With increasing Zr concentration, the tetragonality decreases and F_α phase appears at the composition containing about 45% of Ti. Fig. 3 shows the results in (Sr20–Pb80) $(Ti\text{–}Zr)O_3$ composition. The tetragonality disappears between 42.5 and 40% of Ti, and the rhombohedrality in F_α phase occurs discontinuously. These circumstances are similar to those in the case of $Pb(Ti\text{–}Zr)O_3$ system. The boundaries between F_α and F_β are thus determined in each section of various Sr concentration, and indicated in Fig. 2, where these boundaries are considered to be nearly parallel to the

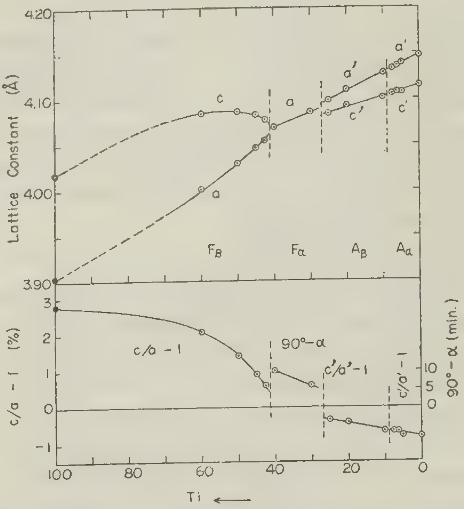

Fig. 3. Lattice parameter of (Sr20–Pb80) $(Ti\text{–}Zr)O_3$ (● after Nomura *et al*)

temperature axis for the same reason as in the earlier works.

In A_β phase, the structure is tetragonal and the axial ratio of the pseudo cell is smaller than one. This fact is also used for the determination of the border of A_β phase, as described above. The phase denoted by A_α is believed to belong to the same crystal class as that of $PbZrO_3$—orthorhombic—and most of the lines can be given indices, by assuming a pseudotetragonal cell. In Fig. 3, the parameters in A_α are thus indicated.

(e) *Phase diagram at room temperature*

Using above results, the phase diagram of this system is easily determined at room temperature and shown in Fig. 4. The location of the boundary between F_α and F_β resembles to the case of (Ba–Pb)(Ti–Zr)O_3 system, except that it is somewhat inflated towards F_α side here. A_β phase, which appears as intermediate phase in (Pb–Sr)ZrO_3 and in Pb(Ti–Zr)O_3 containing less than 3% of Ti, occupies a considerably large region in the present diagram.

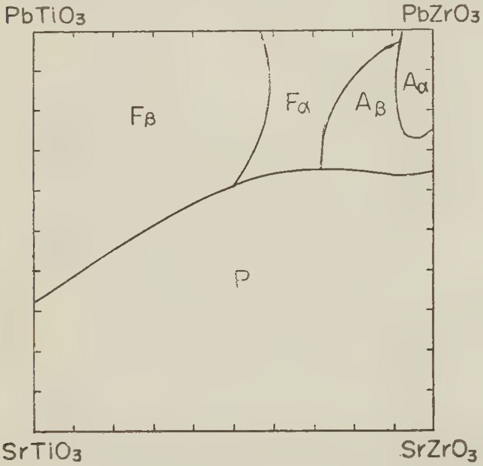

Fig. 4. Phase diagram of (Sr–Pb) (Ti–Zr)O_3

(f) *Dielectric and piezoelectric ceramics*

An outline of the distribution of the dielectric constant at room temperature of the ceramics can be seen even by poorly sintered specimens (porosity: 25–32%), and is shown in Fig. 5(a). Generally speaking, Curie point falls and the dielectric constant increases with increasing Sr concentration, and moreover, its variation with temperature becomes smaller. The ceramics near the boundary between F_α and F_β phases have larger dielectric constants.

The radial electromechanical coupling coefficient k_r of the disc-shape ceramics, prepoled under the field of 30 KV/cm and aged at 95°C in two days (someone at room temperature), is measured and the distribution is shown by a few contour lines in Fig. 5(b). These data are taken with the relatively porous ceramics, and therefore larger value will be expected with carefully sintered ones. The staffs of the Clevite Research Center have made continuous efforts for obtaining piezoelectric ceramics, and recently reported the effects of adding Sr or Ca to PZT ceramics.$^{14)}$ They fired the dense specimens and reported the value of k_r reaching 50% at a certain composition of the same system.

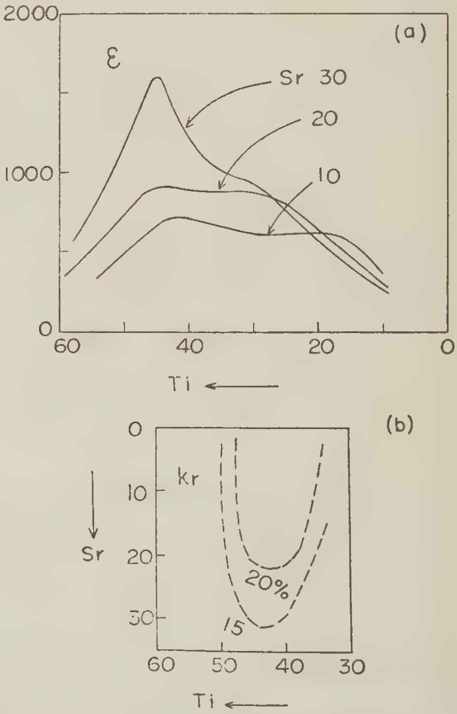

Fig. 5. (a) Dielectric constant ε and (b) radial electromechanical coupling coefficient k_r at room temperature in (Sr–Pb)(Ti–Zr)O_3

§ 3. (Ba-Pb)(Ti-Sn)O_3

(a) *Preparation of samples*

The technique for preparing the samples was the same as that in the former system. $BaCO_3$ and SnO_2 of reagent grade were used. The firing temperature had to be usually lower, and it was difficult to obtain dense ceramics. Hence the dielectric and piezoelectric measurements were performed by rather poorly sintered specimens.

(b) *Dielectric constant versus temperature*

The curves of the dielectric constant *vs.* temperature of the specimens containing less than 90% of Ba show only peaks above room temperature, which correspond to Curie points. In those with smaller concentration of Pb and Sn in the vicinity of $BaTiO_3$, a few humps are shown in the curves, which are known to correspond to the other transition points by observing the shifts of these points with varying composition. In Fig. 6, the transition points as well as Curie points are plotted against compositions. The samples containing smaller amount of Ti are insoluble in the present preparation. F_1 and F_2 in the figure are believed to be the same phases in the case of $BaTiO_3$ at lower temperature, which are both ferroelectric and belong to the rhombohedral and orthorhombic crystal classes respectively. The boundary between F_α and F_β is determined by the X-ray measurement described in the following.

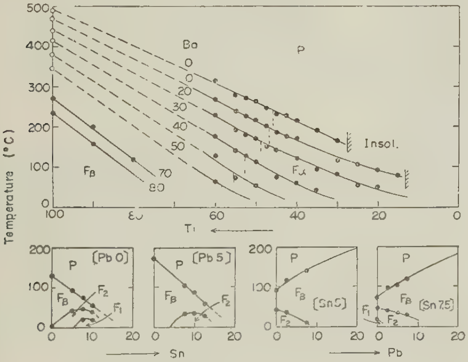

Fig. 6. Transition point in (Ba–Pb) (Ti–Sn)O_3

(c) *X-ray measurement of the sample containing less than 50% of Ba*

The x-ray measurement by the diffractometer, using CuKα radiation, reveals the boundary between F_α and F_β. Some of the results are shown in Fig. 7. The tetragonality in F_β phase on the Ti rich side decreases towards the Sn side and F_α phase appears.

The phase denoted here by F_α was not determined in the system Pb(Ti–Sn)O_3 (0% of Br in the present case) by Jaffe *et al*,[9] who reported only the pseudocubic structure. The back side reflections ($h^2+k^2+l^2=16$, 20, 22, 24 and 26) are examined and the patterns are explained by the rhombohedral class ($\alpha \lesssim 90°$), as described in the previous paper.[4][8] The deviation from 90° decreases with increasing Sn and Ba contents, as seen in the figure.

The boundaries between F_α and F_β in Fig. 7 is thus determined on each Ba content section. Although any shifts of them with temperature are not examined, they may be considered to be nearly parallel to the temperature axis for the same reason as before.

(d) *Phase diagram at room temperature*

The phase diagram of this system is thus obtained at room temperature, and shown in Fig. 8. This resembles that of (Ba–Pb) (Ti–Zr)O_3 system, except the immiscibility near PbO:SnO_2 and the slight shifts of the phase boundaries towards the Ti side. Although the samples containing smaller amounts of Ti and Ba are insoluble, the role of Sn^{4+} ion is infered; that is, Sn ion may be considered to have a little stronger effect than Zr ion for advancing an antiferroelectric tendency.

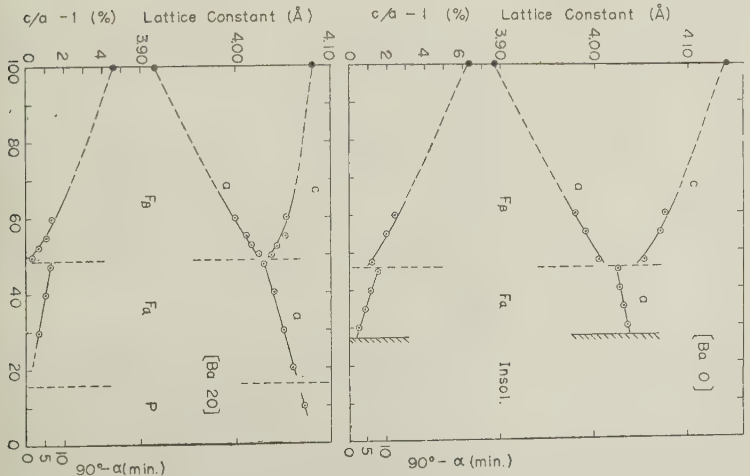

Fig. 7. Lattice parameter in (Ba–Pb) (Ti–Sn)O_3 (● after Shirane *et al*)

(e) *Dielectric and piezoelectric ceramics*

In this experiment, the dense ceramics were not fired and the data for the dielectric and piezoelectric materials are obtained by the poorly sintered specimens (porosity: 21–29%). Fig. 9 shows the outline of them. The higher dielectric constant is found in the samples with composition of Ba~30% and Ti~25–40%.

The electromechanical coupling coefficients shows maximum near the boundary between F_α and F_β, but the value may not be so large as expected, even taking account of their porosity.

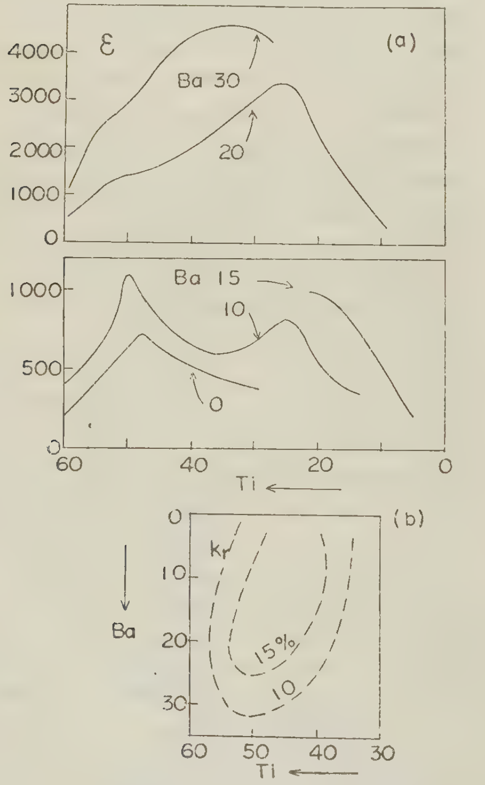

Fig. 9. (a) Dielectric constant ε and (b) electromechanical coupling coefficient k_r in (Ba-Pb) (Ti-Sn)O_3

§ 4. Classification of Perovskite $A^{2+}B^{4+}O_3$ Solid Solutions

Roth7) early reported the classification of ABO_3 type compounds, and one of his results is shown in Fig. 1. In order to advance along his line, let us remember many earlier reports on the phase relations of perovskite $A^{2+}B^{4+}O_3$ solid solutions, including the data by the present author. Fig. 10 shows most of the phase diagrams already published; they are after the following authors:

(Pb–Ba)TiO_3	Shirane and Suzuki1),
(Pb–Sr)TiO_3	Nomura and Sawada5)
(Pb–Ca)TiO_3	Ikeda15),
(Ba–Sr)TiO_3	Gränicher und Jakits15),
(Ba–Ca)TiO_3	Ikeda15; Berlincourt and Kulcsar17),
(Sr–Ca)TiO_3	McQuarrie18),
(Pb–Ba)ZrO_3	Shirane3),
(Pb–Sr)ZrO_3	Shirane2),
Pb(Ti–Zr)O_3	Sawaguchi2),
Pb(Ti–Sn)O_3	Jaffe, Roth and Marzullo9),
Pb(Ti–Hf)O_3	Jaffe *et al*9),
$PbHfO_3$	Shirane and Pepinsky19),
Pb(Zr–Sn)O_3	Takeda20),
Ba(Ti–Zr)O_3	Kell and Hellicar21),
Ba(Ti–Sn)O_3	Novosil'tsev and Khodakov10),
Pb(Ti-Zr–Sn)O	Jaffe *et al*9)
(Pb–Ba–Ca)TiO_3	McQuarrie22); Ikeda15),
(Ba–Sr–Ca)TiO_3	McQuarrie13),
(Ba–Ca) (Ti–Zr)O_3	McQuarrie and Behnke23),
(Pb–Ba) (Ti–Zr)O_3	Ikeda9),
(Pb–Sr) (Ti–Zr)O_3	present paper,
(Pb–Ba) (Ti–Sn)O_3	present paper.

In order to derive them from one diagram, the one giving by Roth in Fig. 1 is not always sufficient; especially, some positions of B^{4+} ions must be shifted.

The present author will propose to classify these solid solutions experimentally by one factor of A^{2+} ion and that of B^{4+} ion. Fig. 11 shows his attempt at room temperature, where the coordinates are arbitrary. The temperature axis is taken vertically to the paper.

The arrangement of A^{2+} ions agrees well with that in Fig. 1, and the electronic polarizability of A ion may play an important role.

As shown by the data on the system Pb(Zr–Sn)O_3 after Takeda20) and on $PbHfO_3$ after Shirane *et al*,19) the ordering of B ions is considered as Zr–Hf–Sn. So far as the

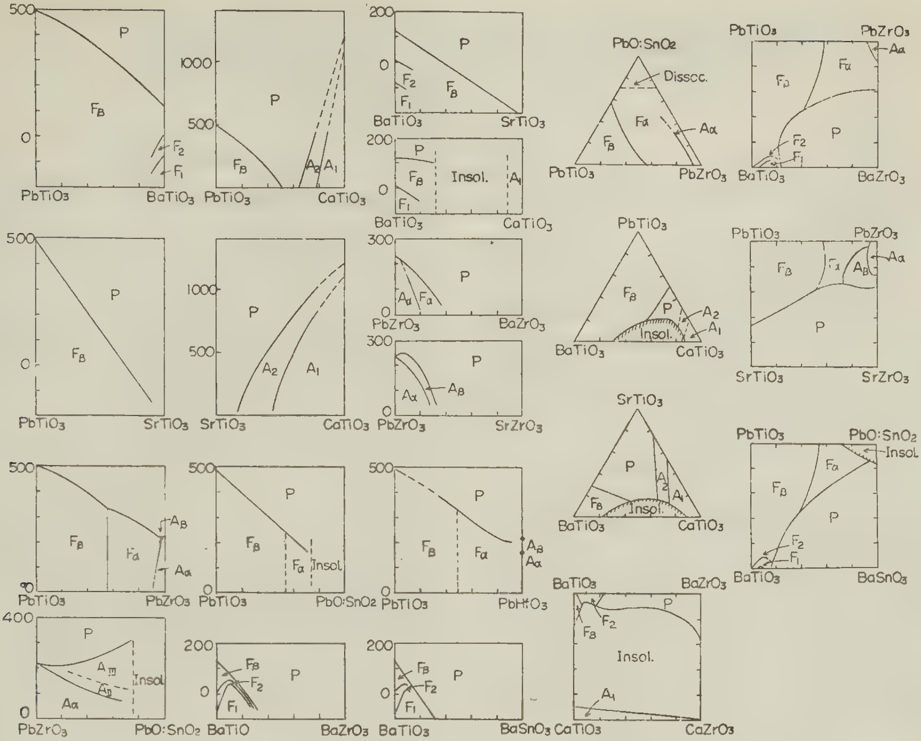

Fig. 10. Phase diagrams of $A^{2+}B^{4+}O_3$ solid solutions

neighbourhood of $PbZrO_3$ is concerned, Sn and Hf ions had to be arranged to the left side of Zr ion. The positions along the abscissa in the present figure are determined by taking account of the shift of Curie point by adding Sn and Zr to $BaTiO_3$ and the position of the boundary between F_α and F_β, shown in several diagrams in Fig. 10.

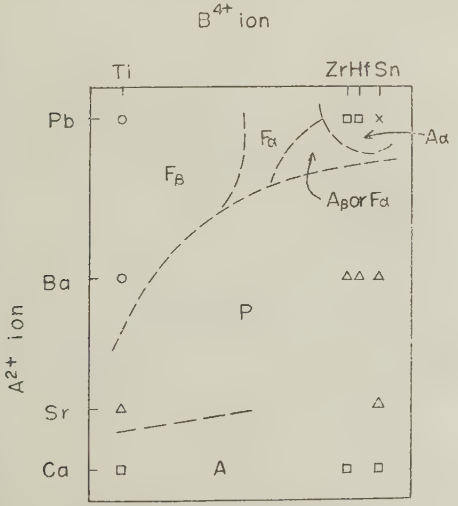

Fig. 11. Classification of perovskite $A^{2+}B^{4+}O_3$ compounds (○ ferroelectric, □ antiferroelectric, △ paraelectric, × insoluble)

The phase F_1 and F_2 in the vicinity of $BaTiO_3$ are seen only in the (Ba–A′)(Ti–B′)O_3 type diagram, and they are not pictured in the figure.

The factor important for producing ferroelectricity has been believed to be the ionic polarizability of B^{+} ion. In the perovskite type compounds, a correction for the Lorentz field is significant at the atomic position of B ion in the unit cell and the polarizability of B ion necessary for occurrance of ferroelectricity is smaller than above; which was shown by Slater[24] in the case of $BaTiO_3$, although he treated a second order transition. It was concluded by his computation that the polarization assigned to Ti ion is 37% of the total polarization in $BaTiO_3$, of which 31% is the ionic contribution. Although the values of electronic polarizabilities of Sn and Hf ions are unknown to the author and so it cannot be discussed by which the arrangement of B ions is determined, the role of the electronic polarizability may not be ignored.

The present attempt of classifying the compounds by a factor of A ion and that of B ion is impossible, of course, to explain the detailed circumstances. None the less, it may be said that this agrees rather well with the various facts.

§ 5. Conclusion

The following results are obtained from above experiments:

(1) The phase changes in the quarternary system (Sr–Pb)(Ti–Zr)O_3 and (Ba–Pb)(Ti–Sn)O_3 are examined and the phase diagrams at room temperature are determined. The effects of Sr and Sn ions are discussed. An enlarged area of A_β phase in the former system may be of interest.

(2) By using the data early published as well as the present results, an experimental classification or perovskite $A^{2+}B^{4+}O_3$ compounds is attempted. This may be applied to classify ABO_3 type solid solutions rather with success, including the distribution of their transition points. The arrangement of A ions agrees well with the ordering by the factor of electronic polarizability. That of B ions is not so simple, but the positions of Sn and Hf ions differ remarkably from Roth's intention, where the ionic radius of B ion was taken into account.

(3) The possibilities for industrial use of the ceramics in these systems are considered, but the more excellent piezoelectric materials may not be felt to meet our expectation. The dielectric ceramics possessing considerably larger dielectric constant are found somewhere in (Ba–Pb) (Ti–Sn)O_3 system.

The author is very grateful to Prof. O. Nomoto, Dr. M. Marutake and Mr. A Takeda, the research members of the Kobayasi Institute of Physical Research, for their helpful discussions. He also wishes to thank to Dr. S. Nomura of the Tokyo Inst. Techn. for giving an information on (Pb–Ba)SnO_3, to Dr. H. Hagihara and Mr. H. Yamashita in the institute for affording facilities for X-ray measurement, and to Mr. T. Ichikawa and Mr. Y. Yasui for their help to the preparation of the samples and dielectric measurement. The present studies were supported by the scientific expenditure of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 10, OCTOBER, 1959

Doping Influences on Activator Diffusion in Oxide-coated Cathode Nickel

By Hiroyuki MIZUNO

Matsushita Electronics Corporation, Takatsuki

(Received May 26, 1959)

The influences of doping on the minute activator diffusion in oxide-coated cathode nickel were measured by a method similar to Swalin and Martin's[1] and the following conclusions were derived; (1) the influences of doping on the activator diffusion in oxide-coated cathode nickel are significant, (2) as the Mn, Fe, or Si content in oxide-coated cathode nickel increases, the diffusion coefficient of Mg in base nickel decreases monotonously, and (3) as the Mg content in oxide-coated cathode nickel increases, the diffusion coefficient of Mn increases monotonously.

§ 1. Introduction

In recent years a number of investigations have been reported which have extended the understanding of the behaviours of oxide-coated cathode. Although there are still a few different opinions, it is now generally accepted that the impurity semiconductor picture seems to interpret the behaviours of oxide-coated cathode fairly well; that is, the impurities responsible for thermionic emission of oxide-coated cathode are free Ba atoms developed in oxide-coating by chemical reduction, thermal decomposition, and electrolysis during the so-called activation process. The chemical reduction by reducing agents (activators) contained in base nickel is, therefore, an important mechanism for the development of such impurities. It is, in general, supposed that the activators in base nickel diffuse out to the boundary between oxide-coating and base nickel, and there react with the BaO coating to yield Ba atoms. On the basis of thermochemistry, one of the most prominent studies on this topic is the theory by Rittner[2]. He proposed the following conclusions from the analysis of the factors limiting the yield of impurity centers (free Ba atoms) of oxide-coated cathode: the reaction mechanism most favourable for generating free Ba in oxide-coated cathode may be the one in which the rate of reducing reaction is limited by the rate of activator diffusion in base nickel. Accordingly, the rate of activator diffusion is one of the most important subjects in the investigations of oxide-coated cathode. At present, dilute nickel alloys containing reducing agents are used as base metal of oxide-coated cathode. However, examining carefully a number of studies on the influences of base nickel on cathode emission and comparing them with each other, one is struck by the mutual contradictions among them. It may be attributed to the fact that even minute quantities of reducing agents in base nickel play a profound rôle. It does not suffice to make studies on the effects of a relatively large, controlled quantity of a main activator added to base nickel; even when we use nickel alloy containing the same amount of a main activator, qualitatively different results may often be obtained. In other words, the effects of doping on the agency of the other activators contained simultaneously in the base nickel should be taken into consideration.

From the facts described above, it is reasonable to suppose in the first place that one has to do essentially with the interaction effects of activators on the diffusion rates of the other activators simultaneously present in base nickel. Swalin and Martin[1] have measured the diffusion rates of Mn, Al, Ti, and W in nickel at temperature range between 1100°C and 1300°C. They carried out, however, the experiments without being aware of the mutual interactions of activators in base nickel and therefore it seems to us that their results do not immediately determine the diffusion rates of activators in base nickel.

Grube and Jedele[3] were the first to find out that the diffusion rate of Cu in pure nickel is about three times larger than that in nickel containing 0.5% Mn at 1000°C. This fact suggests that the diffusion rate of activator in base nickel of oxide-coated cathode should also be influenced by the other doping elements. Thus, a question arises as to the interaction influences of diffusions of activators in base nickel. It is very important to know what kind of influences the doping impurities on the activator diffusion in base nickel have. If the influences can be determined, it will become possible to explain some of the obscure behaviours of oxide-coated cathode. The author has previously reported the outline of these influences observed by a rather simple experimental method⁴⁾. In this paper a method similar to Swalin and Martin's¹⁾ has been introduced to observe exactly the interactions of doping, the results of which we have already reported partly⁵⁾ and the experimental proofs illustrating the interaction influence have been presented.

In section 2 the experimental method is described and in section 3 the results obtained from the experiments are given, while in section 4 these results are discussed. The results of the experiments indicate that the effect of doping influences on activator diffusion in base nickel is very significant to interpret the complex behaviours of oxide-coated cathode.

§ 2. Experimental Method

2.1 *Materials*

The alloys used in the experiments were prepared by vacuum melting to provide strict control on the quality of each alloy specimen. The results of the spectral analysis of these specimens are shown in Tables I and II. These tables also indicate that the influence of one activator (marked as "controlled") on the diffusion of another activator (marked with star *) is observed on each classified specimen; for example, the influence of Mn activator on the diffusion of Mg activator in base nickel is measured on the specimens shown as "*A*" in Tables I and II. In Table III there are shown the total contents of oxygen, hydrogen and nitrogen gases contained in one specimen sampled out at random from each classification, which were determined by *N.R.C.* vacuum melting gas analyser.

Table I. Components in Ni alloy. (weight. p.c.t.)

Element / Classification	Co	Cu	Fe	Mn	C	Mg	Si	S	Al
A	0.01	T_r	T_r	controlled	T_r	0.10*	T_r	T_r	T_r

D	0.80	9.0	0.61

2.2 *Experimental technique*

The strips of nickel alloy were made from the specimens in Tables I and II through successive processes of roll and annealing until about 3 mm thickness was obtained and then the strips were cut into the form of a disk of 2 cm diameter. These disks were polished carefully to remove contaminations from their surfaces with several kind of grinders and at last completely finished with emery papers. Thereafter the surfaces were cleaned with nitric acid and rinsed with acetone. When finished, grains of 0.3∼1.0 mm diameter were observed on the disk surface. The disk with the components as shown in Table I was inserted between the two disks belonging to the corresponding row of Table II. These two side disks contain the same amount of controlled solute as the center disk except the element with star mark. After inserting 10 micron tungsten wires as marker at the diffusion interfaces, the three disks were pressed by the oil press machine of 3000 kg/cm² and then welded together closely in the form of the diffusion couple. Details of the couple are shown in Fig. 1. The two interfaces of the couple were hardly discerned without the tungsten markers.

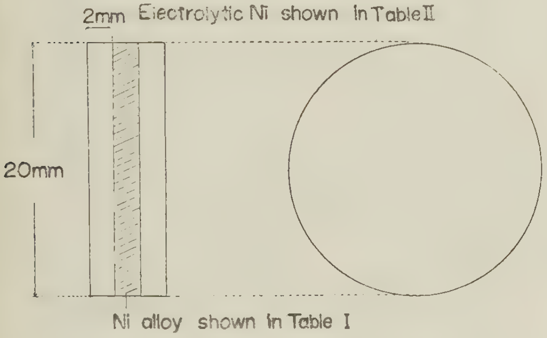

Fig. 1. Design of test couple.

The diffusion couple was put into a silica tube in close contact with a thermo-couple, which was placed in a furnace having an entirely constant temperature distribution. The silica tube was evacuated to 5×10^{-7} mm Hg throughout the experiments. The temperature of the furnace was regulated by an automatic regulator and monitored by a recorder within a tolerance of 0.5% throughout the works. After annealing for long enough to attain a considerable penetration depth of activator, the surfaces of the couple were polished and etched with concentrated nitric acid so that the tungsten markers embedded at the interfaces were readily observed. The couple was cut carefully about 20∼50 micron thickness by the lathe with its axis perpendicular to the interface, the distance from the interface being measured by both micrometer with direct reading to 1 micron and cathetometer. Each cut on both sides weighed from 50 to 80 mg and was parallel within the accuracy of 5 micron. The concentration of the activators in these cuts were measured by spectral analysis within a probable error of 7%.

§ 3. Results

3.1 *Calculation of diffusion coefficient*

Fick's equation of diffusion can be applied to our case, assuming that diffusion coefficient D is constant because of the low solute diffusion in base nickel. Taking x axis perpendicular to the interface and $x=0$ at the interface, the following solution can be easily derived for concentration C at distance x from the interface and annealing time $t>0$;

$$\frac{2(C-C_0)}{C_m-C_0}=1-\mathrm{erf}\,(y)\,, \qquad (1)$$

where $x/2\sqrt{Dt}$, C_m, and C_0 are the uniform concentrations of the activator in the middle and end disks at $t=0$ respectively. As was already shown in Table II, C_0 is always equal to zero in our experiments and so Eq. (1) becomes;

$$C=\frac{C_m}{2}\{1-\mathrm{erf}\,(y)\}\,. \qquad (1')$$

In order to calculate the diffusion coefficient from Eq. (1′), first of all, the impurity content in each cut is plotted as the function of the penetration depth x. The penetration curves of the star marked activator in base nickels containing various contents of the other element were plotted after annealing of 100 hours at 1000°C; for example, the curves for Mg in the base nickels doped with various concentrations of Mn are shown in Fig. 2. On the other hand, in Eq. (1′) it is possible to determine y for the various values of C referring to the table of the integrated error function⁶⁾. Since the relation of C to x is given in the penetration curve, y can be easily determined as a function of penetration depth x. Fig. 3 shows the y as a function of x for Mg in the base nickels doped with various concentrations of Mn. Thus, it is possible to determine exactly the diffusion coefficient D of the activator from the probable line of y

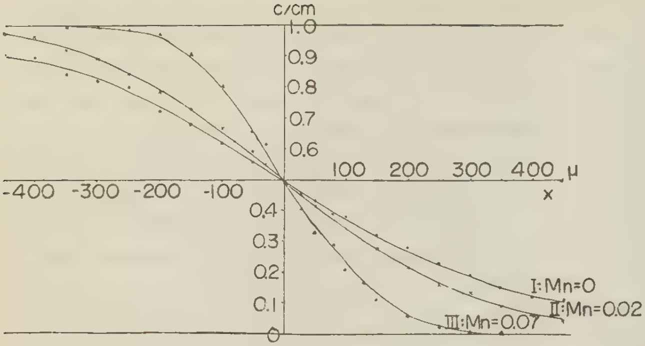

Fig. 2. Mg distribution for various concentrations of Mn. (1000°C, 100 hours)

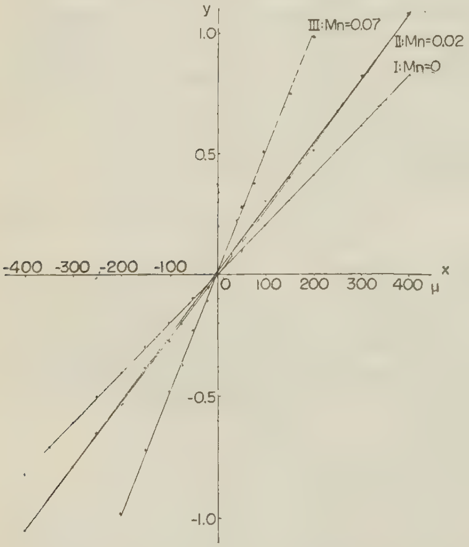

Fig. 3. y versus x plot of activator Mg for various concentrations of Mn. (1000°C, 100 hours)

versus x. The slope of the line of Fig. 3 gives $1/2\sqrt{Dt}$, since $y=x/2\sqrt{Dt}$. Thus the diffusion coefficient of one activator in base nickel of oxide cathode can be obtained in the presence of another element of various concentrations. In Figs. 2 and 3 the curves I, II, and III correspond to the cases for Mn contents of 0, 0.02, and 0.07 weight % respectively. Finally the diffusion coefficient of one activator can be obtained as a function of concentration of another activator.

3.2 *Results of experiments*

The influence of concentration of one activator on the diffusion of another for annealing of 100 hours at 1000°C are shown in Figs. 4, 5, 6, and 7 for various doping cases. Fig. 4 shows the influence of Mn concentration on Mg diffusion in base nickel, Fig. 5 that of Fe concentration on Mg diffusion, and similarly Figs. 6 and 7 that of Si on Mg diffusion and that of Mg on Mn diffusion respectively. The plots on these curves for a given concentration exhibit a considerably good agreement to each other within an experimental error. From these results one can readily understand that the diffusion rate of low solute activator in base nickel is significantly influenced by the simultaneous presence of other activator. Generally speaking, it may be concluded that

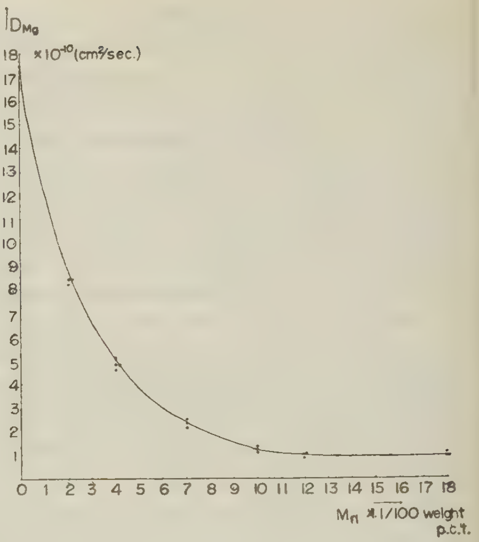

Fig. 4. Diffusion coefficient of Mg for various Mn concentrations. (1000°C, 100 hours)

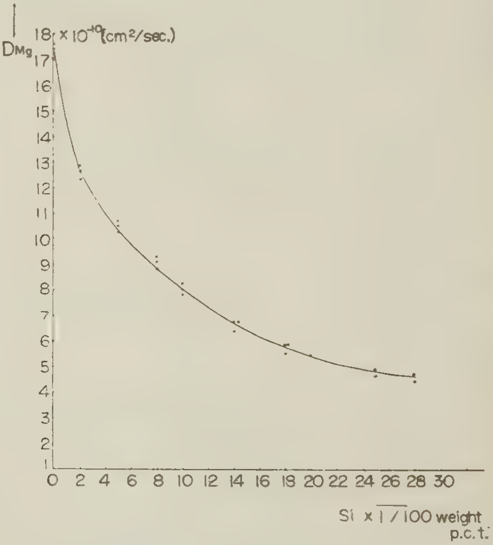

Fig. 5. Diffusion coefficient of Mg for various Fe concentrations. (1000°C, 100 hours)

the diffusion rate of solute Mg of low concentration in base nickel decreases by the addition of another element such as Mn, Fe, or Si into it, whereas that of Mn increases by the addition of Mg.

A large percentage of the errors in our experiments may come from spectral analysis of elements in a minute sample of cut. Particularly for the analysis of Mg the error was most serious because of the difficulties of analysis. Therefore, corrections were carried out by repeating the analysis for the whole amount of each sample. Probable error of analysis was estimated as about 7% even in this case. In order to eliminate the errors as possible as we can, we have carried out these spectral analysis carefully on every pair of cuts which are equidistant from the interfaces and the results have agreed with each other.

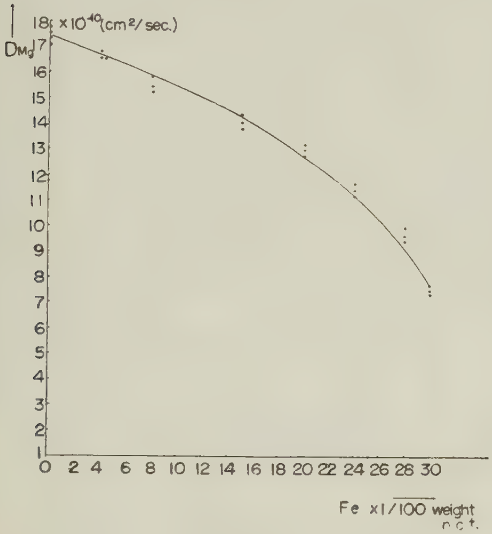

Fig. 6. Diffusion coefficient of Mg for various Si concentrations. (1000°C, 100 hours)

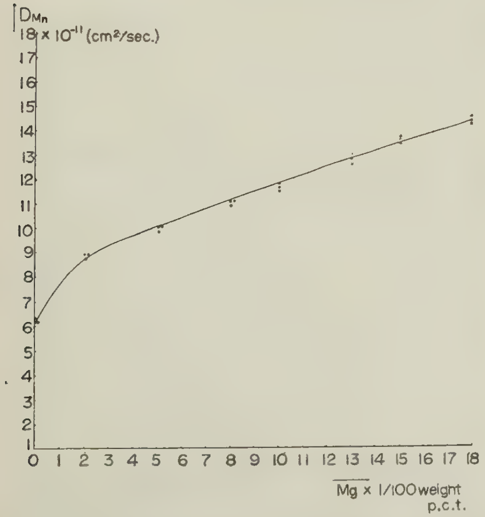

Fig. 7. Diffusion coefficient of Mn for various Mg concentrations. (1000°C, 100 hours)

There are some other factors by which experimental errors may be introduced. They are cutting operation, temperature variation during annealing, and difference of structure defects in samples, etc. The error in thickness of cuts was within the accuracy of 5 micron for each sample. The annealing temperature was automatically controlled and recorded within the fluctuation of ±0.5%, the fluctuation of the temperature being ±5° from the center value of 1000°C. It may be supposed that the defects of the structure of testing nickel give considerable influences on the activator diffusion and therefore much attention was paid to the process of manufacturing of nickel ingot by using a vacuum melting method. The entire surface of each ingot was scraped off in order to take off the shrinkage cavity. Even if a single pore was detected in the disks by microscope, the entire ingot was rejected. By such a careful selection of the ingots the author could get such a consistency as shown in Figs. 4, 5, 6 and 7.

§ 4. Discussions

So far it has been supposed that the diffusion of the reducing agent in base nickel of oxide-coated cathode depends only upon the concentration gradient of itself, and therefore that the rate of activation should be determined only by the amount (density) of reducing agent in base nickel. The mechanism of activation of oxide-coated cathode by reducing agents of low concentration in base nickel is, however, by no means such a simple one. Indeed, there are some experiments to suggest the supposition that the rate of activation due to the reducing agents is not only determined by the relatively large amount of the main reducing agent but also by the minute quantities of solute elements of low concentration. The influences of the latter have been so far neglected. Poehler7) has found that base nickel containing 0.38% Mg or 4.0% Al makes cathode less active than pure nickel. This is contradictory to the results by Benjamin8) with base nickel containing 0.07% Mg and to those by Bound and Briggs with 0.05–0.10% Al–Ni alloy. Rittner[2] has suggested a possibility to explain such contradictions on the basis of the formation of interface layer, that is, the interface layer produced by main activator has a significant influence on the emission afforded by the small quantity of "real activators," which are probably contained in base nickel in addition to the former. He has further proposed a simple explanation of the harmfulness of Mn element in base nickel for emission[7],[8], provided that the interface layer formed by Mn contains no barium. After his opinion, the presence of the reducing element in base nickel, which yields an interface compound containing no barium, may be harmful to emission because the interface layer is not only a barrier separating the real activators from BaO coating but also makes a sink for the activators and free Ba atoms.

According to our opinion, however, the contradictory results of the experiments above mentioned should be explained on the basis of doping influences on activator diffusion in base nickel. Comparing Fig. 4 with Figs. 5 and 6, one can readily see that the deleterious influences of Mn on Mg diffusion are most significant. Therefore, Mn may be most harmful for emission of cathode even at very initial stage of cathode life where the interface may not be grown up so much as it could influence the behaviours of oxide-coated cathode. As shown in Fig. 5, the influence of Fe element on Mg diffusion is also deleterious though not so significant as that of Mn. Thus, it may be safely concluded that the lowering of cathode emission by the poor reducing metals, Mn and Fe, is caused by their suppressive actions for Mg diffusion. Moreover, the above experimental results seem to suggest that Fe is not so harmful as Mn for the emission of oxide cathode. On the other hand, the cathode having considerable amount of Si element in base nickel shows a relatively high emission in spite of its deleterious influence on Mg diffusion (see Fig. 6). This is probably due to the high reducing agency of Si. In this case the degree of activation at the initial stage of life may be considered to depend mainly on the following three conditions; (1) total amount of Si and Mg simultaneously present in base nickel. (2) diffusion rate of Mg decreased by Si concentration. (3) diffusion rate of Si presumably increased by Mg concentration.

As was shown by Fisher[10], the diffusion along grain boundaries can mask the volume diffusion at low temperature. Hoffman and Turnbull[11] have pointed out that the self-diffusion in polycrystalline silver takes place more rapidly than that in single crystal silver at low temperature region. At a higher temperature region, however, the rates of both diffusions approach to each other and become nearly equal. The difference at low temperature is essentially associated with the grain boundary diffusion along the internal interfaces of polycrystal. According to Fisher's calculations, the logarithm of the specific density should vary linearly with penetration depth x in the case of grain boundary diffusion at low temperature, whereas that does linearly with x^2 in the homogeneous volume diffusion at higher temperature. The logarithm of the specific density of activator Mg was plotted against the square of penetration depth x^2 in Fig. 8 as a typical example. From this figure it seems reasonable to conclude that in our experimental temperature range the diffusion coefficient is not significantly different from that of volume diffusion.

Recently, very interesting explanations on our experimental results[5] have been presented by van Zanten[12]. He suggested that the de-

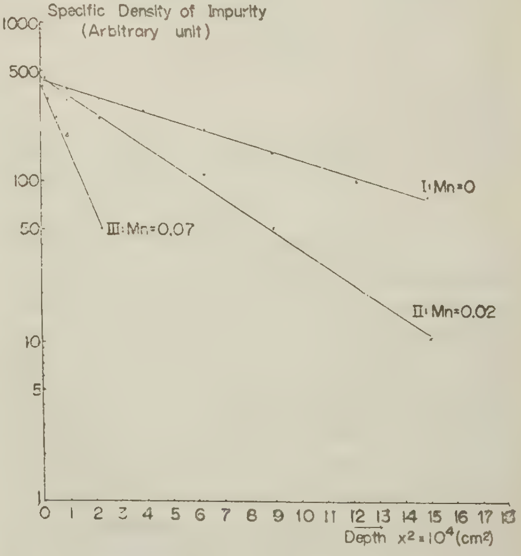

Fig. 8. Penetration curves of Mg for various Mn concentrations. (1000°C, 100 hours)

creases of diffusion coefficient of Mg, when nickel contains Mn, might be due to the reduction of MnO by Mg and that the discrepancy between the diffusion coefficients of Mg obtained by Swalin and those obtained by us or by the group in Philips laboratory might be explained by the concept of "Freies und Gebundenes Magnesium". This may be one possible interpretation for the mechanism of doping interactions, but the exact explanation is still left for future works.

§ 5. Conclusion

We have carried out some experiments concerning the doping influences on activator diffusion in base nickel of oxide-coated cateode and it has become clear that Mn, Fe, and Si decrease the diffusion rate of Mg in base nickel whereas Mg increases that of Mn. From these results it is concluded that the rate of diffusion of activator is determined mainly by the influences of doping elements rather than by its density in base nickel. We have proposed some explanations on the contradictory results of cathode emission so far published by means of doping influences on activator diffusion.

Electrical Properties of N-Type InSb in High Electric Field at 77°K.

By Yasuo KANAI

Electrical Communication Laboratory, Musashinoshi, Tokyo

(Received June 2, 1959)

The current-voltage character and Hall coefficient of n-type InSb with different electron density were measured in a pulsive high electric field, at 77°K. In a high electric field, impact ionization from full band to conduction band occurred and the resistivity and Hall coefficient of n-type InSb decreased rapidly with increasing electric field. In the same region of electric field, Hall mobility decreased and drift velocity reached a maximum value and then decreased. In the curve of the electron density *versus* μE^2, the rate of energy gain from electric field, there existed a critical value of μE^2 where the electron density increased infinitely. This critical value of μE^2 increased with decreasing electron mobility at low field, and, in one sample, also increased with decreasing strength of the transverse magnetic field.

§ 1. Introduction

In a high electric field free carriers in solid obtain sufficient energy from electric field and their distribution function deviates significantly from the form in thermal equilibrium state. In this situation, free carriers are called to be hot and the Ohm's law ceases to be valid. Recently the hot carrier phenomena in semiconductors have been investigated experimentally and theoretically.[1]

As is well known, for a conducting carrier with mobility μ, the rate of energy gain from electric field E is μE^2. Hence one may expect that the hot carrier phenomena in a semiconductor in which the conducting carrier has large mobility will occur at rather low electric field. As such semiconductor with large mobility we chose n-type InSb, because the electron in InSb has the largest mobility in all of semiconductors. In this report our experimental results on the electrical properties of n-type InSb in a pulsive high electric field at 77°K are described.

§ 2. Experimental Procedures

2–1 *Preparation of the samples*

First of all, ingots of InSb were purified by zone refining method. After purification, single crystals of InSb were grown by the zone leveling method. In some cases large single crystals grew naturally in the course of zone refining. In these cases we cut single crystals directly from the ingots.

Next, specimens of n-type InSb were cut from these single crystals in the form approximately $0.2 \times 0.2 \times 1.0$ cm^3 and the resistivity and Hall coefficient of these specimens were measured at 77°K. Furthermore, to check the uniformity of the specimen, Hall coefficients R(A) and R(B) at two positions A and B near the ends of the specimen were also measured at the same temperature, and the quantity $\Delta R/R = R(A) \sim R(B)/R(A)+R(B)$ was used as a measure of the uniformity of the specimen. (See Fig. 1).

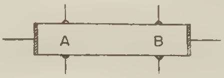

Fig. 1. To check the uniformity of the InSb specimen, Hall coefficients at two positions A and B were measured at 77°K.

All values of electrical properties, i.e., resistivity, Hall coefficient, Hall mobility, electron density, uniformity and degenerate temperature of our specimens are listed in Table I. In calculating the degenerate temperature, we used $m^* = 0.013$m as the value for effective mass, and assumed a standard parabolic form for the conduction band in InSb. The non-parabolic character of the conduction band in this material[2] will reduce the degenerate temperature to lower values for the specimens with high electron density.

After the measurements of the specimens,

Table I. Electrical properties of our samples

Sample No.	Resistivity ρ in ohm-cm	Hall coefficient* R in cm^3/Coul.	Electron density* $n=1/R\cdot e$ in no./cm^3	Hall mobility* $\mu=R/\rho$ in cm^2/V. sec	Uniformity* $\Delta R/R$ in per cent	Degenerate temperature T_D in °K
1	7.55×10^{-2}	1.58×10^{4}	3.95×10^{14}	2.09×10^{5}	12	17.5
2	4.80×10^{-2}	1.06×10^{4}	5.88×10^{14}	2.21×10^{5}	9.1	22.6
3	2.32×10^{-2}	4.26×10^{3}	1.46×10^{15}	1.84×10^{5}	8.3	41.5
4	1.46×10^{-2}	1.20×10^{3}	5.20×10^{15}	0.82×10^{5}	—	96.9
5	9.16×10^{-3}	1.16×10^{3}	5.38×10^{15}	1.27×10^{5}	5.2	99.0
6	5.70×10^{-3}	4.97×10^{2}	1.26×10^{16}	0.87×10^{5}	—	179

* All of these values were measured at 77°K in a low electric field.

samples of approximately 0.05×0.05 0.5 cm^3 were prepared for the measurements in high electric field. Current leads and the probes for measurements of resistivity and Hall coefficient were attached to the samples by soldered contacts. It is said usually that there exist some barrier layer between semiconductor and metal electrode, but fortunately it was found that this undesirable effect was negligiblly small in the case of n-type InSb. Hence in some cases the resistivity was measured not by the probes but by the current leads of the samples (See Fig. 2). These two methods of measurement gave the same values always.

2–2 *Apparatus for measurements*

To avoide the heating effect, pulsive electric field was applied to the samples. The pulse-generator consisted of hydrogen-filled. thyratron and delayed circuit. The output impedance was about 2 ohm and the maximum output voltage was approximately ±300 V. The pulse width was about 2 micro sec., and the repetition rate was 1–700 c/s.

The schematic representation of the measuring circuit is shown in Fig. 2. When the sample impedance was smaller than 2 ohm, matching resistance was omitted. As shown in Fig. 2, the voltage, current and Hall voltage of the samples were measured by the syncroscope at the positions of switch, A or A′, B and C respectively. In the course of measurements, the sample was immersed directly in liquid nitrogen.

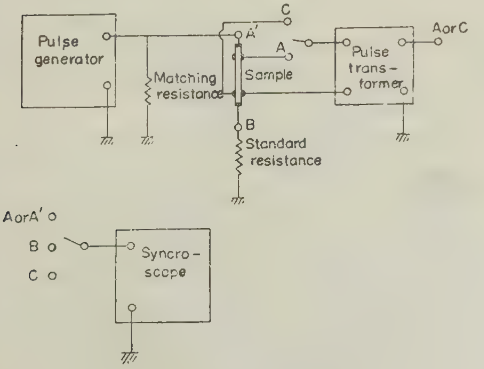

Fig. 2. Schematic representation of the measuring circuit.

§ 3. Results and Discussion

3–1 *Current-voltage character and Hall coefficient of n-type InSb crystals with different electron density*

Fig. 3 shows the current-voltage characters

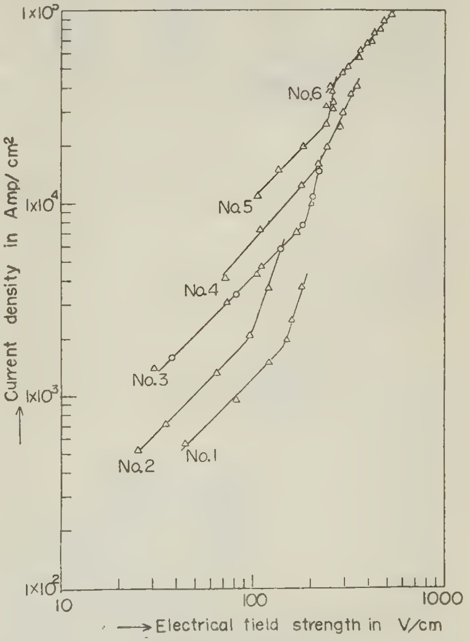

Fig. 3. Current-voltage character of n-type InSb at 77°K. The symbols ○ △ show the values obtained by changing the polarity of electric field.

of various samples with different electron density in the absence of magnetic field. The current-voltage character in a magnetic field and Hall coefficient of these samples are also shown in Figs. 4 and 5. In these figures, it is cleary shown that, in a low electric field the current density was proportional to the electric field and the Ohm's law was valid, but in a high electric field, except the case for sample No. 6, the current density increased more rapidly with increasing electric field, and in the same region Hall coefficient decreased. Namely, in a high electric field the number of conduction electron increased very rapidly with increasing electric field.

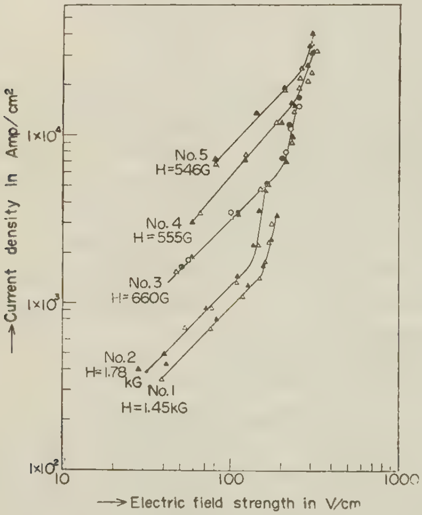

Fig. 4. Current-voltage character of n-type InSb in a transverse magnetic field at 77°K. The symbols ○ △ ● ▲ shows the values obtained by changing the polarity of electric and magnetic field.

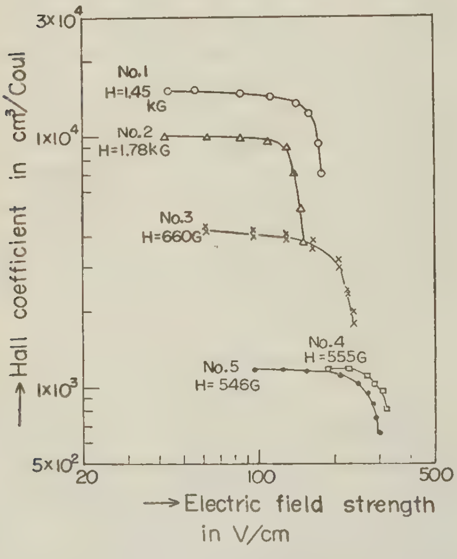

Fig. 5. Hall coefficient *versus* electric field strength curves of n-type InSb at 77°K.

As is well known, the donor impurities in n-type InSb are completely ionized at 77°K, hence the increase of the electron density in a high electric field may be caused by the ionization process from full band to conduction band. Two different mechanism of ionization processes, i.e. the field ionization process and impact ionization process, may be considered in our case. But the fact that the critical value of electric field where the current density begins to increase rapidly with increasing electric field varies from sample to sample will reject the possibility of the field ionization process as the cause of the rapid increase of electron density in n-type InSb in a high electric field. Hence we may believe that the increase of the electron density in high electric field is due to the impact ionization from full band to conduction band by the energetic electrons.3)4)

To analyse our experimental data presented above, there are some difficulties. One of these difficulties is the fact that the current-voltage character depends on the magnetic field strength (See 3–2), and another difficulty is the lack of the expression for the Hall coefficient in a high electric field. As mentioned in §1, in a high electric field, the distribution function deviates significantly from the form of thermal equilibrium state, then the expression for the Hall coefficient will become very complicated. For simplicity, however, we *assume* that the usual expression $R=1/ne$ is also valid in a high electric field. Then we may obtain, as usual, the Hall mobility by the formula $\mu=R/\rho$ and drift velocity by $v_d=\mu E$.

Resistivity, Hall mobility and drift velocity versus electric field strength curves for our samples are shown in Figs. 6–8. Some interesting features are found in Figs. 5–8. Namely, except the cases for samples Nos. 4 and 5, the Hall mobility begins to decrease with the onset of decrease of Hall coefficient, and, with increasing electric field, the drift velocity reaches the maximum value and then decreased.

Fig. 9 shows the electron density versus rate of energy gain curves for various samples of n-type InSb with different electron concentrations. In this figure we may find that at certain critical values of μE^2, the electron density increases infinitely, i.e. electrical breakdown occurs. Furthermore, this critical values of μE^2 increase with decreasing electron mobility at low electric field.

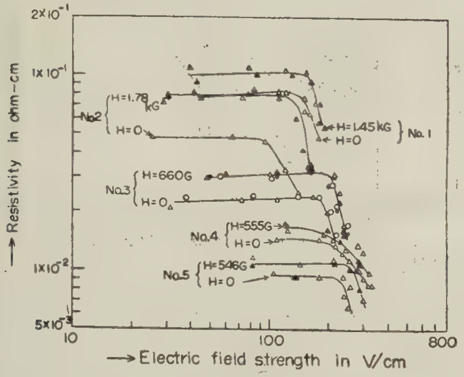

Fig. 6. Resistivity with and without transverse magnetic field *versus* electric field strength curves for n-type InSb at 77°K. The symbols ○ △ ● ▲ show the values obtained by changing the polarity of electric and magnetic field.

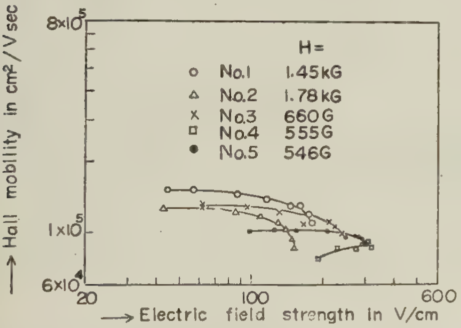

Fig. 7. Hall mobility *versus* electric field strength curves for n-type InSb at 77°K.

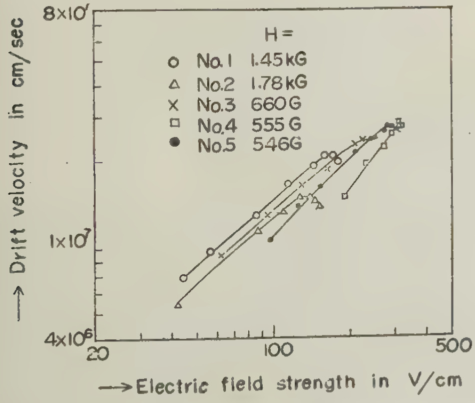

Fig. 8. Drift velocity *versus* electric field strength curves for n-type InSb at 77°K.

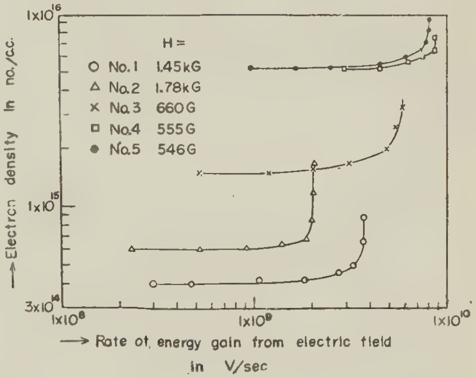

Fig. 9. Electron density *versus* rate of energy gain curves for n-type InSb at 77°K.

3–2 *Effect of the strength or direction of transverse magnetic field.*

Figs. 10–15 show the effects of the strength of transverse magnetic field upon the current-voltage character etc. of a n-type InSb sample No. 1. As one can see in these figures the increase of magnetic field strength results in the decrease of conductivity, Hall mobility, drift velocity and critical values of μE^2. In Fig. 16 the dependence of critical values of μE^2 upon the magnetic field strength is shown.

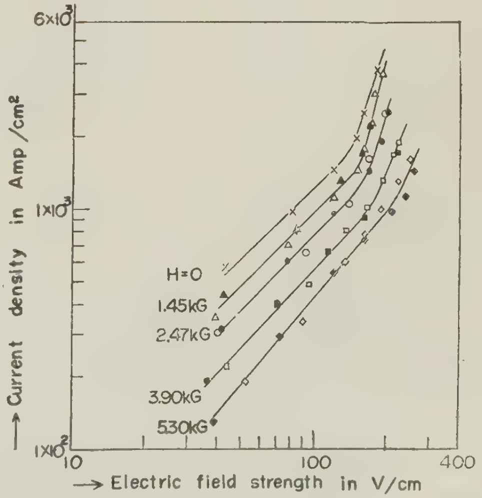

Fig. 10. Current-voltage character of n-type InSb sample No. 1 in various strength of transverse magnetic field at 77°K.

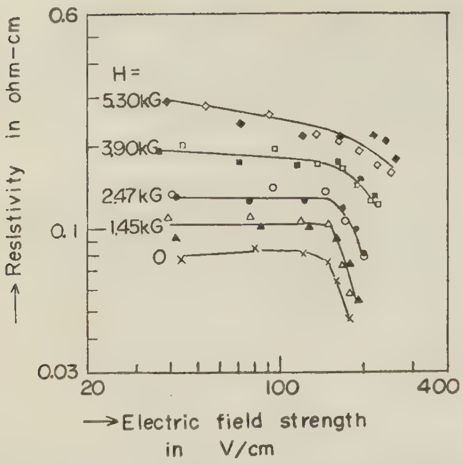

Fig. 11. Resistivity *versus* electric field strength curves of n-type InSb sample No. 1 with and without transverse magnetic field at 77°K.

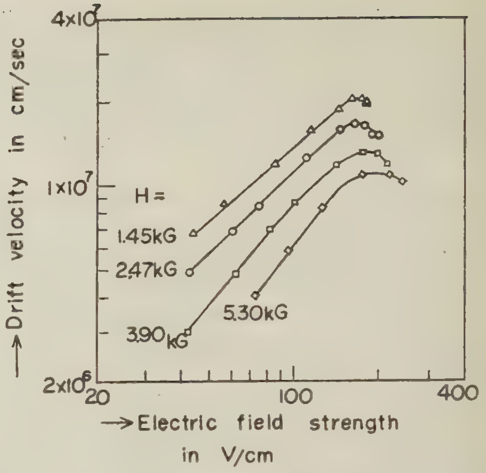

Fig. 14. Drift velocity *versus* electric field strength curves for n-type InSb sample No. 1 at 77°K.

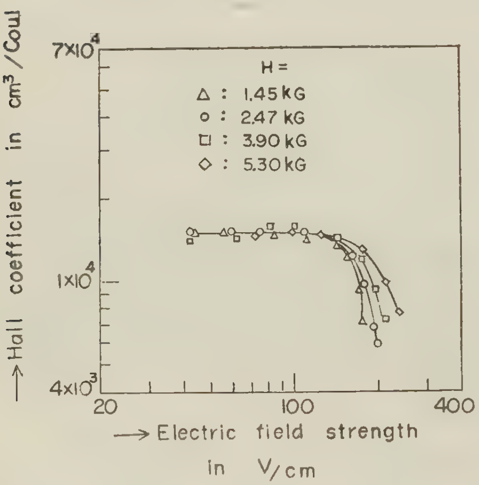

Fig. 12. Hall coefficient *versus* electric field strength curves for n-type InSb sample No. 1 at 77°K.

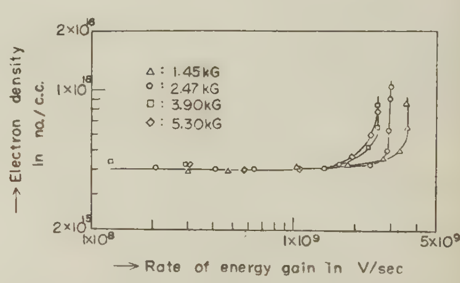

Fig. 15. Electron density *versus* rate of energy gain curves for n-type InSb sample No. 1 at 77°K.

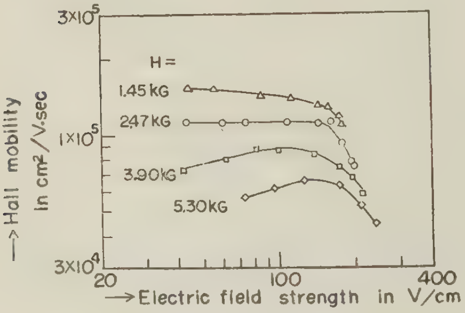

Fig. 13. Hall mobility *versus* electric field strength curves for n-type InSb sample No. 1 at 77°K.

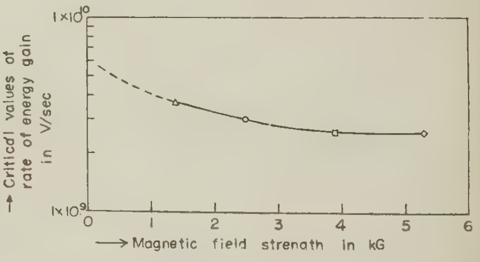

Fig. 16. Critical values of rate of energy gain *versus* magnetic field strength curves for n-type InSb sample No. 1 at 77°K.

Fig. 17 shows the current-voltage character of a sample No. 4 when the current flow was in the [110] direction of crystal axis and the transverse magnetic field was applied in the direction of [001] or [$1\bar{1}0$] or [$1\bar{1}1$]. This result shows that the current-voltage character of n-type InSb is isotropic in the transverse magnetic field which was applied to the various directions of crystal axis.

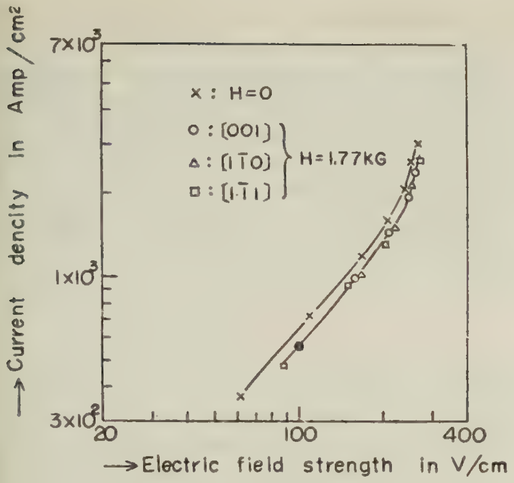

Fig. 17. Current-voltage character of n-type InSb sample No. 4 at 77°K. Current flow was in [110] direction and transverse magnetic field was applied in the direction [001] or [1$\bar{1}$0] or [1$\bar{1}\bar{1}$].

§ 4. Conclusion and Acknowledgement

Several years ago Shockley[5)] calculated the current-voltage character of semiconductor with spherical energy surface in a high electric field, assuming that the acoustic phonon scattering was the main process of energy loss in the material. His results showed that the critical field strength E_c, where the deviation from Ohm's law caused by the reduction of mobility of conduction carrier set in, was given approximately by the formula,

$$\mu_0 E_c \equiv v_{dc} = 1.5\ v_s$$

where μ_0 : low field mobility

v_s : sound velocity in the crystal

His calculation was used to analyse the experimental data of germanium and silicon obtained by Ryder.[6)]

If one applys Shockley's calculation to n-type InSb, one may expect that the deviation from Ohm's law begins at rather low electric field (~10 V/cm),[4)] because of the large electron mobility in InSb. Our experimental results mentioned above didn't show any deviation from Ohm's law near the expected region of electric field. Hence we can believe that the main process of energy loss of electron in InSb in a low electric field is not the acoustic phonon scattering but probably the optical phonon scattering.

In a higher electric field the resistivity and Hall coefficient of n-type InSb rapidly decreased with increasing electric field, and this behaviour was believed to be caused by the onset of impact ionization from full band to conduction band. In these region the mobility also decreased and drift velocity reached a maximum value and then decreased with increasing electric field. As one can see in Fig. 9, we can define the critical values of μE^2 for electrical breakdown where the number of conduction electron increased infinitely. This critical value of μE^2 increased with decreasing electron mobility at low field, and in one sample, also increased with decreasing the strength of the transverse magnetic field.

A few years ago Fröhlich and Paranjape[7)] proposed the mechanism of collective breakdown, and recently Stratton[8)] discussed the pre-breakdown behaviour of polar semiconductor upon the same mechanism. Their results showed that there existed a critical value of the rate of energy gain. Following the Stratton's calculation we can obtain 8.9×10^9 V/sec as the critical value of μE^2 for InSb at 77°K and this value is in good agreement with the experimental value; 6×10^9 V/sec (See Fig. 9). But there are some discrepancies between the Stratton's calculation and our experimental results. For instance his calculation showed the gradual increase of drift velocity with increasing electric field, but in our experiment the drift velocity reached a maximum value and then decreased. Taking into account the fact that there is a critical value of $\mu E^2 (\equiv E v_d)$, however, the decrease of drift velocity with increasing electric field is quite natural.

In a sample with lower mobility at weak electric field, there exist more imperfections than in a sample with higher mobility. So the excess energy gain corresponding to the energy loss due to the imperfections will be necessary to cause the breakdown. This is the reason why the critical value of the rate of energy gain is higher in a sample with lower mobility than in a sample with higher mobility. But the reason why the critical value of μE^2 decreases with increasing strength of transverse magnetic field is not yet understood.

The author wants to express his thanks to Dr. T. Niimi for his kind guidances and to

Messrs. R. Nii and N. Watanabe for their valuable helps.

Study on Vacuum Deposition of Metals, II. On the Change with Aging Time in Thickness and Resistivity of Vacuum Deposited Gold Film

By Yoshibumi FUJIKI

Institute of Physics, Kyoto Prefectural Medical College.

(Received June 6, 1959)

Changes with aging time in electrical resistivity and thickness of vacuum deposited gold film were measured on the same specimen. Kiessig's X-ray interference method was employed for the measurement of film thickness. It was observed that film thickness decreased in exactly the same manner as the resistivity. The proportionality constant between resistivity change and fractional-volume change was about 2.5×10^{-4} ohm·cm which agreed well with the quenching experiment of gold in bulk by Bauerle and Koehler, and this suggests that the resistivity change in vacuum deposited gold film at room temperature is predominantly due to a vacancy mechanism just as the case of quenched material in bulk.

§1. Introduction

In a previous work¹⁾ the writer observed that Au–Pb alloys were formed when Au and Pb vapours were deposited successively in vacuum. But no alloy formation was observed when Pb vapour was deposited on Au deposit which was annealed at room temperature for about a week in vacuum. The writer supposed that this would be due to the annealing of defects, especially vacancies, which were stored in Au film by the deposition.

The electrical resistivity of vacuum deposited film is usually higher than that of bulk material and a part of this excess resistivity can undergo irreversible change upon annealing. Story and Hoffman²⁾ investigated the stress annealing in vacuum deposited copper film and found the parallelism between stress relaxation and resistivity decrease by annealing near room temperatures, and they attributed these phenomena to the disappearance of vacancies with aging.

On the other hand, it is established³⁾⁴⁾ that the quenching of bulk material from high temperature gives rise to the freezing-in of vacancies, and by the annealing after quenching the decrease in resistivity and the volume contraction occur as the result of disappearance of vacancies. Bauerle and Kohler⁴⁾ found that there exists a proportionality between the resistivity change and the fractional-volume change for gold. The annealing temperature was near room temperature.

If the writer's supposition and Story and

Hoffman's suggestion about vacuum deposited film described above were correct, the volume contraction of film and the resistivity decrease with annealing would be observed corresponding to the quenching experiment of bulk specimens. The writer intended to verify this and carried out the simultaneous measurements of thickness and electrical resistivity on a same specimen of vacuum deposited gold film.

§ 2. Experimental Procedure

The evaporation apparatus and procedures were similar to those described in the previous work.[1)] Specimen used was 99.99% Au. The pressure at deposition was near 2×10^{-5} mmHg. Substrate distances were in the range of 6~10 cm. Substrates were standard soft glass microscope slides cut to the size 50mm×3.5mm. These were cleansed with usual procedures. Platinum electrodes, to which the gold film was made electrically contact, were fixed by baking on both ends of each substrate and copper ribbon leads were soldered to electrodes. Electrical resistance was measured by a Wheatstone bridge.

The measurement of film thickness was performed by the X-ray interference method due to Kiessig.[5)] The apparatus used is shown schematically in Fig. 1. The specimen holder, to which a long lever was attached, was supported by a knife edge and the end of the lever was hung from the arm of balance. The other end of the arm was connected to the oscillating lever which was driven with constant angular velocity by the rotation of a heart cum, thus resulting in the oscillation of specimen for a range of small angle around the critical angle of total reflection. The distance between the specimen and the photographic film was 33.3 cm. X-rays used was Cu K_α radiation with nickel filter. To save the exposure time, crystal monochrometer was not used. Voltage applied to X-ray tube was 40 kV and tube current was about 40 mA and the exposure time required for each photograph was 30~40 minutes. To make the measurement accurate, two films were loaded in a cassette simultaneously. All measurements were carried out in air and at room temperature, and the film thickness was measured in every one to three hours just after the deposition.

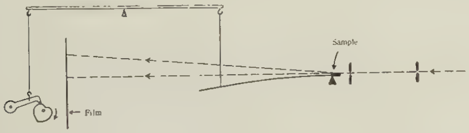

Fig. 1. Schematic diagram of the apparatus for X-ray interference with thin film.

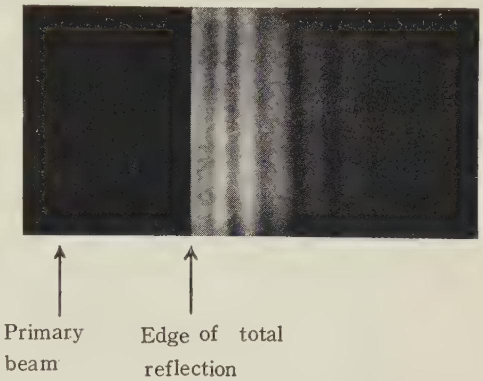

Fig. 2. An example of interference fringes.

One of the photographs of interference fringes obtained is shown in Fig. 2. The condition of interference is given by the following equations:

$$
\begin{aligned}
(2m+1)\lambda/2 &= 2d\sqrt{\alpha^2-2\eta} \quad \text{for maxima,}\\
m\lambda &= 2d\sqrt{\alpha^2-2\eta} \quad \text{for minima,}\\
&\qquad (m=0,1,2,\cdots) \qquad (1)
\end{aligned}
$$

where λ is the wavelength of X-rays, α the glancing angle, η the difference between unity and refractive index, and d the film thickness. Then, using any two interference maxima, d and η are given by the following equations:

$$d=\frac{\lambda}{2}\sqrt{\frac{(m_i+1/2)^2-(m_j+1/2)^2}{\alpha_i^2-\alpha_j^2}}, \qquad (2)$$

$$\eta=\frac{1}{2}\cdot\frac{\alpha_i^2(m_j+1/2)^2-\alpha_j^2(m_i+1/2)^2}{(m_j+1/2)^2-(m_i+1/2)^2}. \qquad (3)$$

There still remains some uncertainty for the determination of the order of interference. Riedmiller[6)] and others used the trial and error method. To eliminate the ambiguity the writer employed the following method.

First, an arbitrary order n $(0, 1, 2, \cdots)$ is given to the observed interference maxima. Then the true order of interference m_i corresponding to the n_ith maximum would be

$$m_i=m'+n_i\,,$$

where m' is a constant which must be determined. Putting this relation in Eq. (2), we obtain

$$(2m'+1+n_i+n_j)\frac{\lambda^2}{4d^2}=\frac{\alpha_i^2-\alpha_j^2}{n_i-n_j}\,. \qquad (4)$$

Plotting values of $\dfrac{\alpha_i^2-\alpha_j^2}{n_i-n_j}$ against n_i+n_j, we shall obtain a straight line. The abscissa of the point where this straight line cuts the x-axis will give the value of $-(2m'+1)$, and m' is thus determined. One of the examples is shown in Fig. 3. (This procedure was also useful for the check of the accuracy of measurements.)

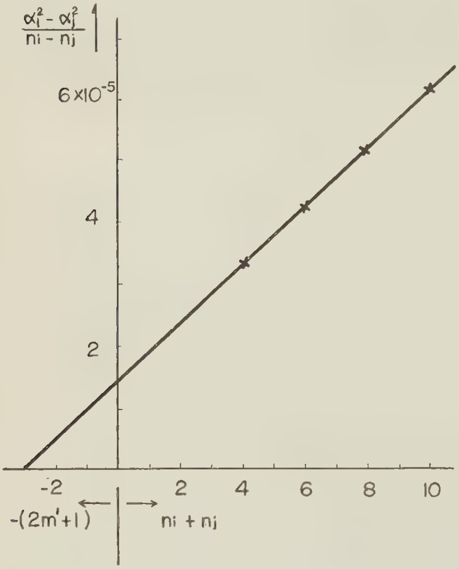

Fig. 3. Graphical determination of the order of the interference maxima.

The accuracy of the thickness measurement seemed to be affected more or less by the quality of photograph. Though the mean error of determined value of film thickness with each photograph was less than 0.5%, the resultant d values plotted against aging time showed somewhat larger fluctuations (*cf*. Fig. 4). This tendency was larger for thicker films because of the greater absorption of X-rays by the specimen (*cf*. Fig. 5). The mean error of η became somewhat larger than that of d as can be seen from Eqs. (2) and (3). The range of error for each photograph was 0.3~2%, but the results plotted against aging time showed comparatively large fluctuations (*cf*. Fig. 6).

§ 3. Results and Discussions

Results obtained are shown in Figs. 4 and 5. Specimen thickness decreased in exactly the same manner as the electrical resistivity at all stages of the annealing process. Proportionality factor between the resistivity change and the fractional-thickness change was about 2.5×10^{-4} ohm cm. The black circles superimposed in Figs. 4 and 5 show d values calculated from resistivity change using the proportionality factor of 2.5×10^{-4} ohm cm. It seems to suggest that vacancies migrate to the surface of the specimen, thus resulting in the decrease in thickness and the resistivity.

The theoretical estimation[7] shows that the resistivity increase per atom per cent of vacancies is about 1.5 micro-ohm cm for gold. It is also estimated[8] that the increase in volume per vacancy is 0.4~0.6 times the atomic volume. In the present case it may be justifiable to suppose that vacancies migrate predominantly to the surface of specimen and consequently the change of thickness is equivalent to the volume change. Taking the resistivity increase as 1.5 micro-ohm cm per atom per cent (Jongenburger's value[7]) and the increase in volume per vacancy as 0.6 times the atomic volume, we obtain the proportionality constant between resistivity and fractional-volume change as 2.5×10^{-4} ohm cm which is the value obtained from the present work. By the quenching experiment of gold wire by Bauerle and Koehler,[4] the proportionality constant between resistivity and fractional-volume change was about 3×10^{-4} ohm cm. Compared this with the present result the agreement of the order of the proportionality factor is fairly well. It is concluded from these results that the resistivity change observed in the vacuum deposited film at room temperature is due to the vacancy mechanism just like the case of quenched material in bulk.

The vacancy concentration obtained by the present work is $5\sim6\times10^{-2}$. This value is extraordinarily high compared with the quenching experiment of bulk specimen. (Equilibrium concentration of vacancies[9] at 1000°C is of the order of 5×10^{-4}.) But Story and Hoffman[2] also found the high concentration of vacancies of the same order as that in the present work in their experiment on vacuum deposited copper film. The mechanism of freezing-in of the vacancies by deposition would presumably be different from the case of quenching of bulk specimen.

The decay curves in Figs. 4 and 5 show some sudden breaks. The cause of these

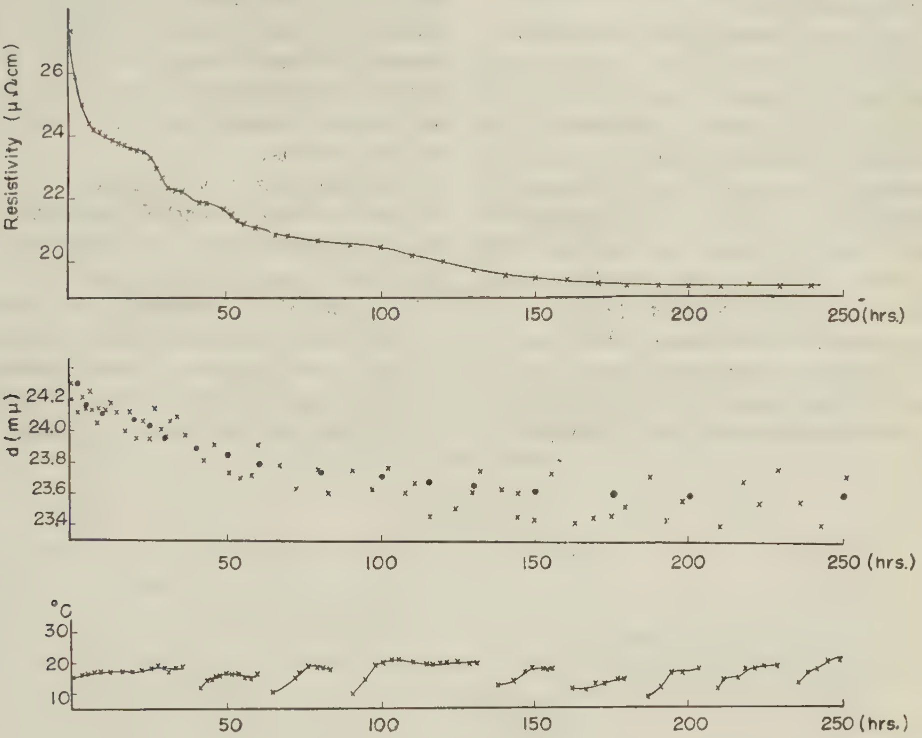

Fig. 4. Resistivity and film thickness change with aging time.

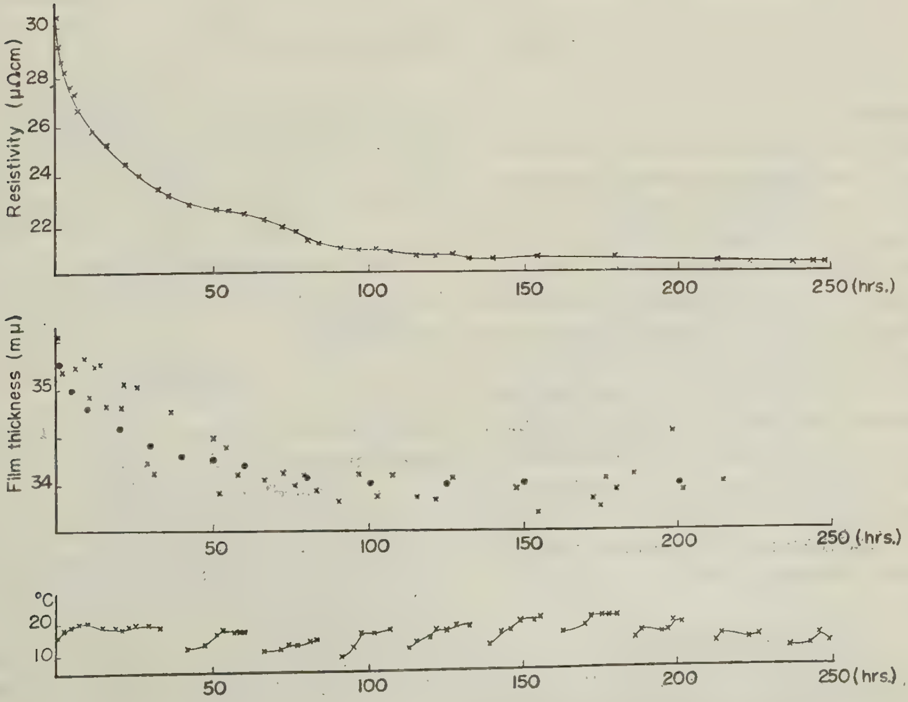

Fig. 5. Resistivity and film thickness change with aging time.

breaks is not clear, but it is not adequate to discuss here the matter, because the annealing temperature was not constant throughout the present experiment.

There are some anxieties for the contamination of film by foreign gas atoms which would strike the film and stick to it by the deposition.[10] This would be checked by the comparison of η values of films with that of bulk specimen, because η of an element is proportional to its density. Unfortunately the writer could not know the correct value of η for gold in bulk. These impurity atoms would affect upon the slope of decay curve, but this is not discussed here. But so long as the amounts of resistivity change and the fractional-volume change are concerned, the effect of the impurity atoms may be neglected in the present work, because the contribution of interstitial atoms to the resistivity change is large compared with that of vacancies, and the proportionality constant between resistivity and fractional-volume change should be much larger than the value obtained in the present work if the resistivity and volume change were attributed to these impurity atoms.

The change of η with aging time is shown in Fig. 6. (Figs. 4 and 6 were obtained by the same specimen). Fluctuations of the observed values of η are comparatively large and the detail of change is not clear. But the tendency of the increase of η, and consequently the increase of density with aging time corresponding to the volume contraction of film may be seen from the figure.

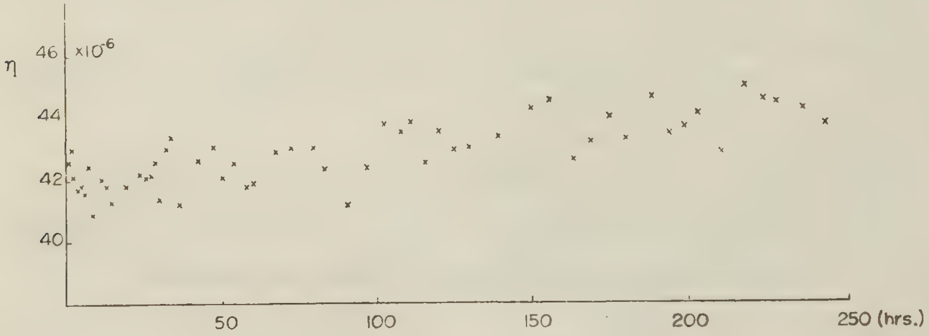

Fig. 6. Change of η with annealing time.

§ 4. Summary

The resistivity change and the decrease in thickness of vacuum deposited gold film with aging were measured simultaneously on the same specimen. It was observed that the specimen thickness decreased in exactly the same manner as the specimen resistance. The proportionality constant between resistivity change and fractional-volume change was 2.5×10^{-4} ohm cm which agreed well with that obtained by the quenching experiment of gold wire by Bauerle and Koehler. It is concluded from the result that the resistivity annealing in vacuum deposited gold film is mainly due to vacancy mechanism just as in the case of quenched material in bulk.

Acknowledgements

The writer wishes to express his sincere thanks to Professor K. Tanaka of Kyōto University for his kind advice and the encouragement throughout the present investigation. The writer's thanks are also due to Professor J. Takamura of Kyōto University for his valuable advice and discussions. Further, he is grateful to Messrs. T. Yoshida and R. Suganuma in our Institute for their assistance.

Elastic Stiffness Constants of Cadmium Sulfide

By Taizō MASUMI
Institute of Physical and Chemical Research,
31, Kamifujimae-Cho, Bunkyo-Ku, Tokyo, Japan
and Toshio TANAKA
Department of Applied Physics, University of Tokyo,
Tokyo, Japan

(Received June 20, 1959)

The elastic stiffness constants $\|c_{ij}\|$ of wurtzite type cadmium sulfide single crystals have been determined on several specimens in the form of cube at room temperature by the ultrasonic pulse echo method at 5.0 and 10 Mc/sec. The results are as follows: $c_{11}=0.778$; $c_{12}=0.447$; $c_{33}=0.881$; $c_{44}=0.147$; $c_{36}=0.159$: in units of 10^{12} dynes per cm^2 by using the value of density $\rho=4.83$ g/cm^3.

§ 1. Introduction

Elastic stiffness constants of a crystal usually inform us of the nature of the binding between constituent atoms in the crystal. We have attempted to examine the elastic properties of large cadmium sulfide single crystals in cube-form as a fundamental study of physical quantities of the crystal.

§ 2. Experimental Procedures

Gobrecht and Bartschat[1][2] have examined the elastic and piezoelectric properties of wurtzite type cadmium sulfide crystals. But, in their experiments, some of the constants have been left undetermined, since they have used flaky crystals with preferred crystal orientations. The samples used in our experiment are the specimens cleaved and machined out of wurtzite type cadmium sulfide ingots[3] produced by the Eagle-Picher Company, whose resistivity ranges from 10^5 to 10^8 ohm·cm in dark at room temperature. The crystal directions are determined with the help of X-rays and the sizes of the specimens are, for example, of the order of 7.54 mm × 7.56 mm × 10.16 mm for the directions of $[01\bar{1}0]$, $[2\bar{1}\bar{1}0]$, and $[0001]$, respectively. Flatness of surfaces prepared with No. 800 carborundum is satisfactory and the crystals are etched in dilute hydrochloric acid.

For the measurement of elastic constants of the crystal, the usual ultrasonic pulse echo method[1] was adopted, because of its convenience and adaptability to a wide range of experimental conditions. In our experiment, an ultrasonic wave in pulse generated by a quartz transducer, whose frequency is 5.0 or 10.0 Mc/sec and pulse width 0.5 μsec, has been chosen. Neither the corresponding wavelength is longer than the sample dimensions, nor the transmitted and reflected waves would interfere with each other in the crystal. Both the longitudinal and transverse shear waves have been used. The elapsed time between initiation and receipt of the pulse is measured in the pattern displayed on a Tektronix 535 type oscilloscope as shown in Photo. 1. Sound velocity v is obtained by

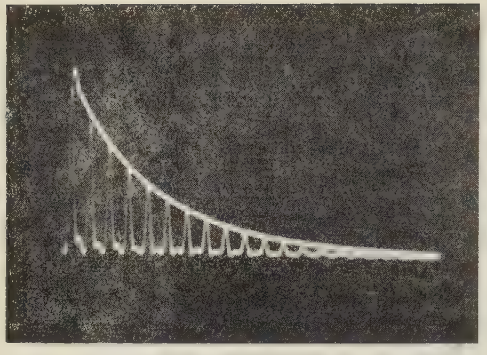

Photo. 1. A displayed pattern of pulse echoes reflected from the rear surface back to the tranceducer.

dividing the round trip distance d by the elapsed time T averaged over several echoes.

§ 3. Results

Sound velocities v's determine the elastic stiffness tensor $\|c_{ij}\|$ of hexagonal crystal[5)]

$$\|c_{ij}\| = \begin{Vmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{Vmatrix}$$

$$c_{66} = (c_{11} - c_{12})/2$$

through the following relations,

$$v_1 = \sqrt{c_{11}/\rho} \qquad \text{(longitudinal wave)}$$

$$\left.\begin{aligned} v_2 &= \sqrt{c_{66}/\rho} \\ v_3 &= \sqrt{c_{44}/\rho} \end{aligned}\right\} \qquad \begin{aligned} &\text{for } \sigma = (\sigma_1, \sigma_2, o) \\ &\text{(transverse waves)} \end{aligned}$$

$$v_1 = v_2 = \sqrt{c_{44}/\rho} \qquad \text{(transverse waves)} \quad \text{for } \sigma = (o_1\, o_1\, \sigma_3)$$

$$v_3 = \sqrt{c_{33}/\rho} \qquad \text{(longitudinal wave)}$$

$$v_{1,3}{}^2 = \frac{1}{2\rho}\Big\{(c_{11}+c_{44})\sin^2\theta + (c_{44}+c_{33})\cos^2\theta \pm \sqrt{(c_{11}-c_{44})^2 \sin^4\theta + (c_{44}-c_{33})^2\cos^4\theta + 2\sin^2\theta\cos^2\theta(c_{11}c_{44}+c_{33}c_{44}-2c_{33}c_{11} + 2c_{13}{}^2 + 4c_{13}c_{44})}\Big\}$$

$$\text{for } \sigma = (\sigma\sin\theta, o, \sigma\cos\theta)$$

$$v_2{}^2 = \frac{1}{\rho}(c_{66}\sin^2\theta + c_{44}\cos^2\theta)\,,$$

where the suffixes i, j are specified from the selected combinations of the stress and strain directions and σ denotes the phonon wave vector with respect to the [0001] direction.

The experimental results of $\|c_{ij}\|$ for wurtzite type cadmium sulfide are shown in Table I except c_{13}, where we have used the value of $\rho = 4.83\text{g/cm}^3$ as the density and c_{12} was determined from the subsidiary relation for the expression $\|c_{ij}\|$.

Table I. Experimental values of elastic stiffness constants of wurtzite type cadmium sulfide at room temperature by the ultrasonic pulse echo method in 5 Mc/sec region.

Elastic stiffness constants $\|c_{ij}\|$	Propagation direction σ	Displacement direction u Type of wave	Round trip distance d(mm)	Elapsed time T (μsec)	Sound velocity v (m/sec)	Values of c_{ij} $\times 10^{12}$ (dyne/cm²)
c_{11}	$[01\bar{1}0]$	$[01\bar{1}0]$ Longitudinal	7.56	3.766	4,013	0.778
	$[2\bar{1}\bar{1}0]$	$[2\bar{1}\bar{1}0]$ long.	7.54	3.756	4,013	0.778
c_{12}	$c_{12} = c_{11} - 2c_{66}$					0.447
c_{33}	[0001]	[0001] long.	10.16	4.76	4,270	0.881
c_{44}	$[01\bar{1}0]$	[0001] Transverse	7.54	8.63	1,750	0.147
	[0001]	$[01\bar{1}0]$ trans.	10.16	11.6	1,750	0.147
c_{66}	$c_{66} = (c_{11} - c_{12})/2$					
	$[01\bar{1}0]$	$[2\bar{1}\bar{1}0]$ trans.	7.54	8.31	1,810	0.159
	$[2\bar{1}\bar{1}0]$	$[01\bar{1}0]$ trans.	7.56	8.36	1,810	0.159

Probable errors are less than 1% for c_{11} and c_{33}. In the measurements for transverse waves, the accuracy is rather worse, though plausible agreements are found between the different directions of propagation. Here, we shall not enter into discussions in detail on these values, because the value of c_{13} has been left undetermined yet.

§4. Acknowledgements

The authors wish to express their sincere thanks to Professor Y. Suge and Professor T. Inui for their encouragements and to Dr. A. Hikata and Dr. M. Tsutsumi of Government Mechanical Laboratory for their kind arrangements for our experiments. Sincere gratitudes are also due to Dr. M. Kobayashi for his kind discussions.

Deformation Twinning of Tin Single Crystals under Impact Loading

By Ken-ichiro ISHII

Chikusa Branch, Nagoya Institute of Technology, Nagoya

(Received January 30, 1959)

The impact test has been carried out on the mechanical twinning of 99.98% pure tin crystals, the time of stressing being 10^{-3} sec. The twinning occurred with a sharp yield process, when the [001] axis was nearly perpendicular (±15°) to the specimen axis. The upper yield stress scattered from 0.7 to 2.5 kg/mm², while the lower yield stress and also the stress for the further thickening of the generated twin lamella were from 0.1 to 0.2 kg/mm².

Twinning occurred where large local stress was expected. The critical shear stress law approximately holds for the upper yield stress after indentation, the stress being 0.8 ± 0.1 kg/mm².

Two explanations for the upper yield stress for twinning appear possible. In the first place, it may be the stress required to initiate the twin with the aid of the local stresses, and in the second place, it may be the stress required for the growth of the nucleated twin lamella across the crystal. It is likely that the growth of the twin nuclei is controlled by the critical shear stress law, and that the growth is suppressed by the appearence of slip.

§ 1. Introduction

In some metals such as tin and iron, it is known that twins are readily formed under impact loading. Chalmers¹⁾ found that the twin in tin crystals will be formed under impact loading, if the stress is applied perpendicular to the [001] axis. It is generally known that the yielding of mild steel occurs at stresses higher than the static yield point if the time of loading is small. For example, Clark and his co-workers²⁾ studied extensively the delayed yield phenomenon of low carbon steel. The delay time was also found in β-brass³⁾⁴⁾ and in zinc⁴⁾ single crystals. It may be expected that the delay time phenomenon would also exist in tin crystals, which might favour twinning under impact loading. A number of reviews⁵⁾⁶⁾⁷⁾⁸⁾ have been published on the general aspects of twinning, to which the readers are referred. In this paper, many literatures, especially those of Russian workers, are quoted from these reviews. The following sections describe the results of the impact test with special reference to the orientation dependence, the location of twins, and the effect of indentation. With these results, the origin of the yield process of twinning is discussed

§ 2. Experimental Procedure

The tin crystals were grown from commercial pure tin in the shape of a cylinder 4 mm in diameter and about 20 mm in length cut undistorted. The specimens were of 99.98 wt per cent purity. The orientation was so arranged that the [103] twinning direction and the [001] direction or the slip direction, will lie in a plane with the cylinder axis. As shown in Fig. 1, the angle λ between the [103] direction and the cylinder axis, were changed from 0° to 60°, and so the angle between the [001] axis and the specimen axis, from 30° to 90°, to observe the orientation dependence of twinning.

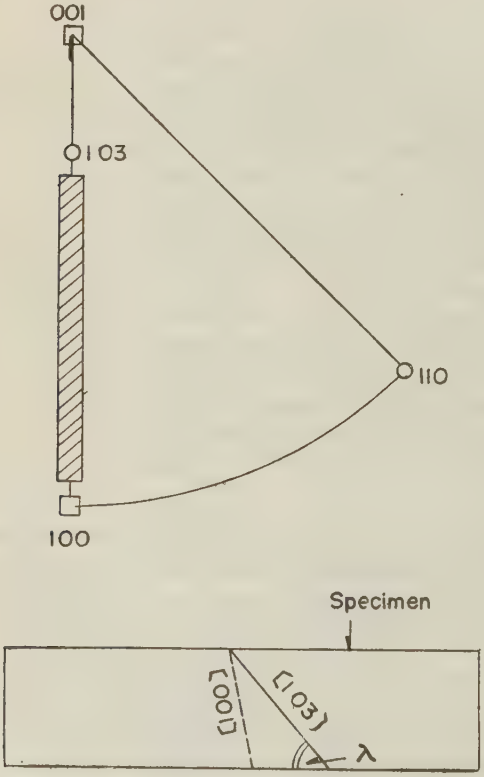

Fig. 1. Orientation of the specimens used.

A small impact tester, which is illustrated in Fig. 2 was used. The specimen was fixed to a massive iron block, about 50 kg, and was struck with a striker pendulum, 28 cm long and about 100 gm. After a high temperature anneal (at 200°C), the specimen was soldered on an end to a brass protecter against the striker and on the other end to a brass base attatched to the holder on the iron block, so that the impact load may be applied uniformly.

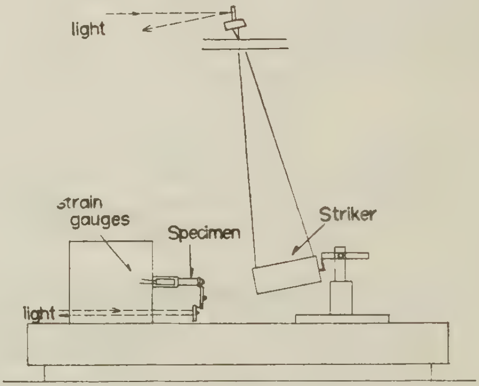

Fig. 2. Apparatus.

The impact load was measured with strain gauges pasted on the holder, or alternatively, the amplitude of repulsion of the striker after impact was used after calibration with these gauges. The period of an impact, from the begining to the end, was about 10^{-3} sec. The contraction of the specimen after impact was measured with a set of mechanical and optical levers, to the accuracy of 10^{-4} cm.

As was done in the earlier experiments[3)4)], the specimen was subjected to increasing amount of impact loads. When the specimen was struck at a small velocity, the collision between the striker and the specimen was elastic, and by increasing the velocity step by step, a velocity was reached where the plastic deformation either with slip or twinning began. In this way, the critical stress was taken as the highest stress obtained before the onset of plastic deformation.

§ 3. Results

(I) *The yield process of twinning*

When the impact test was made with a number of specimens in which the angle λ was about 50°, i.e., the [001] axis was nearly perpendicular to the cylinder axis, no appreciable slip was observed, but a sharp yield process of twinning occurred. An example is shown in Fig. 3. The upper yield stress, as shown in Fig. 6, scattered from sample to sample ranging from 0.7 to 2.5 kg/mm², while the lower yield stress ranged from 0.1 to 0.2 kg/mm². The parallel sided twin lamella appeared with the yielding. The stress for further thickening was measured by further applying a number of impacts. As is shown in Fig. 3, and 4, the stress for thickening is of the same order of magnitude as the lower yield stress, usually accompanied with a small variation.

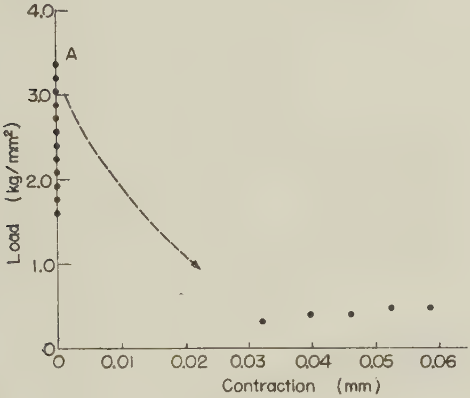

Fig. 3. Load vs. contraction by repeated impact for a specimen in which $\lambda=43°$. The velocity of impact was increased successively until the yield of twinning occurred at Point *A*. After the yield the velocity was kept constant, to observe the stress for the thickening.

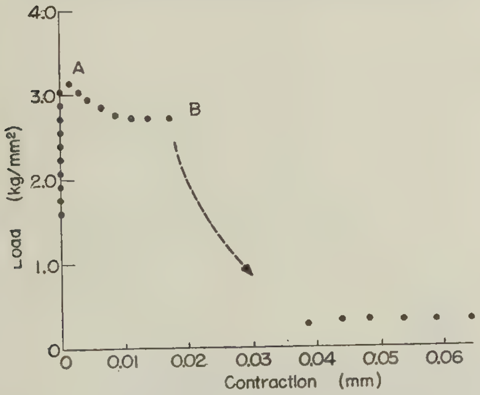

Fig. 4. Load vs. contraction by repeated impact, for a specimen in which $\lambda=38°$. The yield of slip first occurred at Point *A*, followed by several slips. Twinning occurred at Point *B*. The velocity of impact was increased successively until it caused the yield by slip, kept constant during the process of slip, and then at a smaller velocity during the process of thickening of the twin.

(II) *Orientation dependence*

With the specimens in which the angle λ is less than about 40°, and thus the resolved shear stress on the slip plane is large for a given load, the slip first occurred sometimes. The critical shear stress for slip was about 0.9 kg/mm², of the same order of magnitude as the minimum of the observed upper yield stress for twinning. When the slip first occurred, it continued to take place if a number of impact was further applied, and as shown in Fig. 4, twinning eventually occurred. The amount of the preceding slip scattered considerably, and in some specimens the yield process of twinning did not occur until a severe distortion took place. An example is shown in Fig. 5. The condition for the occurrence of twinning after slip is left unknown. The specimens used for the measurements shown in Fig. 4 and 5 were cut from one and the same long single crystal, and were subjected to the impact tests in the same way, but the result was different in that twinning occurred in the one and slip alone in the other.

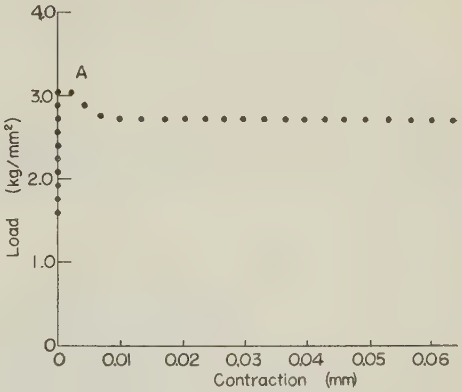

Fig. 5. Load vs. contraction by repeated impact for a specimen in which $\lambda=38°$. Here the velocity of impact was increased successively until the yield of slip occurred at Point *A*, and then kept constant. The yield process of twinning did not occur, but the slip continued extensively.

In Fig. 6, the critical loads observed are shown. As will be seen, the critical shear stress law does not hold for the twinning, while it roughly does for slip.

The result that slip alone occurred when

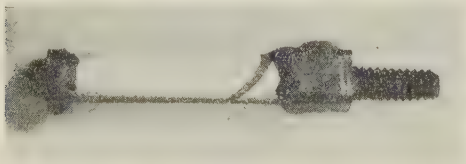
●: slip.
▨: slip, for which twinning occurred later.
+: twinning without prior slip at the indentation.
---: the average of the upper yield stresses after indentation.

the angle λ was less than 30° may be attributed only to the fact that the minimum stress for twinning was not attained with the applied load.

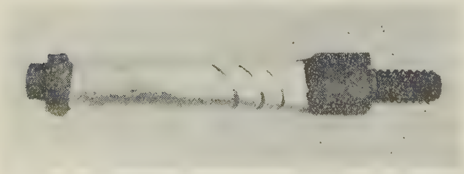
(III) *Location of twins*

(a) Ordinary cases

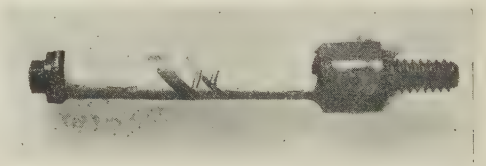
It has been observed with about sixty specimens that the twin lamellae ran through an end of the specimen in the ordinary cases irrespective of whether the yielding occurred without slip or after slip under impact loading. An example is shown in Fig. 7a. Some exceptional cases are described below.



a



b



c

Fig. 7. Location of twins.
(a) The twin lamella running through an end of the specimen as observed in the ordinary cases.
(b) The twin lamellae running through the grain boundaries. The sample was prestrained with steady loading about 1% in contraction.
(c) The twin lamellae generated at the indentations.

(b) Effect of grain boundary

Sometimes, a small grain of different orientation happend to remain in the finished specimen. Twinning seldom occurred through the grain boundary when the impact test was made with such specimens. However, often they were formed through the boundary, if the prior slip was made with steady loading before the impact test. An example is shown in Fig. 7b. (Twinning did not occur with steady loading alone.)

(IV) *Effect of indentation*

Bell and Cahn⁹⁾ observed that if a small indentation was made in the zinc crystal while it was under a sufficiently high stress (about 2 kg/mm², resolved), a burst of twinning resulted. However, if the indentation was made first and load applied after, the small twins so produced would not grow but generally remained unchanged when the specimen broke.

After these experiments mentioned above, the impact test was made on tin crystals *after* giving an indentation with a knife edge. The results did not necessarily coincide with those obtained in zinc crystals, but, as shown in Fig. 7(c), the twin appeared through the indentation. The yielding in this case also occurred as in the ordinary impact test. The upper yield stresses are shown in Fig. 6. As is shown in the figure, the upper yield stress after indentation seems to be relatively lower and has less scatter than in the ordinary cases. It may be said that the critical shear stress law approximately holds for the upper yield stress after indentation, the stress being 0.8±0.1 km/mm².

§ 4. Discussions

Garber¹⁰⁾ studied the process of twinning in calcite and sodium nitrate crystals. He found that, a small wedge or lens shaped twin lamella suddenly appeared at a certain load, grew longer and thicker as the load was increased, shortened and finally disappeared when the load was relaxed. He found further that when the load was large enough, the small twin suddenly spreaded across the whole section of the crystal, becoming parallel sided, and a smaller stress then caused the twin to thicken. As quoted in the preceding section, Bell and Cahn⁹⁾ obtained a good evidence that a high local stress is required to initiate a mechanical twinning in zinc crystals. It is now generally believed that a high local stress is required for the nucleation of twinning, in most substances if not universal.

(a) *Nucleation caused by local stresses*

In tin crystals also this seems to be the case: The twins will have nucleated in ordinary cases with the aid of the local stresses at an end of the specimen, where the twins are observed to run (§ 3. III (a)). The twin observed at grain boundary as described in § 3 III (b) will suggest that they bave been formed with the aid of the local stresses by slip.

(b) *Origin of the upper yield stresses*

Two origins of the upper yield stress appear possible. In the first place, it may be the stress for the nucleation of twins with the aid of the local stresses in the crystal, i.e., at an end, at the concentrated stress by slip, or at the indentation. The wide scatter in the observed upper yield stresses would be attributed to the possible wide scatter in the local stresses.

The second possible interpretation is that it is not the stress for the nucleation, but is the stress for the nucleated twins to grow. When the local stress is large enough, nucleation will occur at a low external stress, and so the stress for the further growth will appear as the upper yield stress. A possible example for this would be the yielding at the indentation. It is not clear whether the twins were always nucleated during the indentation itself or during the impact given after the indentation, but they might be readily nucleated there during the impact, even if they had not been nucleated directly by the indentation. In either case, the observed upper yield stress after indentation will be the stress required for the growth of these twin nuclei.

The critical shear stress law for twinning has been proposed by several workers¹¹⁾¹²⁾¹³⁾¹⁴⁾¹⁵⁾. Hall¹³⁾ suggested that the law might hold for the growth of the twin nuclei. The result of the present experiment that the law approximately holds for the upper yield stress after indentation, may be explained that the growth of the nuclei is controlled by the law.

(c) *Resistance to the growth*

The variation of the upper yield stress may be associated with the resistive stresses against the growth of twins, when the observed yield stress is the stress required for the growth. Garber¹⁰⁾ found that an elastic twin sometimes remained stable. He attributed this to distortion of the lattice by slip. Williams¹⁶⁾ confirmed that a small cleavage crack immobilized a twin which had behaved elastically until it reached there. This idea is supported⁷⁾ by the obsevation that 'stopped' elastic twins are common in calsite crystals at high temperatures and in metals in which slip occurs readily.

J. J. Cox and his co-workers¹⁷⁾ found in iron crystals that the prior slip prevented or inhibited the twinning at low temperatures. One way to explain this is that the growth of the wedge shaped twin is prevented by the imperfections produced by slip.

In the case of twinning in tin crystals under impact load, the restraint by the solder at an end of the crystal or the distortions produced by the indentation may have suppressed the growth. As was described in §3 (II), the slip sometimes occurred extensively, even when the applied load seemed sufficient for the twinning. An explanation would be that the twins would have been nucleated immediately after the slip occurred even if the yield process did not occur, and then the growth was prevented by slip. Further examinations are required to establish the experiment.

§5. Conclusion

The impact test has been carried out on 99.98% pure tin crystals, the time of stressing being 10^{-3} sec. The orientation was so arranged that the [001] and the [103] direction lie in a plane with the specimen axis. The angle λ between the [103] direction and the specimen axis was varied from 0° to 60°, to observe the orientation dependence.

1. Twinning occurred with a sharp yield process when the [001] axis was nearly perpendicular to the specimen axis, i.e., the angle λ being between 45° and 60°. The upper yield stress scattered from sample to sample ranging from 0.7 to 2.5 kg/mm², while the lower yield stress and also the stress for further thickening of the generated twin lamella ranged from 0.1 to 0.2 kg/mm².

2. Slip occurred exclusively, when the angle λ was less than 30°. The critical shear stress for slip was about 0.9 kg/mm² under the impact loading, and so the minimum stress for twinning was not attained in these orientations. With the intermediate orientations, the result scattered among slip, twinning, or twinning after slip.

3. The twin lamellae usually ran through an end of the specimen. It sometimes ran through the grain boundary, if there were any, when the specimen was prestrained with steady loading.

4. If an indentation was made before impact, twinning occurred there accompanied again with the yield process. The upper yield stress after indentation is controlled approximately by the critical shear stress law, the stress being 0.8±0.1 kg/mm².

5. The observations on the location of twins will suggested that they have been nucleated with the aid of the local stresses, as was observed earlier in zinc crystals.

6. Two origins for the upper yield stress appear possible. In the first place, it may be the stress for the nucleation of twin lamella with the aid of the local stresses in the crystal, and in the second place, it may be the stress for the growth of the generated twin lamella across the crystal, when the local stress is large enough. The result that the critical shear stress law holds for the upper yield stress after indentation may be interpreted that it holds for growth of twin nuclei. It is likely that the growth of twin lamellae is often suppressed by slip.

Acknowledgement

The writer wishes to express his thanks to professor K. Tanaka and to Professor Y. Matsunaga for much help and encouragement, to Assistant Professor T. Fukutomi, and S. Maruyama, and to Dr. H. Kihō for many useful discussions, and to many others for their kind assistance.

Monitoring X-ray Tube Output with Ionization Chamber

By Kenzo TANAKA, Jun-ichi CHIKAWA and Tadashi YAMANAKA

Department of Physics, Faculty of Science, Kyoto University

(Received May 26, 1959)

The intensity of X-ray beam can be stabilized by using an ionization chamber as a monitor which is placed between an X-ray tube and a specimen. Namely, the filament current of the X-ray tube is controlled so as to keep the output potential of the ionization chamber constant. The ionization chamber was designed in consideration of the response for wavelengths and the statistical fluctuation of the output voltage. Thus, high stability of a demountable X-ray tube as well as of a sealed-off one was obtained without rigorous regulation of tube voltage. If an X-ray tube is operated at 40 kVp and tnbe voltage is stabilized within ±1%, the fluctuation of intensity can be limited to ±0.1%. Then, the fluctuation of intensity in a broad diffraction line of a polycrystalline specimen which was measured for five hours could not be distinguished from the statistical fluctuation. But the fluctuation of intensity in a diffraction line of a single crystal was ±0.2% for the sealed-off tube and ±0.5% for the demountable one.

§ 1. Introduction

Stability is one of the most important factors that must be considered in intensity measurements with X-ray diffractometer. If the accuracy of the measurements is to be raised, high stability of the X-ray tube is required. Many methods of stabilization and monitoring have already been reported. In monitoring of the X-ray tube output, a second counter[1)] or an ionization chamber[2)] was used in order to register a constant fraction of the tube output. The comparison of different ways of the monitoring with a second counter was discussed by Gillam and Cole[3)], but the accuracy and limitation in monitoring with an ionization chamber have not yet been tested quantitatively. From the point of view to secure the most accurate intensity measurements in the least time, we have adopted monitoring with the ionization chamber[4)].

In this method*, the current for heating X-ray tube filament is controlled so as to keep constant the output potential of the ionization chamber which is placed between the X-ray tube and a specimen. Consequently, the intensity of incident beam irradiating the specimen can be kept constant. And the increase of statistical fluctuation caused by monitoring with the ionization chamber is negligible, because the number of quanta detected per second is very large. Hence the measurements can be performed rapidly. This is an advantage of the method. On the other hand, it is thought to be a disadvantage that the ionization chamber detects not only the characteristic radiation, but also a part of the continuous radiation. However, it was found that this disadvantage was not too important in practical aspect, provided that the ionization chamber was designed so as to possess higher response for the wavelength of the characteristic radiation. In the present paper are described how to design an ionization chamber and the accuracy achieved in this way.

---

* Strictly speaking, this method should be called a stabilizer using an ionization chamber as a monitor.

§ 2. Apparatus

An outline and the principle of the apparatus are shown in Fig. 1. The X-ray beam passes through the ionization chamber which is placed between the X-ray tube and the specimen. The output potential of the ionization chamber is amplified by a D.C. amplifier, and then applied to the grids of tubes V_5, which control the impedance of transformer T_4 connected in series with heating transformer T_3. Thus, the power of heating the filament of the X-ray tube is controlled by the output potential of the ionization chamber.

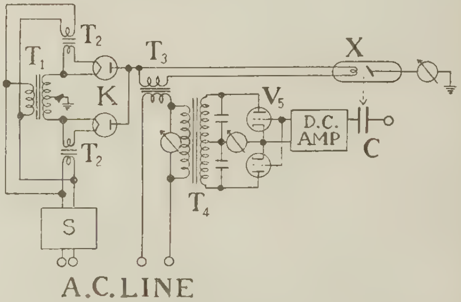

Fig. 1. Principle of the method. T_1: high tension transformer, T_2: filament transformer for kenotron, T_3: filament transformer for X-ray tube, T_4: transformer, K: kenotron, S: ferro resonance type automatic voltage regulator whose stability is ±1%, X: X-ray tube, C: plates of ionization chamber.

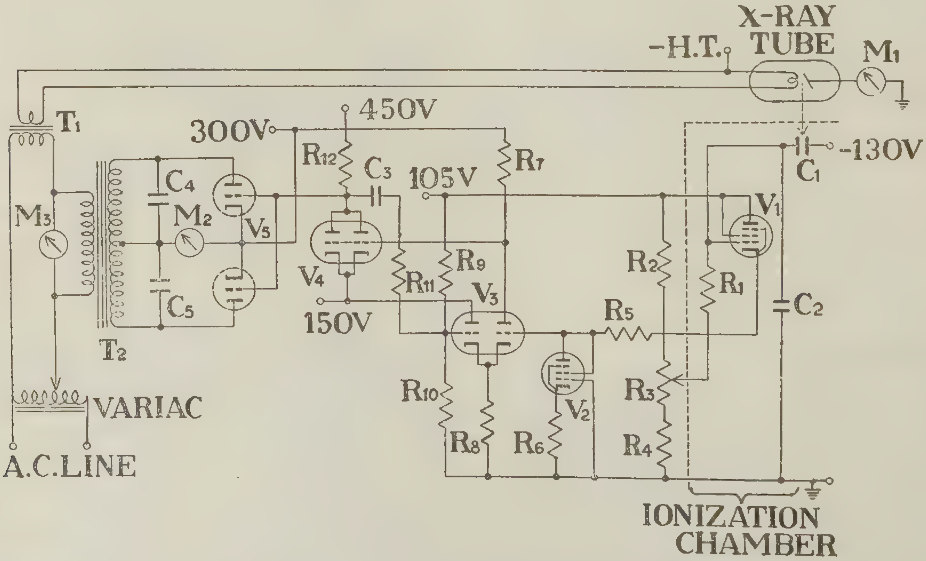

Fig. 2. Circuit diagram of the ionization chamber amplifier. R_1: 1000 M; R_2: 39 K; R_3: 10 K; R_4: 50 K; R_5, R_6: 2 K; R_7: 600 K; R_8: 110 K; R_9, R_{10}: 30 K; R_{12}: 500 K; C_1: plates of the ionization chamber; C_2: 100 $\mu\mu$F; C_4, C_5: 0.25μF; R_{11}, C_3: selected to be suitable for X-ray tube: in our case 2 M and 0.1 μF respectively; V_1, V_2: 6AK5; V_3, V_4: 12AX7; V_5: 6AS7; T_1: filament transformer; T_2: 4:1 transformer; M_1, M_2: mA. meters for X-ray tube current and load tube current; M_3: voltmeter.

The D.C. amplifier is shown in Fig. 2. C_1 is the capacitance between the plates of the ionization chamber. The ionization current produces a potential difference across a resistance R_1. It is amplified by the preamplifier which is composed of tubes V_1 and V_2. These tubes cancel the effect by the variation of their filament voltage so that the change in intensity of X-ray beam is hardly observed, even if the filament voltage varies between 4 and 4.5 volts. The main amplifier is composed of tubes V_3 and V_4 in an ordinary way. In order to prevent the over-all circuit from breaking into the oscillation, the feedback loop between V_3 and V_4 is used. C_3 and R_{11} in the loop are suitably chosen for the X-ray tube used.

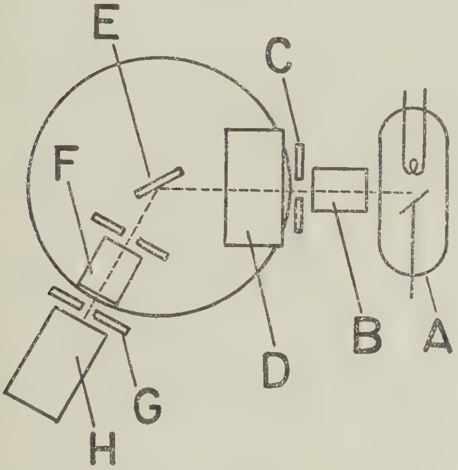

Fig. 3. Position of the ionization chamber. A: X-ray tube; B, F: soller slits; C: divergence slit; D: ionization chamber; E: specimen; G: receiving slit; H: scintillation counter.

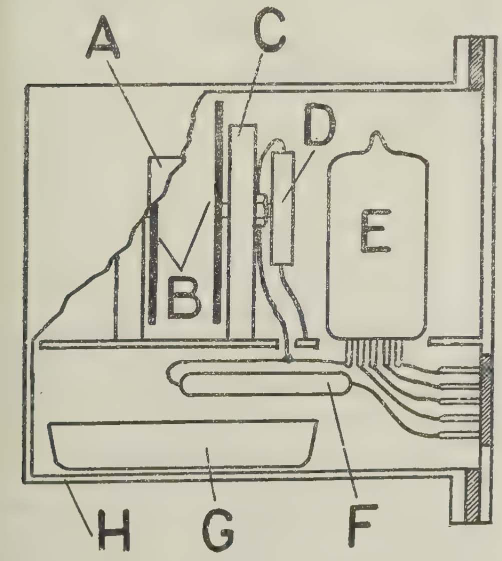

Fig. 4. The ionization chamber. A: Mylar window; B: plates; C: polystyrene rod; D: 100$\mu\mu$F condenser; E: pre-amplifier; F: 1000 M resistor; G: drier; H: air-tight brass box.

The position of the ionization chamber is shown in Fig. 3. The chamber is placed between the divergence slit and the specimen, in order to keep the intensity of incident beam irradiating the specimen constant.

Fig. 4 shows the inside of the ionization chamber. The plates are made of copper and are of 25 mm × 45 mm in dimension. The plates are supported by polystyrene rods parallel to each other with a separation of 14 mm. The size of plates and the distance between the plates were not critical in operation by the use of the amplifier in Fig. 2. Tube V_1, resistor R_1, capacitor C_2 shown in Fig. 2 and plates are mounted in a brass box which is air-tight and serves as an electrical shield. The entrance and exit windows were covered with thin Mylar. The chamber was filled with air of one atmospheric pressure.

§ 3. Fluctuation of Output Voltage of Ionization Chamber

The charges produced by the X-ray quanta in the ionization chamber are collected on its plates whose capacitance is C_1. Then the time constant of this circuit is CR_1, where $C=C_1+C_2$. When CR_1 is too large, the over-all circuit may break into oscillation. In order to prevent this oscillation, the gain of the amplifier for high frequencies must be reduced by choosing suitable C_3 and R_{11} in the feedback-loop between tubes V_3 and V_4 in Fig. 2. Therefore, it is desirable that the value of CR_1 is small. On the other hand, a large value of CR_1 is required to make the statistical fluctuation of the output voltage small. Then, the value of C was so determined that the statistical fluctuation for the minimum intensity of the range used usually was adequately small.

The number of quanta absorbed per second in the ionization chamber can be estimated from the potential developed across the resistance R_1. When the chamber is filled with air, a quantum detected by the chamber will produce a pulse of about 250 unit electronic charges[5)], because a very large portion of the radiation detected with the chamber is CuKα and CuKβ, as will be shown later. If n quanta be absorbed in the chamber per second, the potential of V volts developed across the resistance R_1 is approximately given be

$$V=250neR_1\ .$$

Since the fluctuation of the charge of a pulse produced by a quantum of CuKα radiation is small, the fractional fluctuation of output voltage V is approximately

$$\frac{\delta V}{V}=\frac{1}{(2nCR_1)^{1/2}}=\left(\frac{250e}{2CV}\right)^{1/2}\approx\frac{4.5\times10^{-9}}{(CV)^{1/2}}\ ,$$

where C and V are expressed in fared and volt respectively, and δV is the standard deviation of V, provided that the X-ray source is kept constant. When one wishes to maintain the fluctuation of intensity of the X-ray source below the order of 0.1%, it is desirable that the statistical fluctuation of output voltage of the ionization chamber is of the order of 0.01%, namely:

$$\frac{\delta V}{V}\approx\frac{4.5\times10^{-9}}{(CV)^{1/2}}\sim10^{-4}\ .$$

When the horizontal divergence of the incident beam was limited to 0.5° by the slit and the X-ray tube was operated at 4 mA, 40 kVp full-wave rectification in our apparatus, the output voltage of the ionization chamber was about 1 volt. Therefore, we chose 100 $\mu\mu$F for C_2. When the output voltage of the chamber is larger than 1 volt, we have

$$\frac{\delta V}{V}<4.5\times10^{-4}\ .$$

Thus the above requirement is satisfied. Of course, the increase of the standard deviation by monitoring would be negligible, when the number of photons detected by the counter is taken for a fixed time-interval.

§ 4. Response of Ionization Chamber for Wavelength

We shall here discuss the response of the ionization chamber in case when a Cu-target X-ray tube is used. As the total number of X-ray photons detected with the ionization chamber is kept constant in the present method, the intensity of CuKα varies with the spectrum of the beam from the X-ray tube. Since the spectrum of the beam depends upon the X-ray tube voltage, it is necessary to regulate it. However, the fluctuation of the X-ray tube voltage is allowed to a certain extent, if the ionization chamber has such a response for wavelengths that the intensity of continuous radiation detected by the ionization chamber is small in comparison with

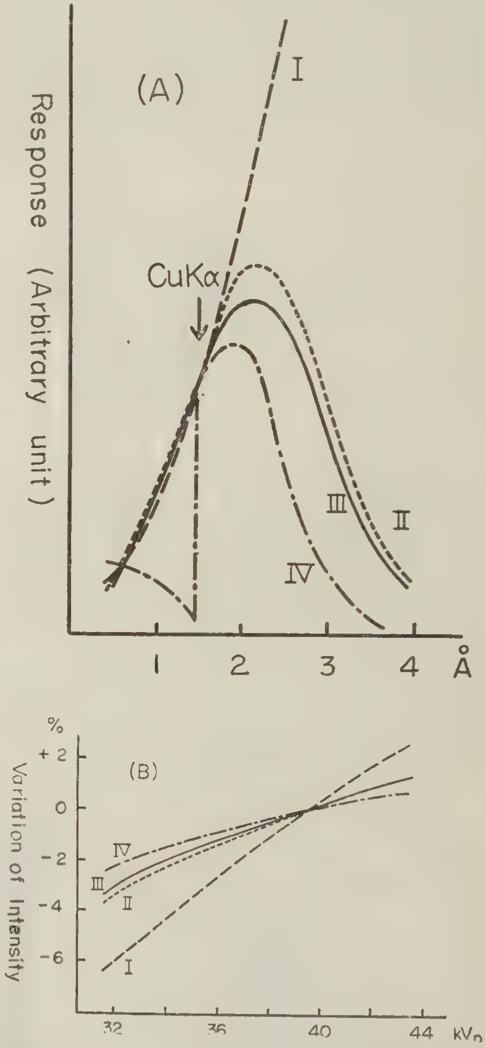

Fig. 5. (A): The response of the ionization chamber calculated from the absorption of air and transmission of the windows of the tube and the chamber, provided that the chamber was filled with air of one atmospheric pressure and that the absorption of Mylar window of the chamber was neglected. The response were normalized for CuKα (1.54 Å).
(B): X-ray tube voltage *versus* intensity of the diffracted beam with X-ray tube stabilized by using the ionization chamber as a monitor. The scintillation counter with a pulse height analyzer was used in intensity measurements. The curves in (A) and (B) were obtained in the cases shown in Table I.

that of characteristic radiation.

In practice, the response of the ionization chamber filled with air for shorter wavelengths than that of CuKα is low, since the length of the plates in the direction of incident beam, which is limited by the space on a goniometer, is about 3 cm. The response for longer wavelengths is reduced by making the window of the X-ray tube thicker or by inserting an Al foil between the chamber and the X-ray tube. Fig. 5 (A) shows the response calculated from the absorption by air and the transmissions of the window of the tube and of the foil inserted, when the length of the plates is 2.5 cm. The curves in this figure were obtained in the cases as shown in Table I. Fig. 5 (B) shows the curves of X-ray tube voltage *versus* intensity of (110) peak of polyethylene specimen in the cases listed in Table I with the X-ray tube stabilized by using the ionization chamber as a monitor. The intensities were measured by a scintillation counter with a pulse height analyzer and a 20μ Ni filter, excepting curve IV for which a 10μ Ni filter was used. The same results were also obtained when the intensities were measured with the balanced filters. It is seen from Fig. 5 that the slope of the curves of X-ray tube voltage *versus* intensity of diffracted beam becomes smaller, as the ratio of the intensity of CuKα to that of the continuous radiation detected by the ionization chamber is increased by inserting a suitable foil or by using an appropriate foil as the window of X-ray tube.

Table I. Description of the curves in Fig. 5.

Curve in Fig. 5	Window of X-ray tube	Inserted foil between tube and chamber
I	Be (0.125 mm)	None
II	Be (0.125 mm) +Mica (0.013 mm)[7]	None
III	Be (0.125 mm)	Al (18μ)
IV	Be (0.125 mm)	Ni (10μ)

In a usual apparatus, the tube current and the tube voltage are regulated, and if high stability of them is obtained by the use of a sealed-off tube, good stability of the X-ray beam will be achieved, as will be seen later. But it is difficult to regulate the tube voltage strictly. In the stabilizer described here, the strict regulation will not necessarily be required. If the X-ray tube is operated at 40 kVp and the tube voltage is stabilized within ±1%, the fluctuation of intensity can be limited to ±0.1%, as can be seen from Fig. 5 (B). The use of line voltage regulator may be sufficient to obtain the stability stated above, though it cannot keep the peak voltage constant.

§ 5. Results

In order to check the ability of the chamber for stabilizing the intensity of diffracted beam, the counter arm of the diffractometer was set at the angle of the (110) peak of a polyethylene specimen and the number of counts detected in a fixed time interval of 16$\frac{2}{3}$ sec was recorded 20 times in every half an hour. The mean, $\bar{n}$, of 20 readings and the variance S^2 about the mean were calculated. These results for the demountable X-ray tube and for the sealed-off X-ray tube are respectively shown on the left-hand sides of Table II. In using the demountable tube with the window of 0.125 mm Be foil, an 18 μAl foil was placed between the X-ray tube and the ionization chamber, as described in § 4. Since the window of the sealed-off X-ray tube was Be 0.12 mm+Mica 0.013 mm, no material was placed between the tube and the chamber. In both cases, the primary voltage of a high tension transformer was stabilized by a ferro resonance type voltage

regulator, whose stability was ±1%, as shown in Fig. 1. Both these X-ray tubes were operated at 40 kVp full-wave rectification. On the right-hand sides of Table II are shown the results obtained by using a tube current stabilizer in place of the stabilizer using the ionization chamber as a monitor.

The stability of the demountable tube is proved by the stabilizer using an ionization chamber as a monitor, so that the fluctuation of intensity cannot be distinguished from statistical fluctuation, because its standard deviation is expected to be $(\bar{n})^{1/2}$, when the increase of variance by monitoring can be neglected. When the demountable tube was used with the current stabilizer, the variance S^2 about the mean was very large, and high stability could not be obtained.

For the sealed-off X-ray tube, the difference between the current stabilizer and the stabilizer using the ionization chamber as a monitor cannot be clearly recognized because of the disturbance caused by the statistical fluctuation. Although the larger fluctuation of $\bar{n}$ in the use of the former stabilizer was found, it might be due to the fact that the tube current was regulated only within ±0.3% by this stabilizer.

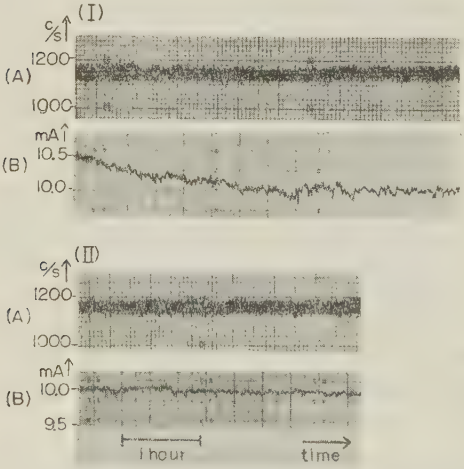

Fig. 6. (I). (A): The intensity of diffracted beam recorded by counting-rate meter; (B): The tube current of demountable X-ray tube recorded continuously at the same time, when the X-ray tube was stabilized by using the ionization chamber as a monitor. Both (A) and (B) were recorded with the time constant of 4 sec.

(II). The results obtained for the sealed-off X-ray tube under the same condition as (I).

When the X-ray tube output was stabilized by monitoring the ionization chamber, the diffracted X-ray intensity was also recorded by the counting-rate meter and the fluctuation of X-ray tube current was recorded at the same time. The results for the demountable tube are shown in Fig. 6 (I) and for the sealed-off tube in Fig. 6 (II). The tube current in the demountable tube was reduced from 10.5 mA to 9.8 mA during the first two hours, and then became roughly stationary for the rest, but its fluctuation was still larger than that of the sealed-off tube. This seems to come from the vacuum condition of the tube. On the other hand, the tube current in the sealed-off tube was nearly constant. This fact means that considerably good stability can be obtained by a current stabilizer for a sealed-off X-ray tube.

As described in § 2, the increase of variances due to using the ionization chamber as a monitor could not be found in these experimental results, as shown in Table II, because the variances S^2 are nearly equal to the theoretical values, namely to $\bar{n}$ for unmonitoring system. (The variances calculated from 20 readings were a little smaller than those expected theoretically. This tendency was also seen in the measurement of a single crystal used as a specimen and cannot be understood theoretically.) These results were obtained under the condition that the output voltage of the ionization chamber was about 1.5 volts. It is an advantage of this method that measurements can be carried out for a shorter time, since the increase of variances by monitoring is negligible.

When an NaCl single crystal was used instead of polyethylene as a specimen, the slow variation in the intensity of the (200) reflection was observed. (In this case, a receiving slit of 1′ was used, and the intensity was attenuated by an Al foil placed in front of the detector, so that the output voltage of the ionization chamber was 1.5 volts.) The result is shown in Table III. It took ten minutes to obtain 20 readings. The variances S^2 calculated from the 20 readings were the same as those in the case of polyethylene specimen, so that these variances S^2 are not given in Table III. This fact shows that the fluctuation in a short time does not occur. However, the variances were calcu-

where $\bar{n}$ is the mean of the 20 readings.

lated from ten values of $\bar{n}$ which were obtained in every 30 minutes. They were 7672 for the demountable tube and 1771 for the sealed-off tube respectively. The variance in the same condition as before is theoretically expected to be $\bar{n}/20$. The fluctuation except for the statistical seems to be equal to the root of difference between the observed and the theoretical values, so that, the fractional fluctuation would be 0.41% for the demountable tube and 0.14% for the sealed-off tube, respectively. These fluctuations seem to be caused by some disturbance such as the wandering of focal spot on the target.

Acknowledgements

We wish to express our sincere thanks to Mr. Y. Hujihara, Mr. K. Katayama and Mr. H. Suita for their interests and discussions. We further appreciate the valuable and kind assistance of Mr. M. Shiojiri in carrying out the present experiment.

A New Fine Focus X-ray Tube

By Yoshihiro KAMIYA

Physical Institute, Nagoya University, Nagoya, Japan

(Received June 4, 1959)

A fine focus X-ray tube of the new type was constructed. The electron gun has double wehnelt cylinders. The size of the X-ray source was measured by means of an X-ray pinhole camera. The size of the source becomes very small for the positive value of the bias voltage on the inner cylinder with which the image of the filament is formed on the anode. The finest X-ray source obtained is 40μ in half width and 400μ in length. The peak specific loading is about 8×10^5W/cm^2 at the filament temperature 1,700°K which assures long life of the filament.

§ 1. Introduction

The recent development of crystal physics demands intense X-ray sources. For this purpose the rotating anode tubes were introduced making the specific loading 5–10 times that of the stationary anode$^{1-2)}$. The high specific loading is also accomplished by reducing the size of the X-ray source to about $50\,\mu$. Such a small source can be obtained by the magnetic focus or by the electronstatic focus. Many investigators used the former$^{3)}$. However, the latter is more convenient for its simple construction and easy operation.

Ehrenberg and Spear⁴⁾ studied the electrostatic system and obtained the fine circular focus about 35 $\mu\phi$ in half width with the total current 0.5 mA and the specific loading 1.1×10^6 W/cm². They used the electron gun of telefocal type provided with a guard cylinder which is at the potential of the filament. Gay et al.²⁾ used the rotating anode and obtained the rectangular focus, the width of which can be varied from 2 mm to 50 μ. Tomita⁵⁾ studied fine rectangular focus and attained the half width 40 μ. Hosemann⁶⁾ developed the positive bias method, while all of the above authors applied negative bias to Wehnelt cylinder. He obtained relatively large focus about 130 μ in half width having clean cut edge.

Fine focus X-ray tubes with high loading are also required in the field of medical radiography, particularly in enlargement radiography as developed by Takahashi et al.⁷⁾ and others⁸⁾. The fine focus is required for high resolution of radiograph and the high specific loading for short exposure time, which indespensable for living objects because of the inevitable movements.

In order to construct X-ray tubes adequate for medical radiography and also for crystal physics, we investigated the electron gun with double Wehnelt cylinders. We studied in detail the focusing characteristics of the gun and obtained rectangular focus of half width 40 μ and length 400 μ. The specific loading was about 5.0×10^5 W/cm² at relatively-low temperature of the filament.

§ 2. Experiment

A demountable X-ray tube with rotating copper anode was used in the present experiment. Although the effect of rotation is small for fine focus, we adopted the rotating anode for safety at large focus. The electron gun consists of a spiral filament, an inner Wehnelt cylinder and an outer Wehnelt cylinder (Fig. 1). The former cylinder has a rectangular aperture 8 mm×3 mm and the latter has a circular hole 10 mmϕ. The spiral filament is thoriated tungsten wire of 0.1 mmϕ. The outer diameter of the spiral is 1 mm and the length 3 mm. The filament was set parallel to the aperture of the inner cylinder. To avoid the misalignment caused by thermal deformation, the filament was heated in air before setting it in the cylinder. Parameter h, which indicates the position of the filament (Fig. 1), was measured by means of a micrometer screw of pitch 0.67 mm. Distance l and L (Fig. 1), the length of the gun and the gun-anode distance, can be varied without breaking the vacuum and are measured by the indicator outside the vacuum. The axis of the gun was set vertically and the whole gun assembly can be rotated about the axis.

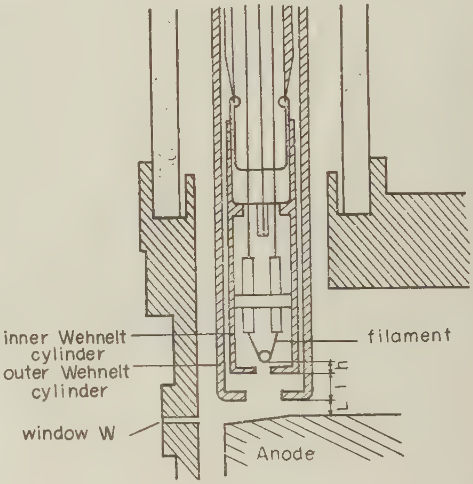

Fig. 1. Schematic drawing of the electron gun.

Bias voltages V_i and V_0 are applied to the inner and the outer Wehnelt cylinder, respectively. They were varied between ±800 V and were supplied from dry cells. Full wave rectified high tension of 30 kV was used without a filtering condensor. Most experiments were carried out at the heating current of the filament 4 A which corresponds to the filament temperature about 1,700°K, as measured by an optical pyrometer. The central ray of the X-ray beam leaves the target at an angle 6° (0.1 rad) and emerges horizontally from window W of the tube. Thus the apparent length of the X-ray source is demagnified by one tenth.

Pinhole cameras were used to study the shape of X-ray source. The magnifications of cameras were 5 and 10, and the diameter of the pinhole was 8 $\mu\phi$. A pinhole of 15 $\mu\phi$ was first bored on a lead plate by a steel pin which was pointed carefully by an oil stone and examined by a microscope. Then,

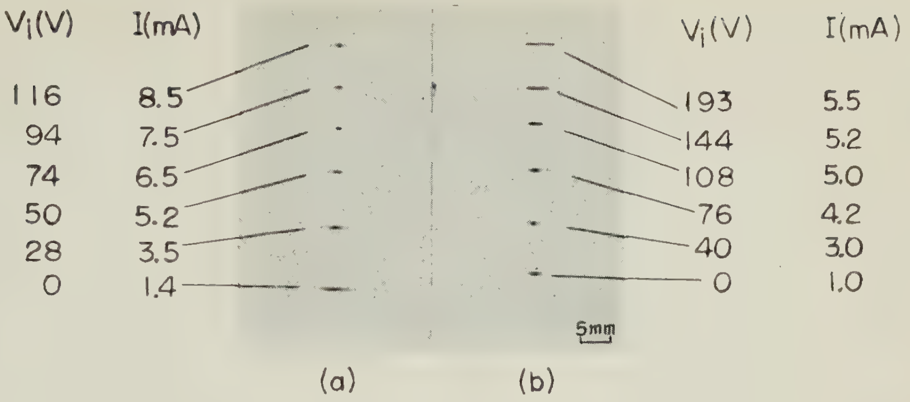

Fig. 2. Sets of pinhole images. Mag. ×10

Geometrical parameters
a) $h=0.54$ mm, $1=11.0$ mm, $L_w=10.0$ mm, $V_0=-130$ V
b) $h=0.54$ mm, $1=11.0$ mm, $L_w=4.0$ mm, $V_0=-680$ V

the plate was hammered on a glass plate until the hole became $8\,\mu\phi$ which was adequate for our purpose.

Many sets of pinhole images were photographed to study the effect of various parameters on the shape of the X-ray source. In every set, V_i was varied keeping all other parameters constant. The image recording was made on Fuji X-ray film with the exposure about 150 mA. Sec. Two examples of the set are reproduced in Fig. 2. In this figure the horizontal and the vertical direction correspond respectively to the width and the length of the rectangular X-ray source, the length being demagnified one tenth due to the geometrical condition mentioned before.

For the detailed study of the intensity distribution along the width of the source, we adopted a steel slit instead of the pinhole, the gap of the slit being about $10\,\mu$. We used Fuji Process Plate in this case because it has low fog-density and small grain size. By microphotometory we obtained the intensity distribution and then determined width w (1/2) at $I/I_0=0.5$ and that w(1/10) at $I/I_0=0.1$, where I_0 is the intensity at the center. In the microphotometory we used short exposure so that the intensity is proportional to the darkness.

In the enlargement radiography, we used the resolution of test-charts as a conventional specification of X-ray source. A test-chart consists of three tungsten fibers of equal diameter, set parallel to each other with gaps nearly equal to the diameter. The diameter used was 13, 17, 20, 25 etc. μ. We took projection micrographs of test-charts at direct magnification about 4, setting the fiber horizontally and vertically. The resolution was indicated by the minimum resolvable

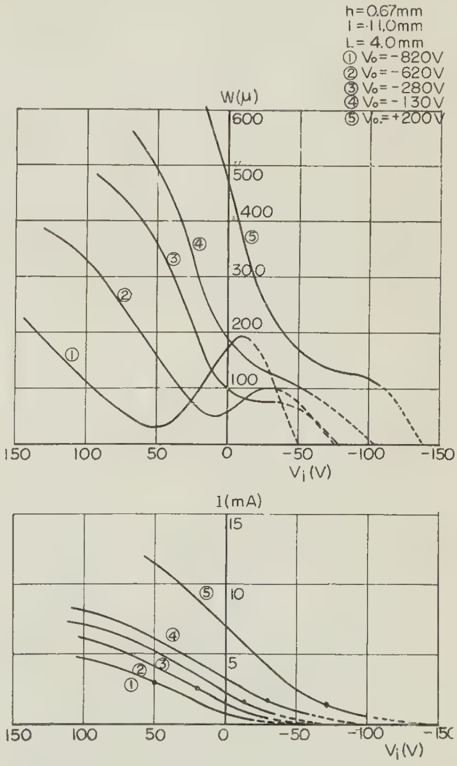

Fig. 3. Width w and current I as the function of V_i.

diameter of the fiber.

§ 3. Results

Effect of bias voltages. Pinhole image in Fig. 2 means that the width of the source varies with V_i, while the length remains almost constant. This variation is caused by change of strength of the cylindrical lens which is formed by the rectangular aperture of the inner Wehnelt cylinder. We estimated the width w from the size of the image. Fig. 3a gives a typical example of the variation of w with V_i, taking V_0 as a parameter. Width w decreases with decreasing V_i and reaches a minimum (Curves 1 and 2 in Fig. 3a, see also Figs. 4 and 5). The minimum is interpreted as the image of the filament (Sec. 4). Width w and voltage V_i at the minimum are denoted by w_m and V_{im}, respectively. The increase of the width with the further decrease of the bias voltage is due to defocusing of the image. Near the *cut-off* the width decreases again due to the action of emission area limiting (Sec. 4). A plateau appears instead of the minimum, when the image is formed near the *cut-off* (Curves 3,4 and 5 in Fig. 3a).

As voltage V_0 is lowered, voltage V_{im} becomes higher and width w_m becomes smaller. This tendency was observed independent of the geometrical parameters (Figs. 4 and 5) and is interpreted in Sec. 4. Variation of beam current I with voltage V_i is given in Fig. 3b. On each curve in Fig. 3b, voltage V_{im} is marked by a circle. The current at V_{im}, which is denoted by I_m, is almost independent of V_0. This tendency was also observed for other geometrical parameters.

Effect of geometrical parameters. For usual triode X-ray tubes, the adjustment of *h*, the parameter indicating the position of the filament, is critical in obtaining fine focus. If parameter *h* is not adequate, a required fine focus cannot be obtained at any value of bias voltages. In our tube, however, it is not critical because at a fixed valued of *h* we can make width w_m small enough by applying adequate V_0 (Fig. 4). The effect of bias voltage V_i becomes more remarkable

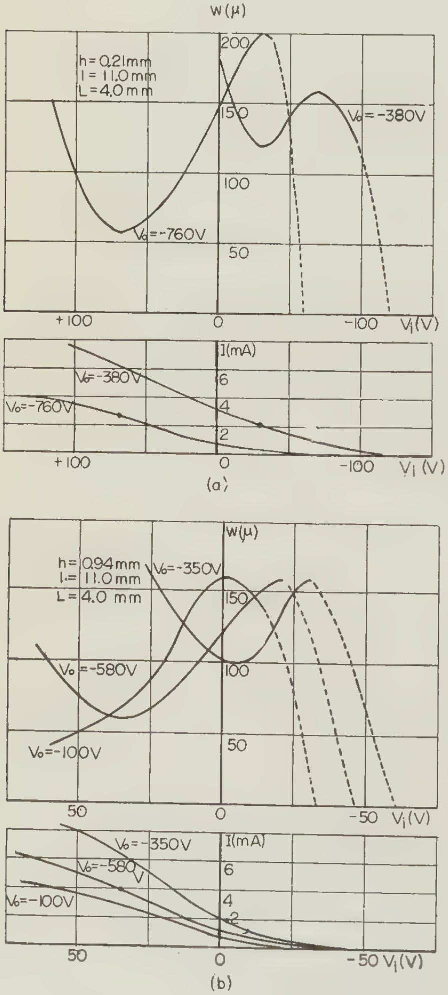

Fig. 4. Effect of *h* on gun characteristics.

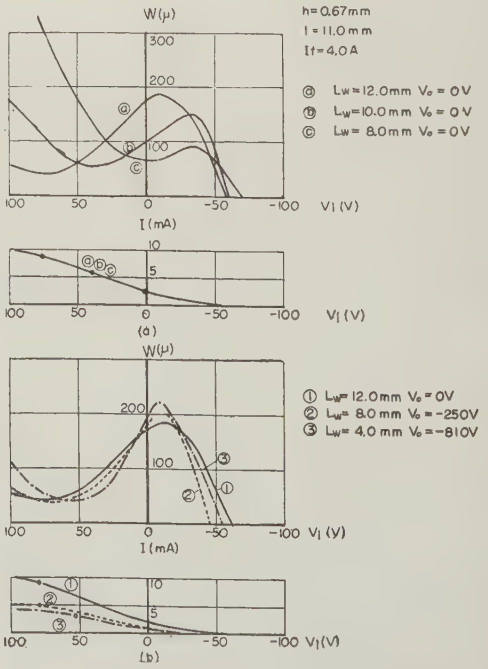

Fig. 5. Effect of *L* on gun characteristics.

for larger h. Therefore, the scale of the abscissa in Fig. 4a is taken twice that of Fig. 4b.

The diagram showing the relation between w and V_i depends on the value of L (Fig. 5a). We found that the dependency can be almost completely canceled by the proper change of V_0 (Fig. 5b). However, this cancellation is only on the w-V_i diagram and the total beam current available at the minimum spot I_m varies with L (Fig. 5b). Thus by increasing L, it is possible to increase the total beam current without accompanying any remarkable change in w-V_i diagram. This relation is important in the practical design of the tubes.

The length of rectangular focus varies with l, the parameter indicating the length of for the gun, while it remains almost constant the variation of the other parameters. Utilising this effect, we obtained proper ratio 10:1 of the length to the width of the rectangular focus.

Finest focus obtained in the present experiment. Rectangular focus of order 400 μ×40 μ was obtained at various combinations of the parameters (Figs. 3, 4 and 5). Typical examples are $L=10$ mm, $l=13$ mm, $h=0.34$ mm, $V_0=-68$ V, $V_i=120$ V and $L=12$ mm, $l=11$ mm, $h=0.54$ mm, $V_0=0$ V, $V_i=80$ V. At these combinations, total current of about 10 mA is available at the filament temperature 1,700°K. So far as we tried, the width less than 40 μ was not obtained.

According to Oosterkamp's formula,⁹⁾ the surface temperature of the stationary anode turns out to be 800°C for specific loading 7×10^5W/cm². In the present experiment, the specific loading less than 3×10^5W/cm² caused no damage on the anode, while that more than 6×10^5W/cm² produced faint trace on the rotating anode surface after several hours. Total current of 10 mA corresponds approximately to specific loading 8×10^5W/cm² which causes damage on the anode.

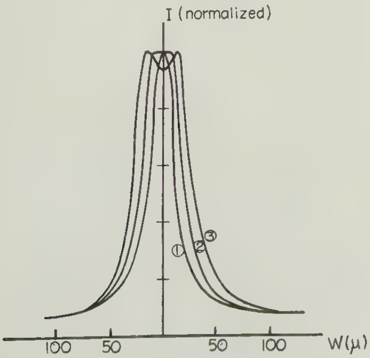

Fig. 6. Intensity distributions on an anode.

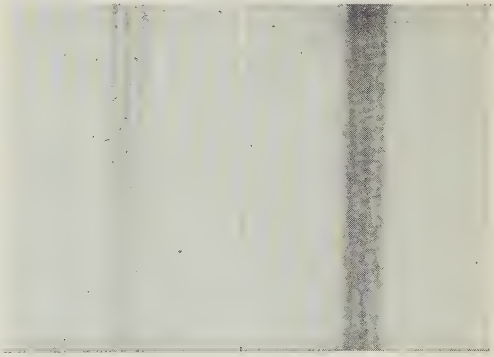
Intensity distribution along the width and resolution of the test-chart. The analysis of slit photographs reveals the exact intensity distribution along the width (Fig. 6). For the finest focus, the half width is 35 μ and width at one tenth intensity is 140 μ. The width of the finest focus measured by the pinhole image is 40 μ. Thus the half width is nearly equal to the width obtained from pinhole image.

Test-chart of 13 μ was resolved by the finest focus in the present experiment (Fig. 7). The chart of 13 μ would not be resolved if the source were homogenous and 30 μ wide¹⁰⁾ or it had Gaussian distribution of the intensity with the half width 30 μ. The resolution of 13 μ in the present experiment may imply that the intensity distribution in our source has a very sharp peak.



(a) (b)

Fig. 7. Projection X-ray micrographs of test-chart 13μ.

(a) and (b) represent respectively the resolutions corresponding to the width and the length of X-ray source.

Grid current. Since a positive voltage is usually applied to the inner Wehnelt cylinder in the present tube, a part of the electrons from the filament flows to the inner cylinder, causing a considerable grid current. The grid current varies with the cylinder voltage as shown in Fig. 8. For the normal operation the grid current is about 20 mA and its power is about 2 W. This caused no trouble in the present experiment.

§ 4. Mechanism of focusing

So far the fine focus was usually obtained by negative biased triode systems. The triode system is equivalent to an immersion lens[11]. For the fine focus X-ray tubes, it is advantageous to make the demagnified image of the filament on the anode.[4] Besides the focusing action, this type of the immersion lens has the action of limiting the emission area of a filament and, at the extreme case, the electron beam is "*cut-off*". Thus the proper combination of focusing action and the action of the emission area limiting may produce a very fine spot on the anode. When, however, this type of the gun is used near the *cut-off* to make the emission area very small, the focusing action of the lens is too strong to form the image on the anode. Therefore, the spot on the anode cannot be very small. Moreover, the space charge formation which limits the emission area reduces the current density at the surface of the filament. Thus a high filament temperature is required to obtain a sufficient beam current. This makes the life of the filament short.

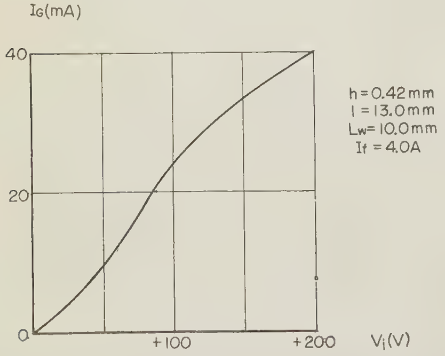


Fig. 8. Grid current I_g an the function of V_i.

When a positive potential is applied to Wehnelt cylinder, a part of the electrons flows to the cylinder (Fig. 9). As a result the area of the filament which can emit electrons outsides the cylinder is limited. The control of the emission area by the bias voltage is not so easy as that for the negative bias. The field before the filament is stronger than that of the negative bias. Thus a large current density is available on the filament surface at low temperature. The positive bias is adequate also to produce a fine focus because it gives high demagnification factor.

The magnification factor M for a unipotential lens is given by $M=f/a-f$, where f is the focal length and a the distance between lens and object. In order to decrease the magnification factor, large a and small f are desireable. The same argument is valid for the immersion systems. In the system of Ehrenberg and Spear, the magnification factor is 1/3. For the negative bias system a short focal length is obtained by heavy bias. When, however, the heavy bias is applied, the principal plane of the lens comes near the filament making a small. The short focal length does not always improve the magnification factor. It is difficult to obtain a magnification factor better than that of Ehrenberg and Spear. For the positive bias,

T$_f$: temp. of filament

on the other hand, the principal plane lies far from the filament making a large. By combining the focusing action of the outer cylinder and the action of positive bias of the inner cylinder, it is possible to obtain a higher demagnification factor than that of the usual negative biased gun.

§ 5. Discussions

Comparison with other fine focus tubes. Fine focus tubes given in references are listed in Table I. The tube of Ehrenberg and Spear gives small half width and low background. However, it is used only at fine focus. In the tube of Gay et al. the width of the rectangular focus can be varied. Since, however, they obtained the fine focus near the *cut-off*, the total current may be small even at high temperatures of the filament. On the other hand, we obtained the fine focus at the image of the filament. Thus the available total current is much larger than that near the *cut-off*. This means long life of the filament which is particularly important for sealed-off tubes for medical radiography. To make the focus very small, we applied the positive bias to the inner cylinder. In this respect our tube is similar to that of Hosemann.

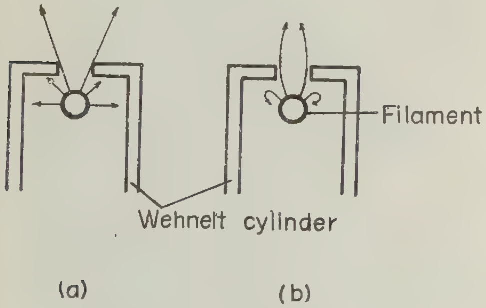

Fig. 9. Illustration of effect of emission area limiting.
a) positive bias
b) negative bias

One of the advantage of the negative bias is the stable performance with the auto-bias method. An auto-bias method is also possible for the positive bias. Our cathode system is a little complicated because it has two Wehnelt cylinders. However, it does not necessarily required two bias voltages. By adopting a proper geometry, we can short-circuit one of the cylinders to the filament or two cylinders to each other.

Further possibility of the fine focus tubes. For the fine focus tube with high loading, the combined action of focusing and emission area limiting is used. It is noteworthy that Ando et al.[12] reported the oxide-cored cathode which emits the electrons from area of the order 30 $\mu\phi$. If such a cathode is used for obtaining a fine focus, the action of the emission area limiting is not required. They showed that the immersion lens can produce sharp image of the cathode. This indicates that the aberrations of the immersion lens is not very large. Thus it may be possible to obtain the focus much finer than 40 μ by the electro-static systems.

Electron Microscopic Observation of the Superlattice in Serpentine*

By Yoshihiro KAMIYA, Minoru NONOYAMA and Ryozi UYEDA

Physical Institute, Nagoya University, Nagoya, Japan

(Received June 3, 1959)

The superlattice of spacing about 90 Å in Yu Yen Stone, a variety of serpentine, was studied by electron microscopy (Brindley et al: Acta Cryst. **11** (1958) 99). About 500 electron micrographs showing fringes corresponding to the superlattice were taken, many of which were through-focus series. The intensity profile of fringes varies with the amount of defocus and it also varies from specimen to specimen even at the exact focus. These phenomena are explained qualitatively by theories of image formation. "Extra" terminating half-lines and stepped structures of fringes were studied and it was concluded that the former represent real dislocations in the crystal but the latter are ghosts. The spacing of the superlattice was found not to be constant and this material is not therefore adequate for magnification calibration of electron microscopes (Uyeda et al: J. Phys. Soc. Japan **13** (1958) 461).

§ 1. Introduction

After Menter's[1)] epoch-making experiment with phthalocyanines, several kinds of crystal lattices were observed directly by electron microscopy[2)–6)]. Among them, Brindley et al.[6)] found the fringe system corresponding to the supperlattice in a variety of serpentine mineral, called Yu Yen Stone. Since the spacing of the superlattice is appropriate, *ca.* 90Å, one of the present authors[7)] used it for the magnification calibration of electron microscopes. In the course of the work, various interesting phenomena were observed concerning the intensity profile of the fringe system and imperfections of the superlattice. The present work was carried out to study these phenomena in more detail.

We took about 500 electron micrographs of the superlattice, many of which were through-focus series. We found that the intensity profile of a fringe system changes with the amount of defocus. A more important result is that the intensity profile is not the same for all specimens, even when the micrographs are taken at the exact focus. We interpret these results by theories of image formation. Dislocations and stepped structures of fringes were also studied by through-focus series. We conclude that the former represent real dislocations but the latter, ghosts. The magnification calibration of electron microscopes by the superlattice in Yu Yen Stone is not reliable because the superlattice spacing is not constant.

§ 2. Experimental

Two kinds of samples were used in the present experiment. The first is a variety of antigorite called 'Yu Yen Stone' from Manchuria (U.S. National Museum, No. 94356) and the second, picrolite from Quebec.** Both belong to the serpentine class of minerals. According to Zussman and Brindley[8)], the former has a superlattice of spacing about 90Å and the latter about 40Å. Most of the experiment was carried out with Yu Yen Stone and picrolite was studied only to confirm that it produces fringe systems with spacing about 40Å.

To prepare specimens for electron microscopy, tiny pieces of sample were first ground in an agate mortar, then water was poured into the mortar. Thus finely ground crystallites floated on the surface of the water. A specimen grid with thin carbon film was put on the surface, then removed and dried. In this way the crystallites were attached to the carbon film.

The specimens thus prepared were examined in the electron microscope (JEM5-G, Japan

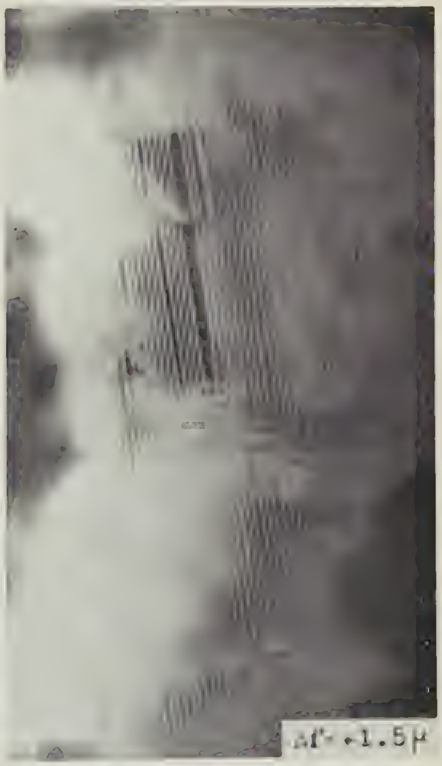

Fig. 3. Irregular spacing. ×80,000

Electron Optics Lab. Co.) operated at accelerating voltages 80 or 100 kv and at a magnification of about ×30,000. Most of the crystallites appeared dark on the screen and did not show fringes. Only those which appeared relatively bright showed fringes. Micrographs were usually taken at ×30,000 with an exposure time of about 10 seconds.

The amount of defocus was estimated from the breadth of Fresnel fringes along the boundary of crystals or supporting film. Crystals were not always flat and they did not always lie in the same plane as that of the supporting film. Moreover, slight astigmatism was sometimes recognized on micrographs. Therefore the estimated values of

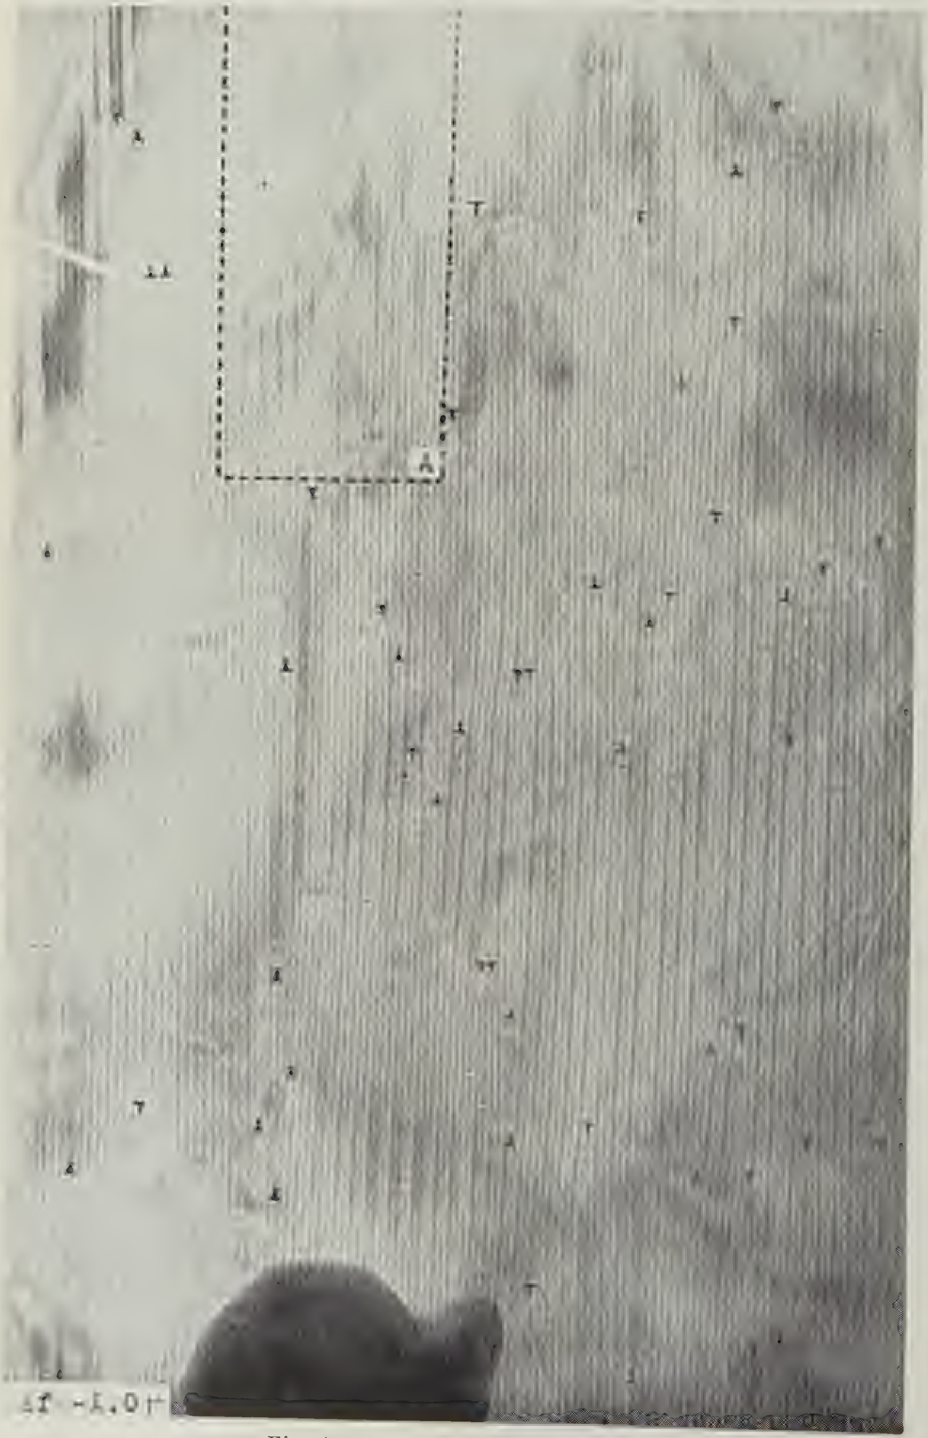

Fig. 4. Dislocations. ×220,000
In Part A fringes are distorted and diffuse.

defocus are not accurate.

§ 3. Explanation of Electron Micrographs

(a) *Regular fringes.* Fringe systems corresponding to the superlattice were observed on most of the micrographs. However, systems containing more than 20 regular fringes were rare. Fig. 1 was taken at considerable

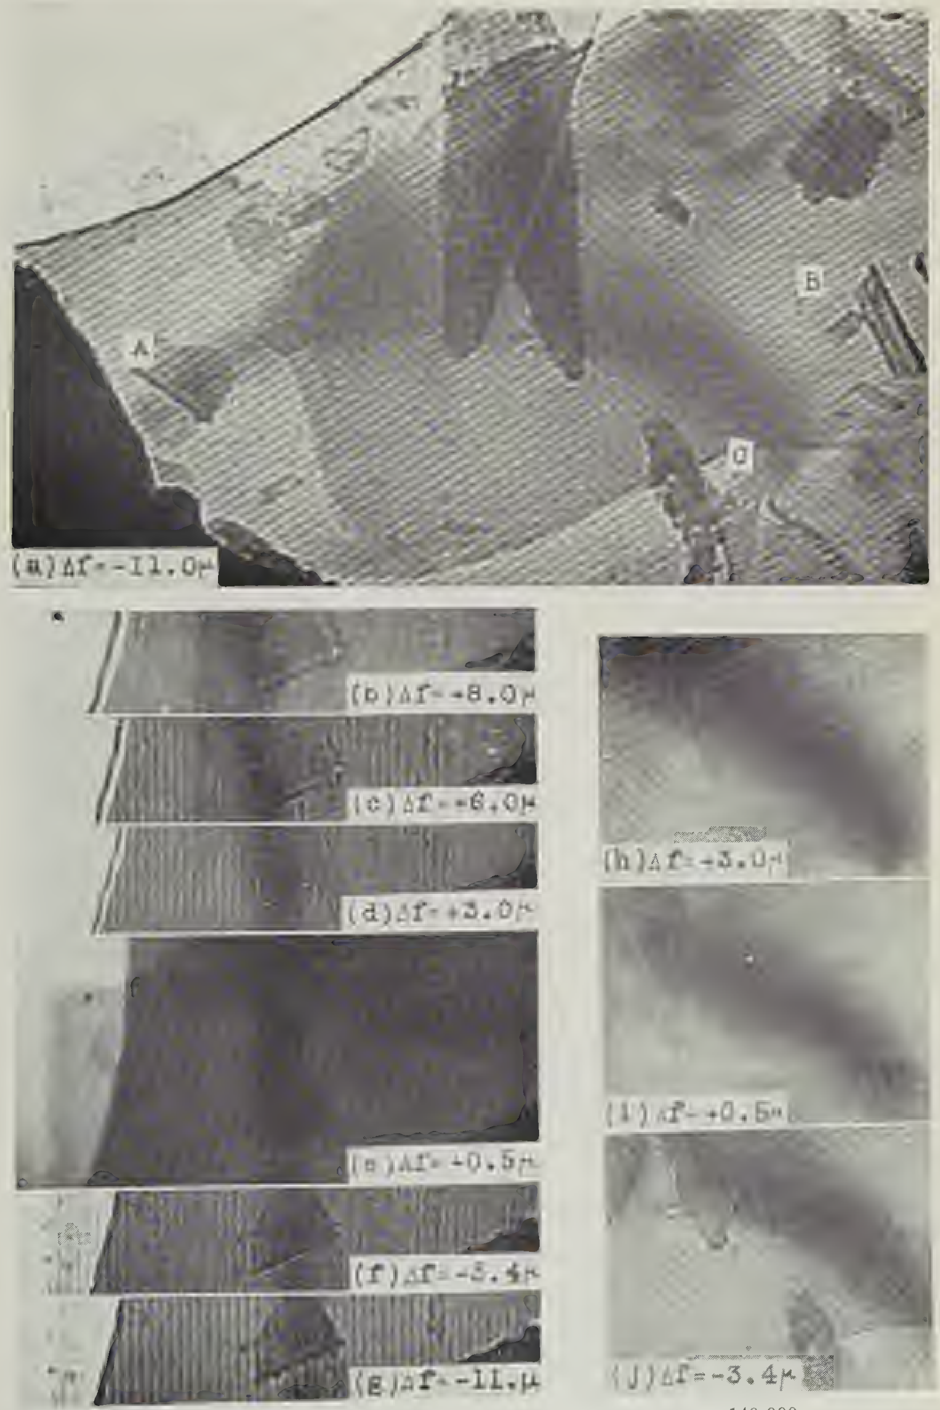

Fig. 5. Through-focus series of regular fringes. ×140,000
(b)–(g): through-focus series of Part A of (a)
(h)–(j): through-focus series of Part C of (a)

defocus. In Part A of the figure, the black and white parts of the fringes appear to have the same width. In the present paper such fringes are referred to as normal. Fig. 5 and 6 give examples of through-focus series of regular fringes.

In Fig. 5 the fringes look almost normal except near the exact focus. However, detailed observation reveals that the intensity profile of the fringe system is not always the same: At Part A of Fig. 5a the fringes are normal (N), at Part B the white lines are sharp (SW), at Part C the white lines are sharp and the black lines split into two (SWp), in Figs. 5d and f the black lines are sharp (SB) and in Figs. 5h and j the black lines are sharp and a weak line appears between two successive lines (SBi). It is most

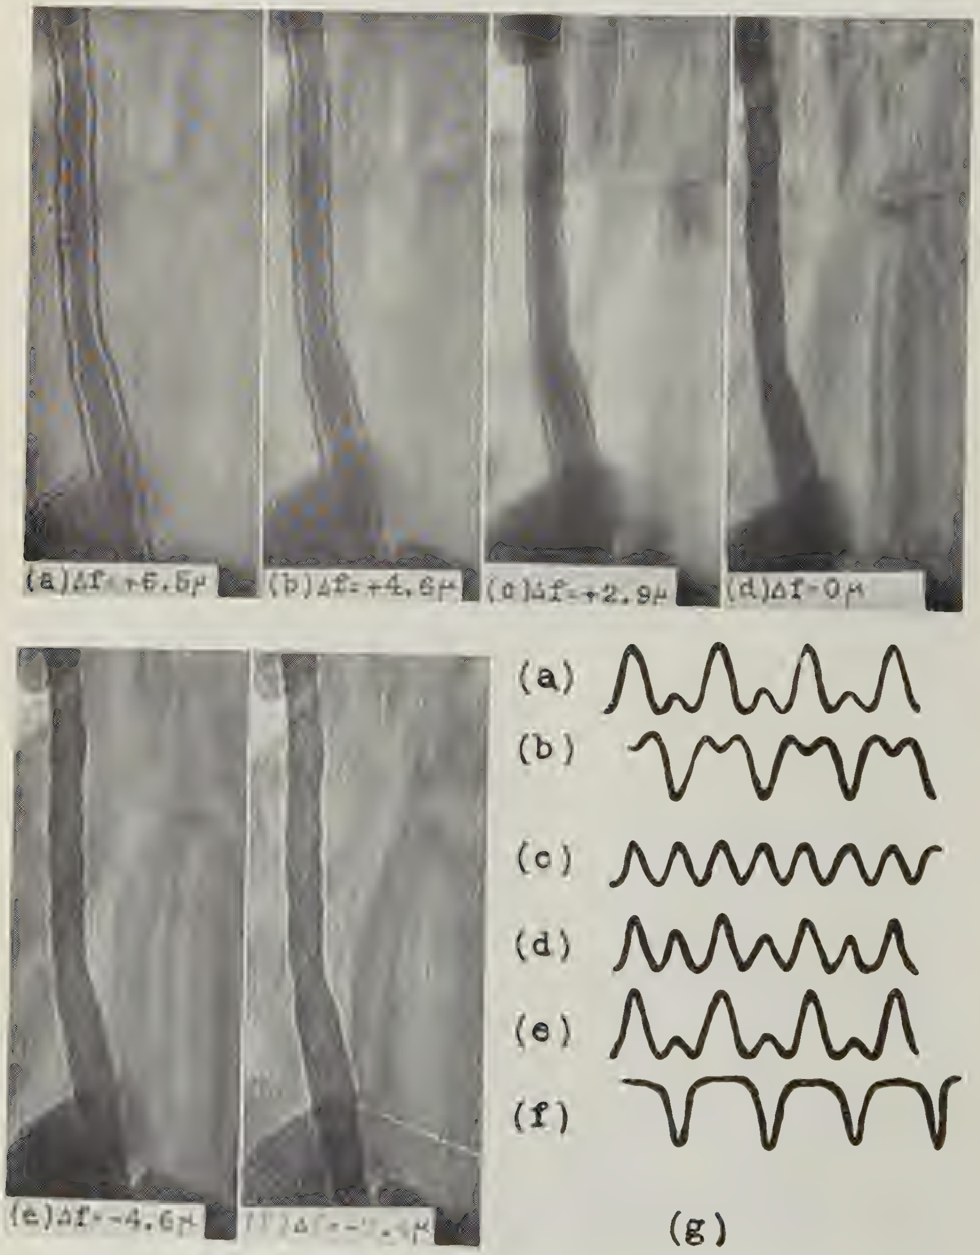

Fig. 6. Through-focus series of regular fringes. ×140,000
(a)-(f): through-focus series.
(g) : schematic illustration of intensity profile.

striking that in Fig. 5e which was taken near the exact focus, the spacing of fringes is one-half that of the normal fringes (H).

In Fig. 6 no normal fringes appear and the variation of the intensity profile is more remarkable than in Fig. 5. Typical intensity profiles are illustrated in the figure. It is noteworthy that the profiles of Figs. 6a and b are similar respectively to those of e and f. The difference of defocus between a and e is about 10μ and that between b and f, 11μ.

The variation of intensity profiles was studied for 14 through-focus series and the results are summarized in Fig. 14. In Fig.

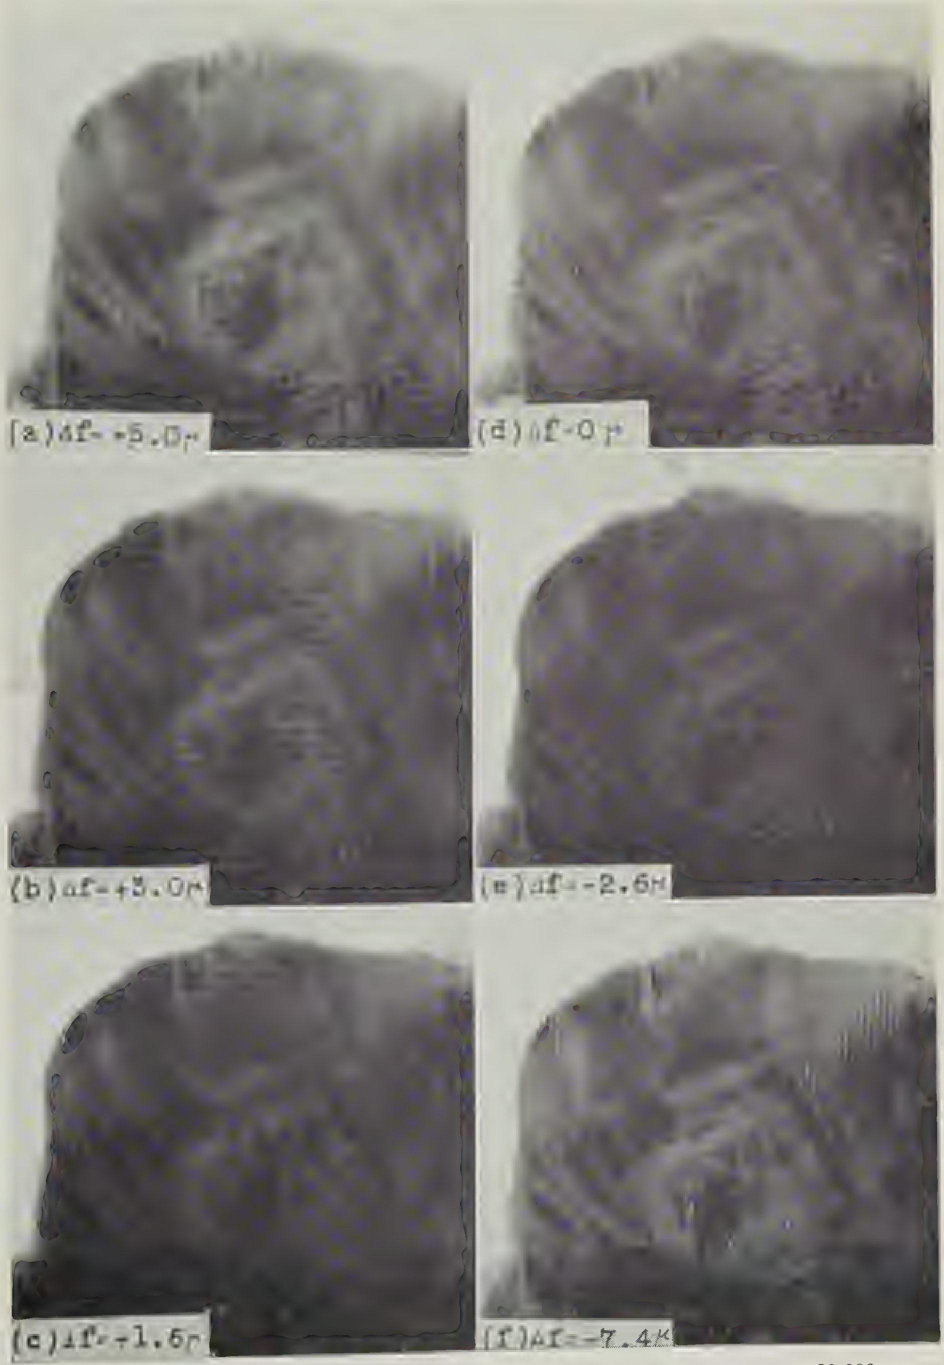

Fig. 7. Through-focus series of fringes disturbed by dark bands. ×80,000

14 we find that:

(1) Intensity profiles vary with the amount of defocus. Normal fringes appear usually in out-of-focus images. Near the exact focus, the contrast of fringes is usually low and the spacing of fringes is often halved. The amount of defocus where normal fringes appear is usually about 5–10μ.

(2) Result (1) gives only the general trend and there are deviations from (1). The manner of variation of the intensity profile is different from specimen to specimen (Fig. 5 and Fig. 6) and at exact focus is not always the same. In an extreme case, normal fringes of good contrast appear at the exact focus (Fig. 7).

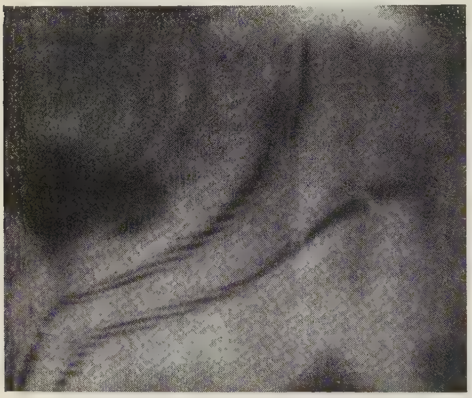

Fig. 8. Extinction contours split up by moiré effect. ×64,000.

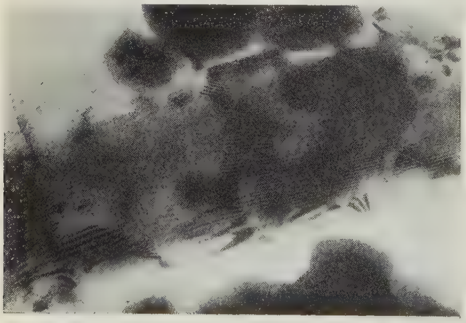

Fig. 9. Moiré pattern. ×60,000

(a) *Irregularities.* Irregularities of fringes may be divided into (a) irregular spacings, (b) dislocations and (c) dark bands sometimes with stepped structures. Figs. 2 and 3 give remarkable examples of irregular spacings. The spacing of the fringes is different from specimen to specimen. We measured the spacing on more that 20 plates, the measured values lying between 80 and 120Å. This in itself does not necessarily imply a variation in spacing, since the magnification of the electron microscope is not very reliable. However, we often found that the spacing is different in different regions of the same plate, for example 92, 97 and 103Å. This proves that the variation of spacing is real. Fig. 12 shows the fringes with the smallest spacing ever observed for Yu Yen Stone (38Å.). This value seems to be true because fringes with spacing 107Å were simultaneously observed on the same plate. Picrolite also produces good fringes (Fig. 13) although as with Yu Yen Stone the spacing may not be constant. In Fig. 13 the smallest spacing is 44Å and the largest 55Å.

In Fig. 4 a number of dislocations are seen. Fig. 11 shows a set of through-focus micrographs of a dislocation.

Dark bands were observed on almost every micrograph. Even in Fig. 5a, showing one of the most regular arrays of fringes, a dark band appears. Fringes in Fig. 6 are also disturbed by dark bands, particularly Figs. 6d, e and f. In these figures the dark bands moved during observation as already described by Uyeda et al⁽⁷⁾. Most of the dark bands move to some extent during observation. On dark bands the intensity profile of fringes is different from that of the other part (Figs. 5a, h, j,; Fig. 10a). The through-focus study in Fig. 10 shows that a stepped structure observed at a certain focus (Fig. 10b) changes gradually to straight fringes (Fig. 10j). Fig. 8 gives another example of dark bands. This suggests that the dark bands are a type of extinction contour.

§ 4. Interpretation and Discussion

(a) *Intensity profile*

Cowley & Moodie⁽⁹⁾ developed the theory of Fourier images of periodic structures and confirmed their results by light optical experiments. According to them, the image of a two-dimensional grating varies with the defocus and when the light source is very far from the grating, as in electron microscopes, the same image is repeated for a defocus

$$\Delta f_0 = d^2/\lambda\,, \tag{1}$$

where d is the spacing of the grating and λ, the wavelength.

The spacing of fringes of phthalocyanine and other crystals as observed by Menter and others[1)-4)] are too small to study the variation of images with defocus. Komoda[10)] reproduced in his paper a series of three through-focus micrographs of Cu-phthalocyanine. The fringes of about 12Å spacing were observed at $\Delta f=-0.2\mu$ and -1.0μ while no fringes were seen at $\Delta f=-0.5\mu$. He interpreted this result in terms of the theory of Fourier images. However, further experiments may be desirable to confirm the result because the experiment is very difficult.

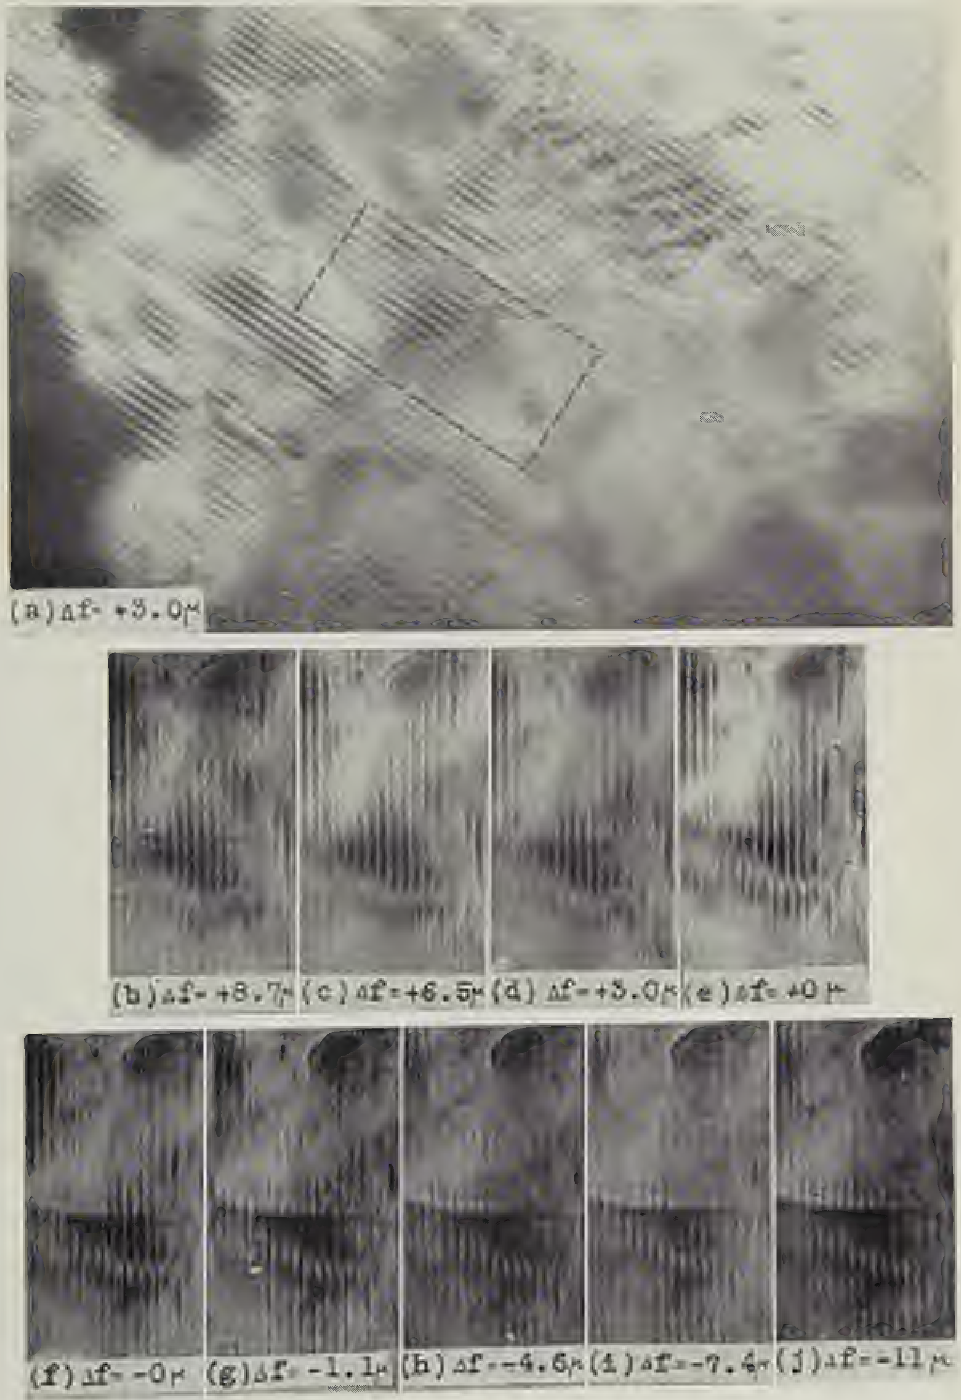

Fig. 10. Through-focus series of stepped structure. × 130,000

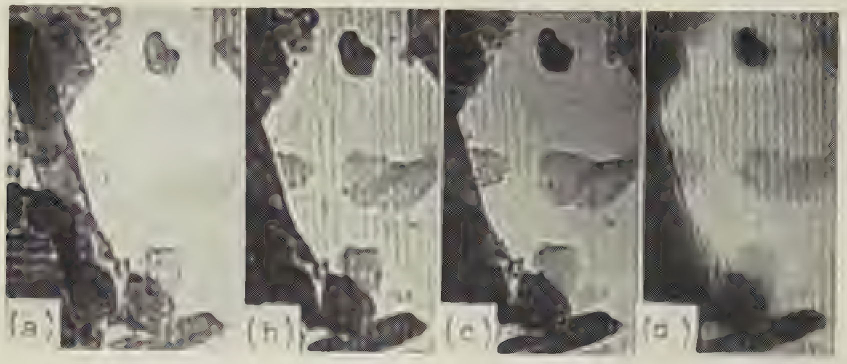
Labaw & Wyckoff[5] studied the fringes from indanthrene scarlet which have spacings of about 20Å. They found that the intensity profile of the fringes appeared sometimes normal, sometimes sharp black etc. similar to those denoted by N, SBi, SW and SWp in the present paper. Labaw & Wyckoff considered that the profile is determined not only by the amount of defocus but also by the crystal thickness and orientation. However, they did not carry out systematic experiments, probably because the spacing was still to small.

Lenz & Scheffels[11] discussed through-focus micrographs of a periodic structure of spacing about 100Å in biological sections. They found that the contrast is low at the exact focus and becomes high out-of-focus. They also found that at a certain defocus a weak intermediate line appears between two successive strong



$\Delta f=-7.4\mu$ $\Delta f=-5.5\mu$ $\Delta f=-3.7\mu$ $\Delta f=+3.4\mu$

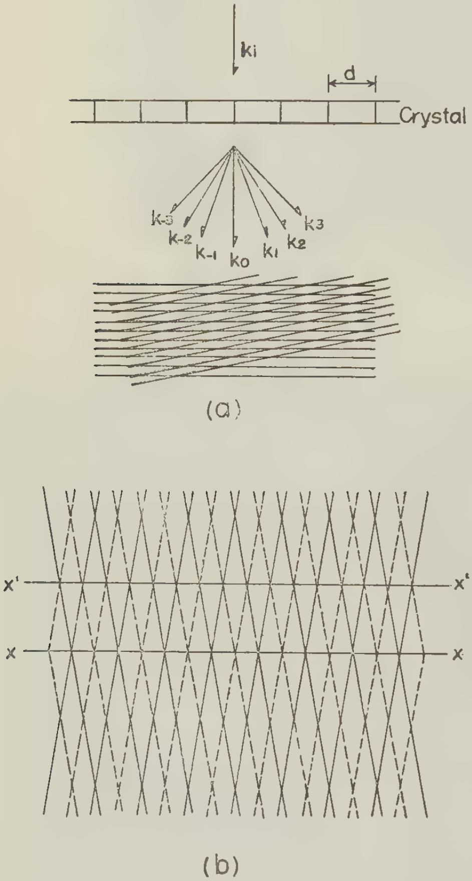
lines. They studied theoretically the defocused image of a phase grating and concluded that the highest contrast is obtained at defocus of $d^2/2\lambda$. This means that the highest contrast appears midway between two invisible images, because a phase grating is invisible at the exact focus and it is again invisible at defocus d^2/λ, according to Eq. (1).

Result (1) of Sec. 3 (a) may be essentially the same phenomenon as that studied by Cowley & Moodie[8)] and others[11)]. The phenomenon may be outlined as follows. When a plane wave falls on a thin crystal, many orders of diffracted waves are simultaneously reflected by the superlattice net-planes. The interference of the 0th order wave and the 1st order wave produces a set of interference fringes below the crystal (Fig. 15a). The interference between the 0th and 1st order and that between the 0th and the -1st order produce two sets of interference fringes (Fig. 15b). What we observe under an electron microscope is a section of the interference fringes on the object plane which is conjugate to the image plane. Since the angle between two sets of interference fringes is $2\theta=\lambda/d$, it is easily understood in Fig. 15b that the same image is repeated with a defocus of $2d^2/\lambda$. When, however, the shift of the image by $d/2$ is overlooked, the repeat period is d^2/λ which is Δf_0 as already given in Eq. (1). The contrast of the image is the highest when plane XX is focused and it vanishes when X′X′ is focused (Fig. 15b). Since the crystal is not very absorbing, it is nearly a phase grating and thus the plane equivalent to X′X′ lies near the crystal, resulting in low contrast at the exact focus. The distance between XX and X′X′ is $d^2/2\lambda$. In the present experiment $d=90\text{Å}$, $\lambda=0.04\text{Å}$ and thus $d^2/2\lambda=10\mu$. This is in agreement with the experimental value 5–10μ given in result (1).

In the present experiment, several orders of reflections are simultaneously excited, as is confirmed by selected area diffraction. Therefore, not only the 1st and the −1st order waves, higher order waves also take part in the formation of interference fringes. The observed variation of intensity profile with defocus may be qualitatively interpreted as arising from the multiple interference of several diffracted waves. We do not here go into the detailed analysis of the observed intensity profiles. The theory of multiple interference, which corresponds to the automatic Fourier synthesis[5)], will be published elsewhere.

It is usually believed that an in-focus image is the most exact image. If this is correct, result (2) means that the superlattice structure of Yu Yen Stone is not always the same. This may partly be correct. However, it is hardly believable that fringes of so high a contrast as those in Fig. 7 are the most exact image, because, as was already pointed out by Brindley et al.,[6] the atoms of Yu Yen Sione are Si, Mg- and O and they are distributed more or less uniformly across the large unit cell of the structure.



(a)

(b)

Fig. 15. Schematic illustration of interference fringes.

High contrast fringes can appear, according to the dynamical theory of diffraction[12], even when a crystal is composed only of light atoms. However, for the appearance of high contrast fringes, the crystal must be as thick as

$$D_0 = \lambda E / 2V_h\,, \qquad (1)$$

where E is the accelerating voltage of electrons and V_h, Fourier coefficient of periodic potential in the crystal. In the present experiments, accurate values of V_h are not known. However, the values given in Table I may be a reasonable estimate for low orders of h. For the superlattice, the estimated value of D_0 is surely much larger than the thickness of the crystal which may be between 500 and 1,500Å. This proves that the observed high contrast is not caused by the simple dynamical effect which is related only to the superlattice. It may be explained when the dynamical effect related to the fundamental lattice is taken into account (Sec. 4c).

Table I.

	V_h	$\lambda E/2V_h$
Fundamental lattice	1–10 volt	200–2,000 Å
Superlattice	0.01–0.1 volt	2–20μ

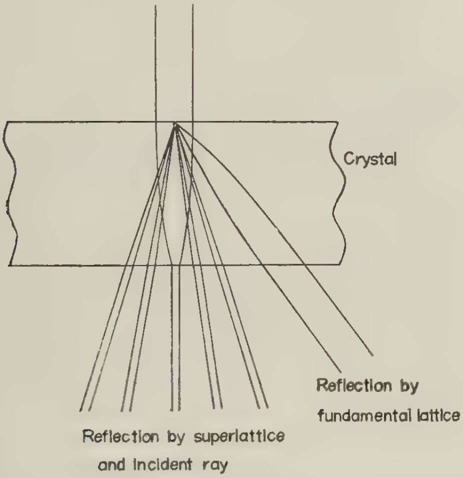
It is noteworthy that for phthalocyanine the thickness of specimens is comparable to D_0 in Eq. (2), and thus a high contrast may appear even at exact focus. It is also noteworthy that, in biological specimens, there is no complicated problem of superlattice and fundamental lattice. However, atomic arrangement in short range is irregular even when the specimen has a periodic structure. The irregularity produces the incoherent scattering[13], most of which is stopped by the objective aperture, resulting in a contrast even at the exact focus. (In both crystalline and biological specimens, the effect of inelastic scattering must be taken into account in the detailed theory of image formation.)

(b) *Dislocations*

Hashimoto[14] pointed out that a dislocation appearing on an electron micrograph does not necessarily indicate a real dislocation in the crystal lattice. When a crystal is covered by an uneven layer of contamination, the fringes corresponding to the crystal lattice periodicity are severely distorted in out-of-focus images, sometimes including ghost dislocations. According to our result, a dislocation which appeared distinctly on one micrograph appeared on all micrographs independent of the degree of defocus. This proves that the observed dislocations are not ghosts. Sometimes, however, the fringes are not distinct around dislocations. For example, in Part A of Fig. 4, it is not clear whether the observed distortion represents a real distortion of the lattice or is an artefact caused by contamination.

(c) *Irregular spacings*

Uyeda et al⁷⁾ pointed out that the fringes of Yu Yen Stone usually appeared undistorted and were adequate for the magnification calibration of electron microscopes. On the other hand, Zussman and Brindley⁸⁾ reported that the superlattice spacing of Yu Yen Stone is distributed between *ca.* 85–110Å. Prof. Brindley¹⁵⁾ pointed out to one of the present authors (R.U.) that Yu Yen Stone is not an adequate material for the calibration and if it is used for this purpose, a supplementary calibration TlCl test as described by Uyeda et al. is indispensable. In the present experiment Prof. Brindley's opinion is proved to be correct.



Crystal
Reflection by fundamental lattice
Reflection by superlattice and incident ray

Fig. 16. Illustration of the extinction of the primary wave.

Hashimoto¹⁶⁾ pointed out that when a crystal is curved the spacing in the image appears different from that in the crystal. However, it is not reasonable to attribute the variation of spacing observed in the present experiment to this effect. Hashimoto's theory is essentially based upon Niehrs' theory which is valid only for thick crystal. In the present experiment crystals are thin, satisfying condition (3) and (4) so far as the superlattice is concerned.

(d) *Dark bands*

Uyeda et al⁷⁾ already described dark bands observed on electron micrographs of Yu Yen Stone and interpreted them as moiré patterns. On the other hand, Cowley¹⁶⁾ assumed that dark bands were extinction contours and gave an explanation for stepped structures. According to him, the incident wave on a dark band is reflected by a net plane of the fundamental lattice. The reflected wave is stopped by the objective aperture of the electron microscope and does not take part in the formation of image. The amplitude of the primary wave, however, is modified according to Pendellösung, because the thickness of the specimens is comparable to D_0 for the fundamental lattice. Since the superlattice reflections are weak, we can assume that they are produced from the modified incident beam. Therefore, at a certain thickness of the crystal, the amplitude of the primary wave can become comparable with those of weak superlattice reflection (Fig. 16). The phase relation between the incident and reflected waves are also modified and high contrast is possible even at the exact focus.

This effect can appear in a variety of ways according to crystal thickness and orientation. Thus, it can explain qualitatively the anomalously high contrast of fringes and the local variation of the intensity profile, including stepped structures. Sometimes, this effect takes place not only on limited bands but also over a wide area; for example, the dark areas with high contrast in Figs. 2 and 3 are probably due to this effect. As is shown by selected area diffraction, a few of the fundamental lattice reflections are usually strong almost everywhere. Therefore, it may be reasonable to consider that the contrast is enhanced more or less everywhere by this effect.

Cowley's theory seems to be essentially correct. However, dark bands observed for Yu Yen Stone are always short while extinction contours should be endless. Therefore this difficulty must be elucidated before Cowley's theory is fully substantiated.

Yu Yen Stone often shows moiré patterns (Fig. 9), indicating that two crystal sheets are overlapping with a small relative rotation. The moiré patterns are produced by low order net planes of the fundamental lattice. When crystals are thick, moiré patterns appear only on extinction contours¹⁸⁾. In Fig. 8 extinction contours split up into short bands as a result of the moiré effect. It is reasonable to interpret the short dark banbs observed for Yu Yen Stone as arising from the moiré effect.

If this interpretation is correct, a sheet of Yu Yen Stone is almost always overlapping another and thus moiré patterns of the superlattice should also appear. In Fig. 8 the angle of rotation is estimated to be of the order of 1/100 rad or more and the spacing of the superlattice moiré is expected to be 0.9μ or less. However, such moirés were very seldom observed (but see Part B of Fig. 1). If we assume that one of the overlapping sheets has the superlattice and the other has no superlattice, we can explain the fact that the moiré patterns of the fundamental lattice always appear but those of the superlattice do not appear. Another possibility is that one of the two sheets is so thin that it does not show fringes of the superlattice. It is not yet confirmed that either of the assumption is really the case.

§ 5. Acknowledgement

The authors offer their sincere thanks to Professor G. W. Brindley of The Pennsylvania State University and Dr. George Switzer of The United States National Museum for furnishing the serpentine samples used in this experiment. The authors also wish to express their thanks to Dr. J. Zussman for helpful discussions, to Dr. J. M. Cowley for sending us the manuscript of his paper before the publication and to Dr. J. W. Menter for valuable advices in preparing this paper.

Transition from Dynamical to Kinematical Intensities of Electron Diffraction by Crystals

By Shizuo MIYAKE

Institute for Solid State Physics, University of Tokyo, Komaba, Tokyo

(Received June 25, 1959)

The transition from dynamical to kinematical intensities of electron diffraction from crystals with the change of wave-length of electrons and crystal thickness is theoretically discussed. It is pointed out that the usual treatment of the dynamical theory by the two-wave approximation fails to apply in the range of very short wave-length and small crystal thickness, even with the correction of the dynamical Fourier potential, so that the advent of some convenient treatments taking account of many reflected waves is of essential necessity for consideration of the transition of reflected intensities. It is pointed out, at the same time, that the application of the pseudo-kinematical theory using the complex atomic scattering amplitude calculated on isolated atoms is not permissible in the case of electron diffraction by crystals even for their thinnest limit.

§ 1. Introduction

The crystal structure determination by electron diffraction method has recently been remarkably developed mainly by the efforts of Soviet school[1),2)] and considerable successes have been reported by them and other researchers on many examples of crystals. There remain, however, a number of difficulties to overcome to meet the increasing demand for higher accuracy and wider applications of this method. Some of them are technical difficulties such as those lying in the choice and the preparation of suitable samples and in the measurement of diffracted intensities.

The other difficulties, being of more theoretical nature, arises from the circumstance that the relation between the structure amplitude and the observed value of reflected intensity is generally not simple due to the strong interactions of electrons with crystals. In this respect, the consideration on the transition from dynamical to kinematical intensities of electron diffraction by crystals, with the change of wave-length of electrons and crystal thickness, is fundamentally important for the theoretical basis of the electron diffraction method in crystal structure determination. The present paper is devoted to the study of this kind of problem in spite of the same problem having been disscussed already in a number of papers and text-books,[1),3)] because the previous treatments contain unsatisfactory points to be criticized as is pointed out later.

For understanding of the considerations in what follows, some of well known relations in the dynamical theory of electron diffraction are briefly quoted below.[4),5),1)]

The solution of Schrödinger equation for electrons in the periodic potential field $V(\vec{r})$ within a crystal is given by the Bloch wave function

$$\Psi_B=\sum_g \psi_g \exp 2\pi i(\vec{k}_0+\vec{g})\cdot\vec{r} \qquad (1)$$

where $\vec{g}$ denotes the reciprocal lattice point vector, and $\vec{k}_0$ the wave vector of the primary wave in the crystal. The amplitudes ψ_g of component plane waves in (1) satisfy the relations

$$(\kappa^2-k_g{}^2)\psi_g+\frac{2me}{h^2}\sum_{g'\neq g} V_{g-g'}\psi_{g'}=0 \qquad (2)$$

where V_g is the Fourier component of $V(\vec{r})$, and

$$\kappa^2=(V_0+E)\frac{2me}{h^2}=\frac{1}{\lambda^2} \qquad (3)$$

E being the total energy of electron, and κ and λ, the mean wave number and wave-length of electron within the crystal, respectively. The simultaneous equations (2) are called the fundamental equations in the dynamical theory.

The number of the component waves ψ_g, and accordingly that of the simultaneous equations (2) is infinite in general. This number is usually reduced to a few by retaining only the strong component waves related to the reciprocal lattice points lying most closely to the Ewald sphere. The lattice planes corresponding to these points are regarded as satisfying more or less nearly the Bragg conditions concerned. When Bragg condition is nearly satisfied only by a lattice plane $h(h_1h_2h_3)$, (2) is reduced to the fundamental equations of the two-wave approximation,

$$\begin{aligned}(\kappa^2-k_0{}^2)\psi_0+\frac{2me}{h^2}V_{-h}\psi_h=0\\ \frac{2me}{h^2}V_h\psi_0+(\kappa^2-k_h{}^2)\psi_h=0\end{aligned}\qquad(4)$$

By applying these equations to a crystal plate of the thickness H, the integrated intensity of transmitted reflexion J is calculated as

$$J\propto|V_h|\qquad \lambda H\to\infty \qquad (5a)$$

$$J\propto|V_h|^2\qquad \lambda H\to 0 \qquad (5b)$$

The relation (5b) indicates that the intensity of reflexion tends to the kinematical value in the limit of small crystal thickness and short wave-length of electrons. This behaviour has usually been received as providing the theoretical basis of the electron diffraction method in crystal structure determination.

§ 2. Invariant Property of the Fundamental Equations

In the treatment of the avove two-wave approximation, the primary extinction effect caused by the dynamical interaction between the primary wave and the h-reflexion is taken into account. However, the influence of other reflexions is generally not negligible in the case of electron diffractio.n In particular, it is important to allow for the interactions among reflexions corresponding to the reciprocal lattice points lying on the lattice point row passing through both the reciprocal space origin and the lattice point $\vec{h}(h_1h_2h_3)$, since the points on this row are necessarily located closely to the Ewald sphere. Hoerni[6)] called the interactions due to this circumstance the systematic interactions, as it may be appreciable in any reflecting condition. When another lattice plane $h'(h_1'h_2'h_3')$ nearly satisfies the Bragg condition additionally, the reciprocal lattice points on the net plane containing the points $\vec{h}$ and $\vec{h'}$ and the reciprocal space origin are crowded near the Ewald sphere. Hoerni called the dynamical interactions which take place under such a condition the accidental interactions, as it arises under special conditions in which the incident electron beam is nearly parallel to some of zone axes of the crystal.

For further considerations, it is to be noted of an invariant property, possessed by the fundamental equations (2) with respect to the change of wave-length, under the conditions that:

(a) κ is quite large compared with the reciprocal lattice periods,

(b) interactions among reflexions other than the systematic and accidental intractions are negligible.

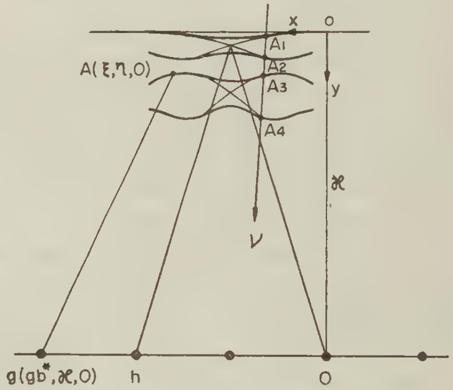

Fig. 1.

For simplicity, we concern with the case in which only the systematic interactions are important. Fig. 1 shows schematically a section of reciprocal space by a plane containing the reciprocal lattice point row concerned. We take the coordinate origin o at the distance κ from the reciprocal space origin O on the line which passes through O perpendicularly to the lattice point row. When this line is chosen as the y-axis and the x- and z-axes are chosen parallel to the lattice point row and perpendicular to the plane of the figure, respectively, the coordinates of an arbitrary lattice point $\vec{g}(g, 0, 0)$ on the row is given by $(gb_1{}^*, \kappa, 0)$, and those of a wave point A on the dispersion surface by $(\xi, \eta, 0)$, where $b_1{}^*$ is the reciprocal lattice period along the point row. Since by the conditions (a) and (b) we have $\kappa \gg b_1^*$ and $\kappa \gg \xi$, we obtain by neglecting higher order quantities the relation

$$\kappa^2 - k_g^2 = 2\kappa\eta - C_g(\xi) \,, \qquad (6)$$

where

$$C_g(\xi) = (gb_1^* - \xi)^2 \,. \qquad (6a)$$

Thus, the equations (2) are written as

$$(x - C_g(\xi))\psi_g + \frac{2me}{h^2} \sum_{g' \neq g} V_{g-g'}\psi_{g'} = 0 \qquad (7)$$

where

$$x = 2\kappa\eta \qquad (8)$$

Since the eigenvalues of x are independent of κ, the ratios of the eigenvectors $\psi_0 : \psi_1 : \psi_2 : \cdots$ are also independent of κ. In other words, the solution of (2) does not depend on the wave-length of electrons under the assumed conditions. The same is valid for the case when the accidental interactions are predominant.

In relation with the above conclusion, it may be worthy to add here a remark to the experimental method developed by Honjo and Kitamura,[7)8)] who showed that the intensity measurement of reflexions with varying wavelengths of electrons, and its extrapolation to the short wave-length limit, give an effective method for obtaining the kinematical values of the intensities of reflexion from a crystal of finite thickness, in accordance with the relation (5b). There might, however, arise the following objection concerning their method: since the curvature of the Ewald sphere becomes reduced with the decreasing wave-length, the number of reciprocal lattice points locating simultaneously in the neighbourhood of the Ewald sphere increases under the conditions of systematic as well as of accidental interactions, so that the dynamical interactions among reflexions might not be reduced by decreasing the wave-length. However, from the invariant property of the fundamental equation as shown above, it is clear that the complexity due to the dynamical interactions among reflexions is never aggravated by the reason of decreasing the wavelength of electrons.

§ 3. Conflicting Results of Different Theories

As mentioned before, the relation (5b) is derived by the two-wave approximation not taking account of the dynamical interactions among reflexions except the primary extinction effect. It appears to be probable that the influence of neglected weak reflexions may be approximately corrected by taking account of the so-called dynamical Fourier potential introduced by Bethe[1)]. By the use of the dynamical potential, however, we are confronted with a confusing result for the reflected intensity in the limit $\lambda H \to 0$, as revealed in what follows.

The reduced fundamental equations of the two-wave approximation corrected for the dynamical Fourier potential are obtained by replacing V_0 in (3) by $V_0 + \varDelta V_0$, or by $V_0 + \varDelta V_0'$, and V_h and V_{-h} in (2) by $V_h + \varDelta V_h$ and $V_{-h} + \varDelta V_{-h}$, respectively, where the dynamical potential terms $\varDelta V_0$ etc. are given by

$$\varDelta V_0 = -\frac{2me}{h^2} \sum_{\substack{g\neq 0\\ g\neq h}} \frac{V_g V_{-g}}{\kappa^2 - k_g^2} \,,$$

$$\varDelta V_0' = -\frac{2me}{h^2} \sum_{\substack{g\neq 0\\ g\neq h}} \frac{V_{g-h} V_{-g+h}}{\kappa^2 - k_g^2}$$

$$\varDelta V_h = \varDelta V_{-h}^* = -\frac{2me}{h^2} \sum_{\substack{g\neq 0\\ g\neq h}} \frac{V_g V_{h-g}}{\kappa^2 - k_g^2} \qquad (9)$$

When this kind of theory is applied to the crystal plate with the thickness H, the integrated intensity J of a transmitted reflexion turns out to be

$$J \propto |V_h + \varDelta V_h| \,, \qquad \lambda H \to \infty \qquad (10a)$$

$$J \propto |V_h + \varDelta V_h|^2 \,, \qquad \lambda H \to 0 \qquad (10b)$$

Since $\kappa^2 - k_g^2$ in (9) is the quantity which is not depending on κ as has been proved for the systematic and accidental interactions, $\varDelta V_h$ is independent of the wave-length of electrons. Furthermore, $\varDelta V_h$ is independent of the thickness of the crystal. Therefore, the integrated intensity of reflexion in the limit $\lambda H \to 0$ as expressed by (10b) never coincides with the result (5b). As the magnitude of $\varDelta V_h$ can be appreciable for low order reflexions from most of crystals, the discrepancy is not trivial so that it amounts to necessitating us a serious reconsideration as to how we should derive the kinematical values of reflected intensities from the observation.

On the other hand, Schoemaker and Glauber,[9)] Cowley,[10)] and Hoerni[6)] anticipated that the reflected intensity from a crystal will tend, in the limit of sufficiently small thickness of the crystal ($H \to 0$), to the pseudo-kinematical value calculated from the crystal structure factor using the complex atomic scattering amplitude, which was introduced by Schoemaker and Glauber[9][10] in order to explain the anomalous values of the atomic distances in molecules containing heavey elements derived from electron diffraction by gases. However, the intensity thus calculated agrees in general with neither (5b) nor (10b).

§ 4. Failure of the Two-wave Approximation in the Limit $\lambda H \to 0$

We have now the three kinds of conflicting results for the reflected intensity in the limit $\lambda H \to 0$ by different approaches, of which the former two are based on the two-wave approximation, one being taking account of the primary extinction effect only, and the other the influence of weak reflexions also. In order to reach *a* unified result, we point out, first of all, the fact that the treatments of two-wave approximation of either forms are not permissible in the consideration of the reflected intensity in the limit $\lambda H \to 0$, when the dynamical effects other than that due to the primary extinction are remarkable as is usually the case in electron diffraction.

The wave field of electron in the crystal, being subjected to the boundary condition with respect to the given incident beam, is expressed by a superposition of the Bloch functions

$$\Psi = \sum_i \alpha^{(i)} \Psi_B^{(i)} \tag{11}$$

where i is the index of the wave points and $\alpha^{(i)}$ the weighting amplitude. The wave points are determined as the intersecting points of the dispersion surface in reciprocal space with the straight line ν running in the direction perpendicular to the crystal surface through the end point of the vector $-\vec{K}_0$ drawn from the reciprocal space origin, where $\vec{K}_0$ is the wave vector of the incident electron wave. We designate the wave points determined in this way by $\cdots A_1, A_2, A_2 \cdots$, according to the increasing value of the η-coordinate of them (Fig. 1). The intensity of the reflexion $g(g_1g_2g_3)$ transmitting the crystal plate is given by

$$I_g = \sum_i \sum_j u_g^{(i)} u_g^{(j)*} \exp \pi i (x^{(j)} - x^{(i)}) \lambda H, \tag{12}$$

$$x^{(i)} = 2\kappa \eta^{(i)} \tag{13}$$

where

$$u_g^{(i)} = \alpha^{(i)} \psi_g^{(i)} . \tag{14}$$

$u_g^{(i)}$,s satisfy the relations due to the boundary condition

$$\sum_i u_g^{(i)} = \begin{cases} 1, & g=0 \\ 0, & g \neq 0 \end{cases} \tag{15}$$

where the amplitude of the incident wave is assumed to be unity.

For thick crystals, the reflected intensity averaged over H is given, from (12) and (15), by

$$\bar{I}_g = \sum_i | u_g^{(i)} |^2 = - \sum_{i \neq j} \sum u_g^{(i)} u_g^{(j)*} \tag{16}$$

When the Bragg condition is nearly satisfied with respect to the lattice plane $h(h_1h_2h_3)$, the straight line ν intersects with the part of the dispersion surface near the intersection of the spheres of radius κ drawn around the reciprocal space origin O and the lattice point h; the position of the wave points A_1 and A_2 are located there. Under the assumed condition, only the amplitudes $u_h^{(1)}$ and $u_h^{(2)}$ may be predominant in (16) for the h-reflexion. Disregarding the second order of other small amplitudes, we obtain the averaged intensity

$$\bar{I}_h = | u_h^{(1)} |^2 + | u_h^{(2)} |^2 = - (u_h^{(1)} u_h^{(2)*} + u_h^{(1)*} u_h^{(2)}) \tag{17}$$

This procedure corresponds to the two-wave approximation, by which the results (5a, b) and (10a, b) have been obtained.

When the value of λH is small, on the other hand, the intensity for the h-reflexion is written by using (12) and (15) in the following expansion form

$$I_h = - \sum_{i \neq j} \sum u_h^{(i)} u_h^{(j)} \left\{ \left[(x^{(i)} - x^{(j)}) \frac{\pi \lambda H}{2} \right]^2 + \cdots \right\} \tag{18}$$

where, for simplicity, the crystal is assumed to be centrosymmetrical so that $u_h^{(i)}$ are real quantities.[12] In (18) the contributions of the amplitudes $u_h^{(i)} (i \neq 1, 2)$ are not necessarily negligible as in (16) even when they are small compared with $u_h^{(1)}$ and $u_h^{(2)}$, since the magnitudes of the terms in (18) depend not only on those of $u_h^{(i)}$ but also on the positions of the wave points concerned. The conflicting results of the two-wave approximations is a natural consequence of the inappropriate application of them to the range of small λH, disregarding the wave points other then A_1 and A_2.

§ 5. Discussions

It may be clear from the above consideration that, for the argument of the reflected intensity in the limit $\lambda H \rightarrow 0$, it is of essential necessity to develop a more elaborated theory taking account of many weak reflexions. Very recently, Fujimoto13) has succeeded in formulating the dynamical theory by the method of scattering matrix,* extending the theory of Niehrs and Wagner14), and studied the dependence of the intensities of transmitted reflexions on the change of wave-length of electrons and crystal thickness in detail. By his theory, which takes account of the interactions among reflexions other than the primary extinction effect also, it was shown that the integrated intensity of reflexion tends to the kinematical value in the limit $\lambda H \rightarrow 0$. The similar conclusion was independently obtained by Fujiwara15), who developed a theory which is a more complete formulation of the theory of a new approach to the dynamical theory given by Cowley and Moodie16). He has taken account of the interactions of different reflexions by the iteration of the Born approximation for the wave field *within* the crystal, starting from the field due to the first order Born approximation formerly derived by Artmann17).

By the theories of Fujimoto and Fujiwara, we can conclusively believe that the relation (5b) holds even under complicated interactions among reflexions, although the validity of (5b) is fortunate so long as it is derived from (4) neglecting the interactions to be taken into account.

It can be at the same time concluded from their theories that the intensity of reflexion in the limit $H \rightarrow 0$ does not tend to the pseudo-kinematical value. The reason for the failure of the pseudo-kinematical theory even for the thinnest crystals may be physically understood as follows. The complex atom scattering factor used in the pseudo-kinematical theory is calculated by the knowledge of the distorted wave field in an isolated atom, whereas the wave field in atoms composing the crystal is entirely different from that in the isolated atom as the result of the superposition of scattered waves from a large number of atoms. In order to reproduce the distorted wave field in an isolated atom, infinite number of plane waves of continuously varying directions of propagation are needed, while the wave field in the crystal is expressed by the superposition of plane waves with discrete directions of propagation even for the thin limit of the crystal. In other words, it is not enough to reduce the thickness of the crystal plate in order to attain the isolated-atom limit. This limit will be reached by reducing the surface area of the plate also. The application of the complex atom scattering amplitude obtained for isolated atoms to thin crystals may give, therefore, nothing but a misleading conclusion.

So far as the above consideration is concerned, the reduction of λ and of H result in the same kinematical limiting value for the intensity of reflexion. However, the additional complex term to the Fourier potential due to the inelastic scattering, as was formulated in the theory of Yoshioka18), will vanish only by reducing the value of λ. Therefore, the simultaneous reduction of the wave-length of electrons and the crystal thickness may be most advantageous for the work of crystal structure determination by the electron diffraction method.

As pointed out in the present paper, the two-wave approximation corrected for the dynamical Fourier potential is not permissible for the calculation of the intensity of reflexion when λH is quite small. However, this approximation may not be meaningless so far as it is applied to argue qualitatively the reflected intensity from thick crystals, or the refractive index for electrons within the crystal, although the numerical accuracy of the correction terms (9) seems to be doubtful in general.

(Received May 28, 1959)

$MnTiO_3$ and $NiTiO_3$ have a rhombohedral crystal structure similar to $FeTiO_3$ in which layers of Fe and Ti atoms alternate along the rhombohedral axis with oxygen layers between them. A powder neutron diffraction study shows that $MnTiO_3$ has a magnetic structure with the Mn^{2+} spins antiparallel within each layer. On the other hand, $NiTiO_3$ has the same magnetic structure as $FeTiO_3$, in which the spins are parallel within each layer and adjacent layers are antiparallel. The spins are directed along the [111] direction in $MnTiO_3$ and perpendicular to it in $NiTiO_3$. In addition to the magnetic study, the nuclear intensities indicate that the Ni and Ti in $NiTiO_3$ are only 88 per cent ordered.

§ 1. Introduction

Extensive studies have been carried out within the past few years on the magnetic properties of ilmenite-type compounds. Ilmenite ($FeTiO_3$) has a rhombohedral lattice[1] very closely related to the corundum structure of hematite (α-Fe_2O_3). Several solid solution systems between these two types of compounds are known, the most thoroughly studied among them being the ilmenite-hematite system.[2,3,4] The antiferromagnetic spin structures of both the end members of this system were determined by neutron diffraction analysis.[5,6] An interesting feature of the solid solutions is the appearance in some of the ilmenite-rich compositions of a strong spontaneous magnetization, which was shown to be due to an ordering of Fe and Ti in the α-Fe_2O_3 spin arrangement.[6)]

---

* This work was carried out in part at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission and the National Security Agency.

Ishikawa and Akimoto[7)] have reported recently on the magnetic properties of other compounds isomorphous with ilmenite, such as $MnTiO_3$, $CoTiO_3$, and $NiTiO_3$, as well as their solid solutions with α-Fe_2O_3. The magnetic behavior of the systems containing $CoTiO_3$ and $NiTiO_3$ was found to be quite similar to that of the $FeTiO_3$ series. The $MnTiO_3$ system, however, showed no appreciable spontaneous moment at any composition, a result suggesting that pure $MnTiO_3$ has a different spin structure from pure $FeTiO_3$ and $NiTiO_3$.

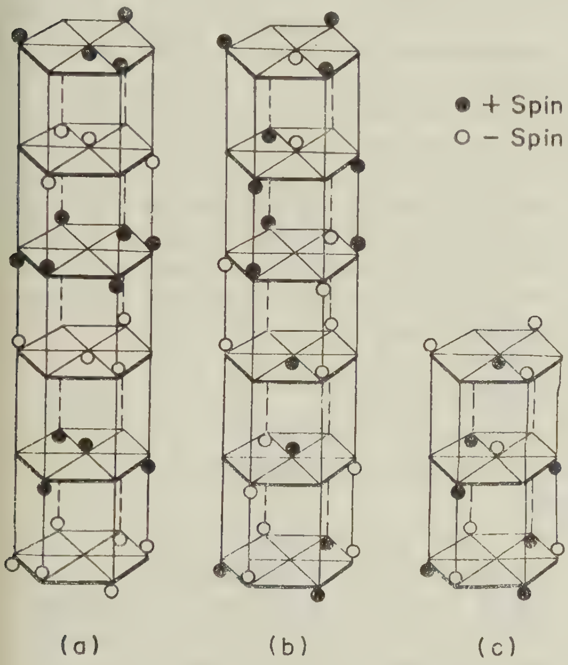

Fig. 1. Three possible magnetic structures for ilmenite-type compounds. The structures are idealized and the Ti layer (the B layer) is omitted. Model (a) is observed in $FeTiO_3$ and $NiTiO_3$ and Model (c) in $MnTiO_3$.

The three possible spin arrangements for ilmenite are illustrated in Fig. 1, in which a hexagonal unit cell containing only the magnetic atoms has been adopted. The layers of magnetic atoms, which may be designated the A layers, are separated by O–B–O layers, where O represents an oxygen layer and B a Ti layer. When α-Fe_2O_3 is added to this ilmenite structure, the magnetic atoms enter the B layers and those on the A layers will result in different structures depending upon the spin configuration of the end member, $MeTiO_3$, where Me represents magnetic atom.

$FeTiO_3$ was found to have the structure shown in Fig. 1(a). in which the arrangement within each layer is ferromagnetic. The addition of Fe on the B layers in this case destroys the ferromagnetic ordering on the A layers, as shown by the neutron diffraction study. The ferrimagnetic ordering based upon the hematite spin lattice develops when the concentration of α-Fe_2O_3 reaches a critical value of about 15 per cent.

Models (b) and (c) have the common feature that the spins in the A layers are antiparallel. In the light of a molecular field calculation[7)] showing that the moments on the B layer are parallel in (b), the observed moment should increase linearly with increasing concentration of α-Fe_2O_3. On the other hand, model (c) results in antiparallel spins on the B layer, and on this basis model (c) was predicted for $MnTiO_3$.

The present paper describes a neutron diffraction study of $MnTiO_3$ and $NiTiO_3$. Besides the magnetic structure there is additional interest, for the case of $NiTiO_3$, in the degree of order of Ni and Ti. Because the two metal positions in the lattice are almost equivalent, some disorder might be expected. Neutron diffraction offers a particular advantage over x-ray diffraction in fixing the degree of order, since the scattering amplitude of Ti (-0.38×10^{-12}cm) and Ni ($+1.03\times10^{-12}$cm) have opposite signs. The same is not true for $MnTiO_3$ because of the manganese scattering amplitude (-0.36×10^{-12}cm).

Approximately 30 grams of $NiTiO_3$ and $MnTiO_3$ powder were prepared for the neutron diffraction study. $NiTiO_3$ was fired according to the method described previously.[8)] A mixture of NiO and TiO_2 was heated in air at 1350°C for three hours, then cooled in the furnace at a rate of approximately 300°C/hr. This compound is quite stable in air and exhibits high electrical resistivity. A chemical analysis of the sample gave the stoichiometric ratio within experimental limits. $MnTiO_3$ was obtained by the reaction of $Mn_3O_4+3TiO_2$ in a vacuum furnace with 10^{-4}mm Hg pressure. The sample was kept at 1300°C for 24 hours and cooled in the furnace to room temperature, the total cooling time being 5-6 hours. Chemical analysis revealed a slight deficiency in Mn content (about 2 per cent). However, an X-ray powder picture did not show any trace of impurities, and the lattice constants are identical with a sample[7] having a Néel temperature of 41°K and an effective moment corresponding to Mn^{2+}. In the present calculation for $MnTiO_3$, the stoichiometric ratio was used with the assumption of divalent manganese. The possible implication of non-stoichiometry will be discussed later.

§ 2. Crystal Structures

Although a hexagonal unit cell is used in Fig. 1 for the magnetic models, the crystal structure can be described more conveniently by using a rhombohedral cell containing two molecular units. The atomic positions are given by the following five parameters for the space group $R\bar{3}$:

2 Me at $\pm(u_1, u_1, u_1)$ Me=Fe, Mn or Ni
2 Ti at $\pm(u_2, u_2, u_2)$
6 O at $\pm(x, y, z)$

If Me and Ti are incompletely ordered, as in the case of $FeTiO_3$, the ordering parameter S must be treated as an additional parameter. Since the magnetic atoms Me constitute the A layers of Fig. 1, S is the fraction of Me at $\pm(u_1, u_1, u_1)$, which ranges from unity for complete order to one half for complete disorder. These six parameters determine the X-ray intensities as well as that part of neutron intensities due to nuclear scattering.

When a magnetic order develops, the total neutron intensity can be written as (see Bacon[9].)

$$I_{hkl}=K(F^2_{\text{nucl}}+q^2F^2_{\text{mag}})$$

where q is determined by the direction of the spins with respect to the scattering vector. The magnetic structure factor, F_{mag}, depends only on the magnetic stoms and is therefore a function of u_1 and S, as well as p, the magnetic scattering amplitude. It should be noted that

$$p=0.269\,\mu f$$

where f, the form factor, is not a well established quantity. The effective magnetic moment μ depends upon the degree of quenching of orbital moment and must be determined experimentally together with the form factor.

The main purpose of the present study, the determination of the magnetic structure, requires the accurate determination of only two parameters from the nuclear scattering peaks, u_1 and S. The oxygen parameters are nevertheless quite important, not only to determine the scale factor K (which in turn decides the magnitude of the magnetic moment for each model considered), but also to calculate the proper metal-oxygen distances. For these reasons a careful analysis of the nuclear diffraction data was carried out. Since only about twenty reflections are available to determine six parameters, the two metal parameters were first fixed by X-ray measurements, and then the remaining four parameters, x, y, z and S, adjusted to obtain the best agreement with the neutron data.

The crystal structures of $MnTiO_3$, $NiTiO_3$, and $FeTiO_3$, were studied by Posnjak and Barth.[1,10] They established the structure of $FeTiO_3$ by using single crystals as well as powder specimens; powder intensities alone were used for $NiTiO_3$. The parameters determined were:

$$u_1(\text{Fe})=0.358 \quad u_2(\text{Ti})=\frac{1}{2}-u_1\,,$$
$$u_1(\text{Ni})=0.353$$

with the same oxygen parameters in each case

$$x=0.555 \quad y=-0.055 \quad z=0.250\,.$$

Though no intensity calculations were performed explicitly for $MnTiO_3$, parameters similar to those of $FeTiO_3$ were expected because of the close resemblance of the powder intensities in these two compounds.

X-ray powder intensities of $NiTiO_3$ and $MnTiO_3$ were taken with a Norelco diffractometer using Cu Kα radiation. The first 13 lines up to (211) were used to determine the metal parameters, by assuming the oxygen parameters given by Posnjak and Barth. The best values are:

$$u_1(\text{Ni})=0.353\pm0.002 \quad u_1(\text{Mn})=0.357\pm0.002$$

is good agreement with the reported values. The assumption $u_2=1/2-u_1$ made in these calculations is borne out by the agreement between calculated and observed values.

Powder neutron data were obtained at room temperature and 4.2°K (Figs. 2 and 3). Samples were placed in a cylindrical aluminium container of 3/8 inch diameter; the intensities were measured at angular intervals of 0.1° in 2θ, the counting time (approximately 10 minutes) being determined by a monitor. The nuclear intensities at the two temperatures agree with each other quite satisfactorily for both compounds. The observed intensities were compared with computed ones after applying appropriate normalization and angular factors; the small correction due to the temperature factor was neglected in the calculation. With the use of the two metal parameters given by the X-ray data, the three oxygen parameters and the ordering parameter S were adjusted to fit the data.

The intensities calculated for $NiTiO_3$ with the reported oxygen parameters did not give satisfactory agreement, especially for (111), (100), and (210), if $S=1$. Reflection with $h+k+l=2n+1$ have a structure factor proportional to (b_1-b_2), were b_1 is the effective scattering amplitude at (u_1, u_1, u_1). On the other hand, reflections with $h+k+l=2n$ are

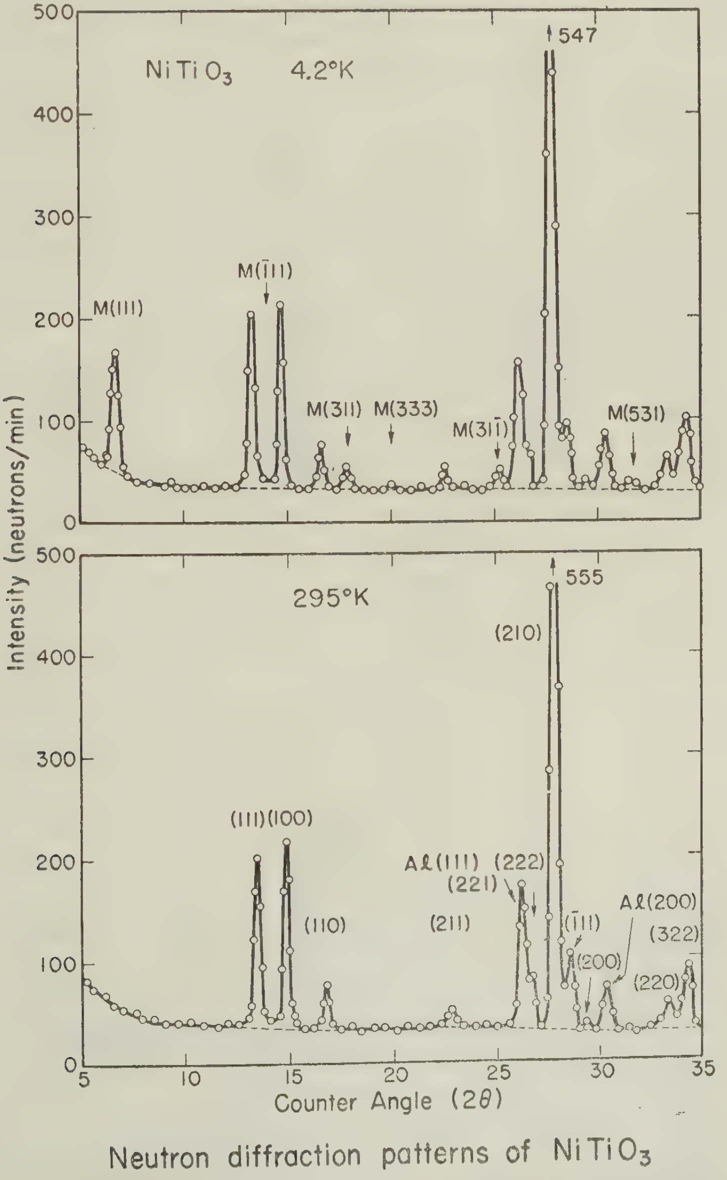

Fig. 2. Neutron diffraction patterns of $NiTiO_3$ taken above and below the Néel point. The wave length $\lambda=1.064$A.

proportional to (b_1+b_2) and are independent of the distribution of Ni and Ti on the different sites. The agreement was considerably improved by adjusting S from 1 to 0.92. Still better agreement was obtained by refining the oxygen parameters and then readjusting the ordering parameter. The best values of the parameters are:

$$x=0.555 \quad y=-0.045 \quad z=0.235 \quad S=0.94\,.$$

Agreement with the (210) peak could be obtained only by use of the S parameter. The oxygen parameters are very close to the improved values found for $FeTiO_3$.[6] One may note that the oxygen parameters reported previously satisfy the requirements of the higher symmetry **R**$\bar{3}$C of α-Fe_2O_3, that is, $y=1/2-x$ and $z=1/4$, though these are not necessary for **R**$\bar{3}$. The new oxygen parameters give more reasonable metal-oxygen bond distances, as shown in Table I. The agreement between calculated and observed intensities is presented in Table II (a).

$MnTiO_3$ requires somewhat different oxygen parameters than $NiTiO_3$:

$$x=0.560 \quad y=-0.050 \quad z=0.220$$

This is expected because of the difference in the ionic radii of Mn and Ni. As for the ordering of Mn and Ti, no information can be obtained because of the similarity of b_{Mn} (−0.36) and b_{Ti} (−0.38); moreover, it is even difficult to assign Mn to the position $u=0.357$ instead of $u=0.143$. The final assignment of Mn to u_1 gives more consistent interatomic distances and is also slightly favored by the intensity calculations (see Table III). It may be added that the oxygen parameters of this compound could be determined more accurately than in $NiTiO_3$ because of the insensitivity of the diffraction data to the ordering parameter S.

§ 3. Magnetic Structure

The neutron diffraction patterns obtained below the Néel temperature show several changes in the intensities (see Figs. 2 and 3). The new lines in $NiTiO_3$ require the doubling of the rhombohedral unit cell as was the case in $FeTiO_3$; on the other hand, the "magnetic" unit cell of $MnTiO_3$ is identical with the "chemical" unit cell.

All of the observed magnetic lines of $NiTiO_3$, when indexed with the double cell, have h, k, and l all odd. This implies that only the hexagonal **c** axis is doubled but not the **a**, satisfying the condition for models (a) and (b). Model (b) cannot satisfy the strong magnetic (111) reflection with any possible spin direction. The observed intensities can be explained satisfactorily by assuming model (a) and a spin direction lying in the (111) plane, as shown in Table II (b). The specific direction within this plane cannot be defined by powder data alone. Assuming this spin structure, the magnetic moment obtained was 2.25 μ_B, in good agreement with susceptibility measurements[7)], and suggesting a contribution from unquenched orbital moment. The form factor falls off much more slowly than that of Mn^{2+} [11)] and Fe^{3+} [12)], and is closest to that of Ni metal as determined by the polarized neutron technique[13)]. It should be noted, however, that because of the limited accuracy of the magnetic intensities at higher angles, the conclusion should be taken with some reserve. In the calculations an ordering parameter $S=0.94$ was used and it was assumed that the remaining Ni on B layers are not magnetically ordered. If their spins form an ordered arrangement such as (a) or (b) within the B layers, they will contribute to the calculated values of the magnetic intensities, but this correction is small.

The magnetic intensities of $MnTiO_3$ can be explained by assuming model (c) and a spin direction along [111]. If we assume $S=1$, the observed intensities require a moment of 4.55 μ_B, which is 91 per cent of the Mn^{2+} moment. This value was determined mainly by the intensities of (100) and (110). With this effective moment and the Mn^{2+} form factor[11)], quite satisfactory agreement was obtained between observed and calculated values, as shown in Table III.

It is of course possible that the ordering of Mn and Ti is incomplete, as in $FeTiO_3$ and $NiTiO_3$. If we attribute the decrease of the moment from the spin-only value to disorder, S must be 0.91. Though this is not unreasonable compared with the value 0.94 for $NiTiO_3$ and 0.95 for $FeTiO_3$[6)], one might expect a larger activation energy of disorder for $MnTiO_3$, because of the larger difference between Mn-O and Ti-O distances. Moreover, there are several other possible causes for the smaller effective moment. Chemical analysis indicated a slight excess of Ti over Mn, and this departure from stoichiometry is in the correct direction to explain the low observed value. The existence of some manganese in the trivalent state cannot be excluded. In this respect, we may note that the effective Mn moment obtained by the susceptibility measurements[7)] is slightly (2 per cent) smaller than the expected value for Mn^{2+}. Thus the observed effect may be a combination of these factors with disorder playing a major part, and it is not possible, at present, to separate them unambiguously.

§ 4. Discussion

The results of the present neutron diffraction study are in good agreement with the previous magnetic measurements. In particular, the magnetic structure of $MnTiO_3$ proved to be the model predicted by the magnetic measurements on the $MnTiO_3$–α-Fe_2O_3 system. Another important result is the observation of incomplete order of Ni and Ti in $NiTiO_3$. Though direct evidence could not be obtained in the case of $MnTiO_3$, the estimated magnetic moment seems to indicate some disorder in this compound. From these results one might conclude that this is a general characteristic of ilmenite compounds. It would be an interesting problem to investigate the dependence of this disorder on the heat treatment of the specimen and its effect on the magnetic properties.

Superexchange interactions in rhombohedral sesquioxides have been discussed by Li14) and Iida15). There are three important Me-O-Me configurations, two of which, Γ_a and Γ_b, involve metal atoms on different layers and are expected to be stronger than the third one, Γ_c, which is the interaction within the same layer. If, however, the ordering of Me and Ti in $MeTiO_3$ is perfect, and all Ti atoms are in the tetravalent state, the antiferromagnetic order must be propagated three-dimensionally through two layers of oxygen by Me-O-O-Me interactions. As pointed out by Kramers16), such interactions would normally be expected to be much weaker than the singleanion superexchanges.

When the order is incomplete, some magnetic atoms enter on the B layers, and their role cannot be deduced from the neutron diffraction data. However, indirect evidence was obtained in the study of the $FeTiO_3$-α-Fe_2O_3 system6), where the addition of α-Fe_2O_3 decreases the antiferromagnetic Néel temperature of $FeTiO_3$. This was interpreted as a destruction of the ferromagnetic coupling within the A layers by a strong antiferromagnetic coupling between the A and B layers. This indicates that at least trivalent magnetic atoms on the B layers are not taking part in the three-dimensional propagation of the $FeTiO_3$-type magnetic order. This conclusion should also apply to $NiTiO_3$, which has essentially the same magnetic structure as $FeTiO_3$ except for the spin direction. Nevertheless, a further study of the $NiTiO_3$–α-Fe_2O_3 system is desirable to provide additional evidence.

$MnTiO_3$ has an antiferromagnetic arrangement within each A layer. A molecular field calculation7) has shown that the moments introduced on the B layer are arranged antiparallel to each other. In this case strong interactions Γ_a and Γ_b do not disturb the ordering on the A layers, implying that the addition of α-Fe_2O_3 should not change the magnetic structure. Experimental confirmation of this point has yet to be carried out.

If pure $MnTiO_3$ is partially disordered it is possible that Γ_a and Γ_b, as well as a long range Me-O-O-Me interaction, may play a role in the propagation of order between the layers. At present we cannot separate these two effects. It may be worthwhile pointing out that there are two kinds of configuration:

$$\mathrm{Mn}\overset{p}{-}\mathrm{O}-\mathrm{O}\overset{q}{-}\mathrm{Mn} \quad \text{positive}$$

$$\mathrm{Mn}\overset{q}{-}\mathrm{O}-\mathrm{O}\overset{q}{-}\mathrm{Mn} \quad \text{negative}$$

where p and q are bond distances corresponding to 2.10A and 2.26A respectively.14) This situation is analogous to the case of Cr_2O_3 where the interaction is through only one oxygen.

§ 5. Acknowledgments

The authors are very grateful to Drs. R. Nathans and W. J. Takei for stimulating discussions.

On Galvanomagnetic Effects in P-Type Crystals of PbTe

By Kisaburo SHOGENJI

Hitachi Central Research Laboratoty, Kokubunji, Tokyo

(Received June 5, 1959)

This paper describes measurements of the magnetoresistance and of the planar Hall effect of p-type PbTe crystals; it also describes an interpretation of the electronic band structure of the crystal. The measurements were made at 90°K as a function of the magnetic field strength and of the angle between the magnetic field and the current through the specimen. The coefficients relating to the galvanomagnetic effects were determined from the experimental data. Using these coefficients the electronic band structure of the crystal is shown to be $\{111\}$ energy spheroids, presumably prolate with a mass ratio of 0.3.

§ 1. Introduction

Several investigations on the electrical properties of PbTe crystals have been made by us recently[1][2]. It is also desirable to know the electronic band structure of PbTe in order to get more systematic information about its electrical properties. Therefore measurements of magnetoresistance and of planar Hall effect of p-type PbTe were made; also its band structure was interpreted by analyzing the experimental data.

Many investigations have been made on magnetoresistance effect of semiconductors, for example: a theoretical one by Seitz[3], experimental ones on germanium by Esterman-Forner[4] and by Pearson-Suhl[5], on Silicon by Pearson-Herring[6], and many others[7]. However it seems to us that investigations on the magnetoresistance of semi-conducting intermetallic compounds are fewer and less detailed than those made on germanium and Silicon. Research has been reported on InSb by Frederikse-Hosler[8], and on Bi_2Te_3 by Drabble *et al*[9]. For a group of PbS, PbSe and PbTe semiconductors, investigations have been made by Putley[10], Hirahara-Murakami[11], Irie[12] and Algaier[13]. Also the planar Hall effect has been investigated theoretically and experimentally by goldberg-Davis[14], and has been measured on PbSe crystals by Hirahara-Murakami[11]. Theoretical investigations on the relationship between magnetoresistance and band structure of semiconductors have been made by Abeles-Meiboom[15], Shibuya[16] and Herring[17].

In this paper measurements of magnetoresistance and planar Hall effect are reported. Before these experiments are described, a phenomenological description of magnetoresistance and planar Hall effect will be made, in section 2, as a function of the magnetude and the direction of the applied magnetic field and of the applied electric current through the specimen. This description has the form of a mathematical series of ascending powers of the magnetic field. The terms up to the fourth power of the field are calculated, since the experimental results, which will be given in this paper, show us the necessity of at least the fourth power into consideration. In section 3 several expressions relating the constants of the galvanomagnetic effects to the band structure will be deduced by means of Shibuya's theory[16]. The experimental results will be analyzed according to Shibuya's theory in the following section.

The experiments will be described in section 4. The specimens used have their long axes in the [100] and the [110] directions respectively. The measurements of the magnetoresistance and of the planar Hall effect were made as a function of the magnitude and of the direction of the applied magnetic field. The constants of the galvanomagnetic effects were determined by the dependence of these effects upon the field, and these constants were used in the determination of the band structure of the crystal.

§ 2. Phenomenological Description of the Galvanomagnetic Effects.

PbTe crystals have the NaCl type lattice structure with the symmetry O_h. Seitz[3] deduced a phenomenological formula for the magnetoresistance of a cubic crystal. Also Mason *et al*[18]. calculated expression for the magnetoresistance and Hall effect up to the fifth power of H for a crystal with the symmetry O_h. In this paper phenomenological expressions for the magnetoresistance and for the planar Hall effect are deduced, and the expressions are transformed into forms suitable for comparison with the experimental results. These calculations were made using Mason's results[18].

An early paper by Seitz[3][5] gave the following expressions for the magnetoresistance of a semiconductor.

$$\mathbf{I}=\sigma_0\mathbf{E}+\alpha(\mathbf{E}\times\mathbf{H})+\beta\mathbf{E}H^2+\gamma\mathbf{H}(\mathbf{E}\cdot\mathbf{H})+\delta T\mathbf{E}\ , \tag{2–1}$$

$$\mathbf{E}=\rho_0[\mathbf{I}+a(\mathbf{I}\times\mathbf{H})+b\mathbf{I}H^2+c\mathbf{H}(\mathbf{I}\cdot\mathbf{H})+dT\mathbf{I}]\ , \tag{2–2}$$

where **I** is the current density, **E** and **H** are the electric and magnetic fields ; σ_0 and ρ_0 are ordinary conductivity and ordinary resistivity; T is a diagonal tensor with elements $H_1{}^2$, $H_2{}^2$ and $H_3{}^2$; α and a are constants relating to the Hall effect ; β, γ, δ, b, c and d are constants of the magnetoresistance. A later report by Mason *et al*[18]. contained an expression for the magnetoresistance and the Hall effect as a function of the electric current and of the magnetic field which extended to the fifth power of the magnetic field. The expression is

$$\begin{aligned}E_i=&[\rho_{ij}+\pi_{ijkl}H_kH_l+\zeta_{ijklmn}H_kH_lH_mH_n+\cdots]I_j\\&+\varepsilon_{ijk}[R_{km}H_m+\kappa_{kmno}H_mH_nH_o+\lambda_{kmnopq}H_mH_nH_oH_pH_q+\cdots]I_j\ ,\end{aligned} \tag{2–3}$$

where $i, j, k, \cdots$ are suffixes expressing directions ; ρ_{ij} is the resistivity ; π_{ijkl} and ζ_{ijklmn} are coefficients relating to the magnetoresistance ; κ_{kmno} and λ_{kmnonq} are coefficients relating to the Hall effect, and R_{km} is the Hall coefficients at low field ; ε_{ijk} is as follows :

$$\varepsilon_{ijk}\begin{cases}=\ \ 1 & \text{for}\quad i, j, k\quad \text{is}\quad (1, 2, 3), (2, 3, 1), (3, 1, 2)\\ =-1 & \text{for}\qquad\qquad\qquad (2, 1, 3), (1, 3, 2), (3, 2, 1)\ .\end{cases}$$

Hereafter the following abbreviations will be used for the pairs of suffixes in conformity with the notations used in Mason's paper[18] :

$$11\rightarrow1,\ 22\rightarrow2,\ 33\rightarrow3,\ 23=32\rightarrow4,\ 13=31\rightarrow5,\ 12=21\rightarrow6\ .$$

The independent coefficients of Eq. (2–3) for O_h can be shown as follows[18] :

$$\begin{aligned}\rho_{ij}&\rightarrow\rho_0\\R_{ij}&\rightarrow R\\\pi_{ijkl}&\rightarrow\pi_{11},\ \pi_{12},\ \pi_{66}\\\kappa_{ijkl}&\rightarrow\kappa_{11},\ \kappa_{12}\\\zeta_{ijklmn}&\rightarrow\delta_{111},\ \zeta_{112},\ \zeta_{122},\ \zeta_{123},\ \zeta_{441},\ \zeta_{442}\\\lambda_{ijklmn}&\rightarrow\lambda_{111},\ \lambda_{112},\ \lambda_{123}\ .\end{aligned}$$

Therefore Eq. (2–3) becomes

$$\begin{aligned}E_1=&\rho_0 I_1+\pi_{11}I_1H_1{}^2+\pi_{12}I_1(H_2{}^2+H_3{}^2)+2\pi_{66}H_1(I_2H_2+I_3H_3)\\&+\zeta_{111}I_1H_1{}^4+6\zeta_{112}I_1H_1{}^2(H_2{}^2+H_3{}^2)+\delta_{122}I_1(H_2{}^4+H_3{}^4)+6\zeta_{123}I_1H_2{}^2H_3{}^2\\&+12\zeta_{441}H_1H_2H_3(I_2H_3+I_3H_2)+4\zeta_{442}H_1[I_3H_3(H_1{}^2+H_3{}^2)+I_2H_2(H_1{}^2H_2{}^2)\\&+(R+3\kappa_{12}H^2+5\lambda_{112}H^4)(I_2H_3-I_3H_2)+(\gamma_{11}-3\gamma_{12})(I_2H_3{}^3-I_3H_2{}^3)\\&+(\lambda_{111}-5\lambda_{112})(I_2H_3{}^5-I_3H_2{}^5)+(30\lambda_{123}-10\lambda_{112})[I_2H_3H_1{}^2H_2{}^2-I_3H_2H_1{}^2H_3{}^2]+\cdots\,.\end{aligned}\tag{2–4}$$

Similar equations can be derived for E_2 and E_3. The voltage appearing in any direction across the specimen can be calculated for simple geometry for any possible combination of directions of the electric current and the magnetic field.

When an electric current flows in the [100] direction and a magnetic field is in the $x-y$ plane, namely ; the magnetic field rotates about an axis in the z-direction, we obtain

$$\begin{aligned}E^{100}_{100}\langle 001\rangle = I\,[&\rho_0+(\pi_{11}\cos^2\theta+\pi_{12}\sin^2\theta)H^2\\&+(\zeta_{111}\cos^4\theta+6\zeta_{112}\cos^2\theta\sin^2\theta+\zeta_{122}\sin^2\theta)H^4]\,,\end{aligned}\tag{A–1}$$

where θ is the angle between I and H. The superscript expresses the direction of the voltage, the subscript the direction of the current, and $\langle 001\rangle$ expresses the direction of the rotational axis of the field. In a similar way, when the magnetic field lies in the $y-z$ plane we obtain

$$E^{100}_{100}\langle 100\rangle=I[\rho_0+\pi_{12}H^2+\{\zeta_{122}(\cos^4\theta'+\sin^4\theta')+6\zeta_{123}\cos^2\theta'\sin^2\theta'\}H^4]\,.\tag{A–2}$$

In this case the angle between I and H is always 90°, and θ' is the angle between the H and the z-direction. When the current flows in the [110] direction, the electric field appearing in the same direction for various rotational axes of the magnetic field is given by

$$\begin{aligned}E^{001}_{001}\langle 001\rangle=I\Bigg[&\rho_0+\Bigg\{\frac{\pi_{11}+\pi_{12}}{2}+\pi_{66}(\cos^2\theta-\sin^2\theta)\\&+\Bigg\{\frac{\zeta_{111}+\zeta_{122}}{4}(1+4\sin^2\theta\cos^2\theta)\\&+\frac{3}{2}\zeta_{112}(\cos^2\theta-\sin^2\theta)+2\zeta_{442}(\cos^2\theta-\sin^2\theta)\Bigg\}H^4\Bigg]\,.\end{aligned}\tag{B–1}$$

$$\begin{aligned}E^{110}_{110}\langle 1\bar{1}0\rangle=I\Bigg[&\rho_0+\Bigg\{\frac{\pi_{11}}{2}\cos^2\theta+\pi_{12}\left(\frac{\cos^2\theta}{2}+\sin^2\theta\right)+\pi_{66}\cos^2\theta\Bigg\}H^2\\&+\Bigg\{\frac{\zeta_{111}}{4}\cos^4\theta+3\zeta_{112}\cos^2\theta\left(\frac{\cos^2\theta}{2}+\sin^2\theta\right)+\zeta_{122}\left(\frac{\cos^4\theta}{4}+\sin^4\theta\right)\\&+3(\zeta_{123}+2\zeta_{441})\cos^2\theta\sin^2\theta+2\zeta_{442}\cos^4\theta\Bigg\}H^4\Bigg]\,,\end{aligned}\tag{B–4}$$

$$\begin{aligned}E^{110}_{110}\langle 110\rangle=I\Bigg[&\rho_0+\Bigg\{\frac{\pi_{11}}{2}\cos^2\theta'+\pi_{12}\left(\frac{\cos^2\theta'}{2}+\sin^2\theta'\right)-\pi_{66}\cos^2\theta'\Bigg\}H^2\\&+\Bigg\{\frac{\zeta_{111}}{4}\cos^4\theta'+\zeta_{112}\cos^2\theta'\left(\frac{\cos^2\theta'}{2}+\sin^2\theta\right)+\zeta_{122}\left(\frac{\cos^4\theta'}{4}+\sin^4\theta'\right)\\&+3(\zeta_{123}-2\zeta_{441})\cos^2\theta'\sin^2\theta'-2\zeta_{442}\cos^4\theta'\Bigg\}H^4\Bigg]\,.\end{aligned}\tag{B–5}$$

In Eq. (B–5) θ' express the angle between H and the $[1\bar{1}0]$ direction.

When the current flows in the [100] direction and the magnetic field rotates in the $x-y$ plane, the electric field that appears in the [010] direction is a measure of the planar Hall effect. Thus

$$E^{010}_{100}\langle 001\rangle=I(\pi_{66}H^2+2\zeta_{442}H^4)\sin 2\theta\,.\tag{Ap–1}$$

Similarly

$$E^{1\bar{1}0}_{110}\langle 001\rangle=\frac{1}{2}\{(\pi_{11}-\pi_{12})H^2+(\zeta_{111}-\zeta_{112})H^4\}\sin 2\theta\ . \qquad \text{(Bp—1)}$$

Table I gives the directions of the current, of the voltage and of the axis of rotation in the above equations.

The potential gradient which appears through the specimen for special directions of the applied field and current can be calculated from the above equations as follows:

$$E^{100}_{100}[100]=I[\rho_0+\pi_{11}H^2+\zeta_{111}H^4]\ , \qquad \text{(i)}$$

$$E^{100}_{100}[001]=I[\rho_0+\pi_{12}H^2+\zeta_{122}H^4]\ , \qquad \text{(ii)}$$

$$E^{110}_{110}[110]=I\left[\rho_0+\frac{\pi_{11}+\pi_{12}+2\pi_{66}}{2}H^2+\frac{\zeta_{111}+6\zeta_{112}+\zeta_{122}+8\zeta_{442}}{4}H^4\right], \qquad \text{(iii)}$$

$$E^{110}_{110}[1\bar{1}0]=I\left[\rho_0+\frac{\pi_{11}+\pi_{12}-2\pi_{66}}{2}H^2+\frac{\zeta_{111}+6\zeta_{112}+\zeta_{122}-8\zeta_{442}}{4}H^4\right], \qquad \text{(iv)}$$

$$E^{110}_{110}[001]=I[\rho_0+\pi_{12}H^2+\zeta_{122}H^4]\ , \qquad \text{(v)}$$

$$E^{110}_{110}[\theta=45°]=I\left[\rho_0+\frac{\pi_{11}+3\pi_{12}+2\pi_{66}}{4}H^2\right.$$
$$\left.+\frac{\zeta_{111}+18\zeta_{112}+5\zeta_{122}+12\zeta_{123}+24\zeta_{441}+8\zeta_{442}}{16}H^4\right]^{*}, \qquad \text{(vi)}$$

$$E^{010}_{100}[110]=I[\pi_{66}H^2+2\zeta_{442}H^4]\ , \qquad \text{(vii)}$$

$$E^{1\bar{1}0}_{110}[010]=I\left[\frac{\pi_{11}-\pi_{12}}{2}H^2+\frac{\zeta_{111}-\zeta_{112}}{2}H^4\right]. \qquad \text{(viii)}$$

Table I. Specifications of the curves in Figs. 2~5 and corresponding equations.

(viii)	[110]	[11̄0]	[010]	45°	Bp-1

The superscripts indicate the direction of the potential gradient, the subscripts the direction of the current, and [110] or [010] indicates the direction of the magnetic field. Equations (vii) and (viii) give the planar Hall voltage, while the other equations give the magnetoresistance.

Table II shows the directions of the current, of the potential gradient and of the magnetic field; θ is the angle between the current and the magnetic field. The last column gives the curves of Table I which contain as a special case the condition listed in the corresponding row of Table II.

§ 3. Theoretical Considerations

Shibuya[16)] calculated magnetoresistance effect of semiconductors in which the electrons or the holes obeyed Maxwell statistics and interacted with the accoustical mode of the lattice vibration. In his paper the electronic energy is assumed to be expressed as families of spheroidal surfaces in $\boldsymbol{k}$-space. The calculations were made for the following three cases: the spheroids have six {100} axes as symmetrical axes (case **a**), twelve {110} axes (case **b**), and eight {111} axes (case **c**). One of the most important results of his calculations is that there exist the following relations between the coefficients of the magnetoresistance in connection with the electronic band structure of the crystals.

---

* Eq. (vi) is the special case for $\theta=45°$ in Eq. (B-4).

$$\begin{aligned} \beta+\gamma+\delta=0 &\text{ and } \delta>0 \text{ for (case } \mathbf{a}) , \\ \beta+\gamma-\delta=0 &\text{ and } \delta<0 \text{ for (case } \mathbf{b}) , \\ \beta+\gamma=0 &\text{ and } \delta<0 \text{ for (case } \mathbf{c}) , \\ \delta=0 &\text{ for spherical energy surface.} \end{aligned} \tag{3-1}$$

We may obtain information on the band structure from magnetoresistance experiments by using Eq. (3–1). But Eq. (3–1) only is not enough to decide whether the spheroids are prolate or oblate. Here we deduce several formulas from Shibuya's theory in order to obtain additional information about the band structure from our experiments.

First we calculate the conductivity tensor for various directions of the magnetic field. The tensor form becomes the same as for the above three cases, although the expressions for the tensor elements are different from one another.

When **H** is in the [100] direction, the conductivity tensor is

$$L=\begin{vmatrix} L_1 & 0 & 0 \\ 0 & L_2 & L_3 \\ 0 & -L_3 & L_2 \end{vmatrix} . \tag{3-2}$$

The resistivity is expressed in terms of the elements of tensor (3–2) as follows:

$$\rho_{11}=1/L_1 , \tag{3-3}$$

$$\rho_{\perp}=L_2/(L_2^2+L_3^2) , \tag{3-4}$$

where ρ_{11} is the resistivity when the current is parallel to the magnetic field, and $\rho_{\perp}$ is the resistivity when the current is perpendicular to the magnetic field. In this case $\rho_{\perp}$ is expressed by Eq. (3–4) for any direction of the current is perpendicular to the field. When **H** is in the [110] direction.

$$L=\begin{vmatrix} L_1 & L_3 & -L^4 \\ L_3 & L_1 & L_4 \\ L_4 & -L_4 & L_2 \end{vmatrix} , \tag{3-5}$$

$$\rho_{11}=1/(L_1+L_3) . \tag{3-6}$$

When **H** is in the [1$\bar{1}$0] direction, the conductivity tensor is expressed with the same elements L_i's as tensor (3–5) by

$$L=\begin{vmatrix} L_1 & -L_3 & L_4 \\ -L_3 & L_1 & L_4 \\ -L_4 & -L_4 & L_2 \end{vmatrix} . \tag{3-7}$$

When the current flows in the [110] direction and **H** is in the [1$\bar{1}$0] direction the resistivity becomes, tensor elements (3–7) being used,

$$\rho_{\perp}=L_2/\{L_2(L_1-L_3)+2L_4^2\} . \tag{3-8}$$

The planar Hall effect is a phenomenon in which a voltage appears across the specimen in a plane fixed by the current and the magnetic field and is perpendicular to the current. The planar Hall voltage has its maximum value at $\theta=45°$. Therefore the maximum planar Hall voltage for a [100] specimen is obtained when the following conditions are satisfied: the direction of **I** is [100], the direction of **H** is [110] and the direction of **E** is [010]. Thus, using the elements of conductivity tensor (3–5), E is expressed as

$$E=\frac{I(L_4^2-L_2L_3)}{(L_1+L_3)\{2L_4^2+L_2(L_1-L_3)\}} . \tag{3-9}$$

For a [110] specimen, the maximum value of the planar Hall voltage appers when the direction of **I** is [110], the direction of **H** is [100], and the direction of **E** is [1$\bar{1}$0]. Using the elements of Eq. (3–2)

$$\begin{aligned} E&=\frac{I}{2}\left\{\frac{1}{L_1}-\frac{L_2}{(L_2^2+L_3^2)}\right\} \\ &=\frac{I}{2}(\rho_{11}-\rho_{\perp}) . \end{aligned} \tag{3-10}$$

Thus the resistivity and the planar Hall voltage are expressed in terms of the conductivity tensor.

Next we give explicit forms of some of the above formulas for the resistivity. The expressions are different from one another for the three cases so that some information on the band structure can be obtained by comparing the results of calculations with experimental results. Shibuya[16] expressed his calculated result by a closed formula. Eq. (3–1) was obtained by the expansion of the closed formula in a series of ascending powers of **H** and examination of the coefficients of H^2. We shall mention here the terms proportional to H^4 as we did in section 2. Expansition of Shibuya's formula into an ascending power series of **H** up to the fourth power, which has been performed below is not mathematically precise. Nevertheless we have performed the expansion and compared the calculated results with the experimental results with the expectation that we would be able to obtain some information on the band structure, for example, the shape of the spheroids.

Eq. (3-3) is expanded as an ascending power series of **H** and this series is compared with Eq. (i). Thus we obtain relations between the constants of magnetoresistance and the parameter which is related to the band structure. For the three cases mentioned above the relations obtained are

$$\rho_0=3/NeA(r+2) \qquad \text{for all three cases,} \tag{3–11}$$

$$\pi_{11}=0 \quad \text{and} \quad \zeta_{111}=0 \qquad \text{for (case } \mathbf{a}\text{),} \tag{3–12}$$

$$\left.\begin{aligned} \pi_{11}&=\frac{(r-1)^2B^2}{2(r+2)}\rho_0 \\ \xi_{111}&=\frac{(r-1)^2(r+1)B^4\rho_0}{4(r+2)}Ei\left(-\frac{r+1}{2}B^2H^2\right) \end{aligned}\right\} \qquad \text{for (case } \mathbf{b}\text{),} \tag{3–13}$$

$$\left.\begin{aligned} \pi_{11}&=\frac{2(r-1)^2B^2}{3(r+2)}\rho_0 \\ \zeta_{111}&=\frac{2(r-1)^2(2r+1)B^4\rho_0}{9(r+2)}Ei\left(-\frac{2r+1}{3}B^2H^2\right) \end{aligned}\right\} \qquad \text{for (case } \mathbf{c}\text{),} \tag{3–14}$$

where $r=m_2/m_1$ is the ratio of the mass perpendicular to the rotational axis of the energy spheroid to that parallel to it, N being the carrier density. A and B are given in Shibuya's paper[16]; A being generalized mobility. $Ei(-X)$, the exponential integral, by itself becomes infinite at $X=0$, but Eq. (i) combined with coefficients (3–13) or (3–14) converges at $H=0$ because of the factor H^4. Strictly speaking, expressions (3–13) and (3–14) are not to be considered as the coefficients of the power series corresponding to Eq. (i), as they contain a function Ei of H. For the present purpose, however, we use such expressions as Eqs. (3–13) and (3–14), and comment upon this point will be made later.

Similarly comparison between Eqs. (3–6) and (iii) is made. At first Eq. (iii) is rewritten as follows:

$$\rho=\rho_0+\Pi H^2+ZH_2\,. \tag{3–15}$$

Then

$$\rho_0=3/NeA(r+2) \qquad \text{for all cases,}$$

$$\left.\begin{aligned} \Pi&=\frac{(r-1)^2}{2(r+2)}B^2\rho_0 \\ Z&=\frac{(r+1)(r-1)^2B^4\rho_0}{4(r+2)}Ei\left(-\frac{r+1}{2}B^2H^2\right) \end{aligned}\right\} \qquad \text{for (case } \mathbf{a}\text{),} \tag{3–16}$$

$$\left.\begin{aligned} \Pi&=\frac{3(r-1)^2}{8(r+2)}B^2\rho_0 \\ Z&=\frac{3(3r+1)(r-1)^2\beta^4\rho_0}{32(r+2)}Ei\left(-\frac{3r+1}{4}B^2H^2\right) \end{aligned}\right\} \qquad \text{for (case } \mathbf{b}\text{),} \tag{3–17}$$

$$\left.\begin{aligned} \Pi&=\frac{(r-1)^2}{3(r+2)}B^2\rho_0 \\ Z&=\frac{(r-1)^2B^4\rho_0}{9}Ei\left(-\frac{r+2}{3}\beta^2H^2\right) \end{aligned}\right\} \qquad \text{for (case } \mathbf{c}\text{).} \tag{3–18}$$

§ 4. Experiments

Procedures. The specimen used were of synthetic *p*-type. The method of crystal growing was the same as that described in a previous paper[1]. Two parallelepiped specimens about 3 × 2 × 1 mm^3 were cut from a single crystal. The directions of the long axes were [100] and [110]. Current leads and resistivity probes were attached to the specimen in the manner previously described[1]. Magnetoresistance and planar Hall effect were measured by the usual *dc* method using these two specimens. The current during the measurements was 50 *mA* and 100 *mA*; at these currents the voltage to be measured was verified to be proportional to the current. The magnetic field extended up to 10300 gauss produced by an electromagnet of 9 *A* exciting current. The polepiece of the magnet was 200 *mm* in diameter, the gap between polepieces 38 *mm*. All measurements were made at 90°K using a Dewar vessel and liquid air. When the measurements were made, the specimen was rotated about an axis which was perpendicular to the magnetic field, and the strength of the magnetic field was varied.

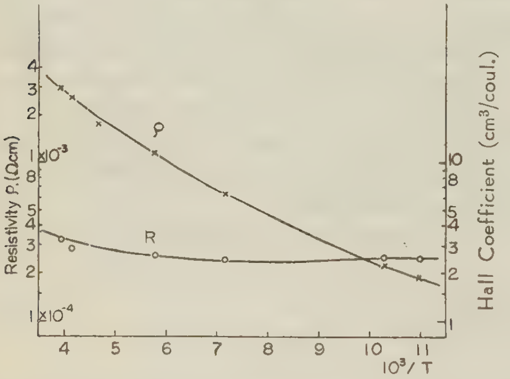

Fig. 1. Temperature dependence of resistivity and low field Hall coefficient.

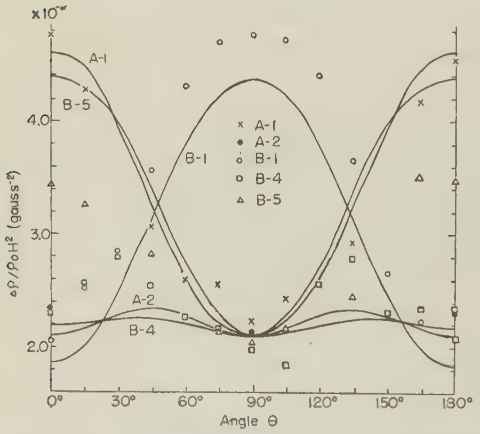

Fig. 2. Angular dependence of magnetoresistance at 5500 gauss.

Results. Fig. 1 shows the resistivity and the low field Hall coefficient of the crystal as a function of $1/T$, T being the absolute temperature. Their temperature variations are normal for PbTe crystals[1]. The resistivity is $1.93 \times 10^{-4} \Omega cm$ and the Hall coefficient is $+2.48\ cm^3/coul.$ at 90°K.

In Figs. 2 and 3 magnetoresistance is shown as a function of the angle between the current and the magnetic field. The ordinate is $\Delta\rho/\rho_0 H^2 = \{\rho(H) - \rho(H=0)\}/\rho(H=0)H^2$, and the abscissa is the angle between **I** and **H**, except curves A-2 and B-5 for which the angle between **I** and **H** is always 90° and θ in the figures represents the angle between the mag-

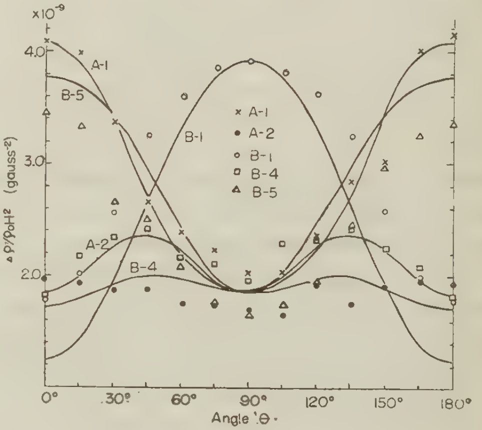

Fig. 3. Angular dependence of magnetoresistance at 8000 gauss.

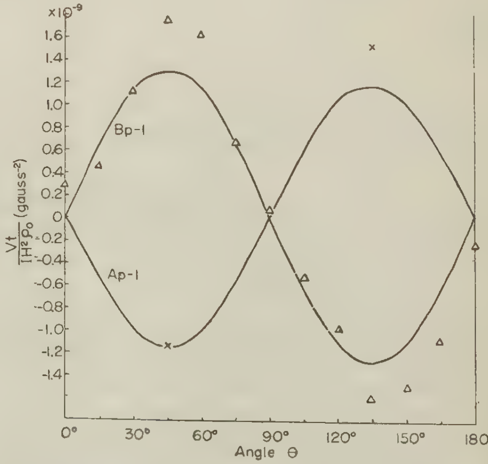

Fig. 4. Angular dependence of planar Hall effect at 5500 gauss. The dimension of the ordinate is the same as that of Figs. 2 and 3. The ordinate represents $Vt/IH^2\rho_0$, where V is the measured voltage, t the thickness of the specimen, I the current through the specimen.

netic field and the [010] and the [110] directions respectively. The field strength is 5500 gauss in Fig. 2 and 8000 gauss in Fig. 3. The nomenclature used for the curves corresponds to that of Table I. From these figures it is seen that the angular variation of magnetoresistance does not necessarily follow the $A+B\sin^2\theta$ law predicted by low field theory[3]. The curves shown in the figures are those obtained by calculation, which will be described later.

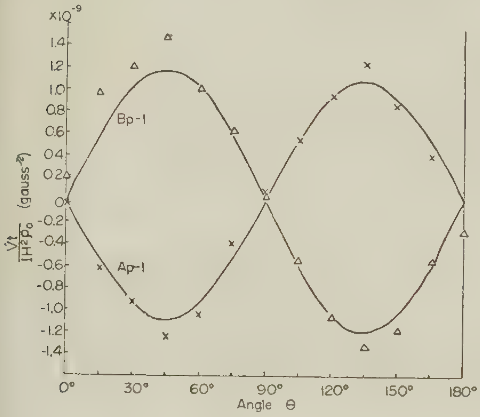

Fig. 5. Angular dependence of planer Hall effect at 8000 gauss.

Figs. 4 and 5 show the planar Hall effect as a function of the angle θ for magnetic field of 5500 gauss and 8000 respectively. The dimension of the ordinate is chosen to be the same as that in Figs. 2 and 3 for the sake of convenience of comparison. The angular variation seems to follows, within experimental accuracy, the $\sin 2\theta$ law as described by the theory[14].

Magnetic field dependence of magnetoresistance and planar Hall effect is shown in Fig. 6, log. $\Delta\rho/\rho_0$ *vs.* log H being plotted. Variation of magnetoresistance and planar Hall effect with respect to the magnetic field is smaller than that given by the H^2 low. The straight lines shown in the figures are so drawn that they fit the experimental points. The exponents n's of the lines with respect to **H** are listed in Table III.

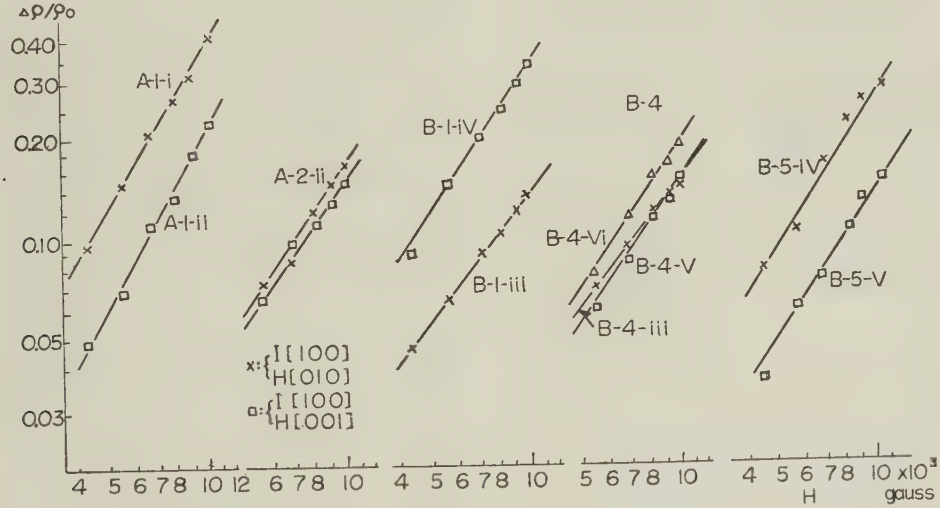

Fig. 6. (a) Field dependence of magnetoresistance, $\Delta\rho/\rho_0$ as a function of H.

The angular variation shown in Figs. 2 and 3 does not necessarily satisfy the $A+B\sin^2\theta$ low. This fact suggests that terms of higher powers of **H**, namely; terms proportional to H^4, have appreciable effect on the results. And the results shown in Fig. 6 also support the view that the experiments deviate from the law. When we plot $\Delta\rho/\rho_0 H^2$ vs. H^2, we can see whether the magnitude of the magnetoresistance is proportional to H^2 or not. If the plots are horizontal straight lines, the field dependence is expressed as H^2 rigorously. If they are inclined straight lines, the field dependence is expressed by $\Delta\rho/\rho_0=(\Pi H^2+ZH)^4/\rho_0$, and Π and Z are determined from the point of intersection with the ordinate axis and from the slope respectively. The results are shown in Fig. 7. It is seen from the figure that the experimental points are fairly well approximated by inclined straight lines. The coefficients determined from these lines are indicated in Table III. The agreement is satisfactorily good between coefficients which are evaluated from different curves but correspond to the same conditions, e.g. A-1-ii and A-2-ii. By combining these values and Eqs. (i)~(iv) we can determine consistently the constants of galvanomagnetic effects, which are indicated in Table IV.

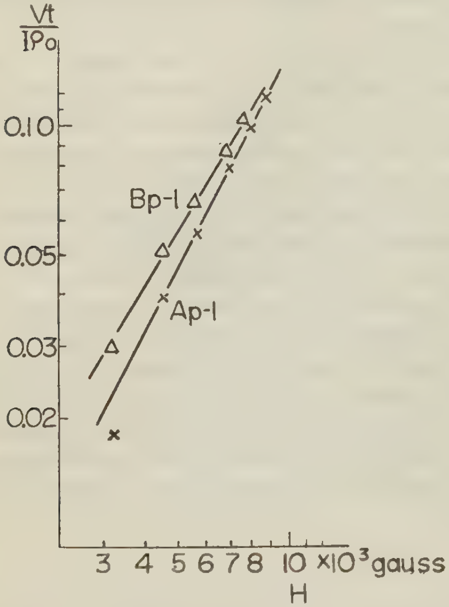

Fig. 6. (b) Field dependence of planar Hall effect. The dimension of the ordinate is the same as that of Fig. 6 (a).

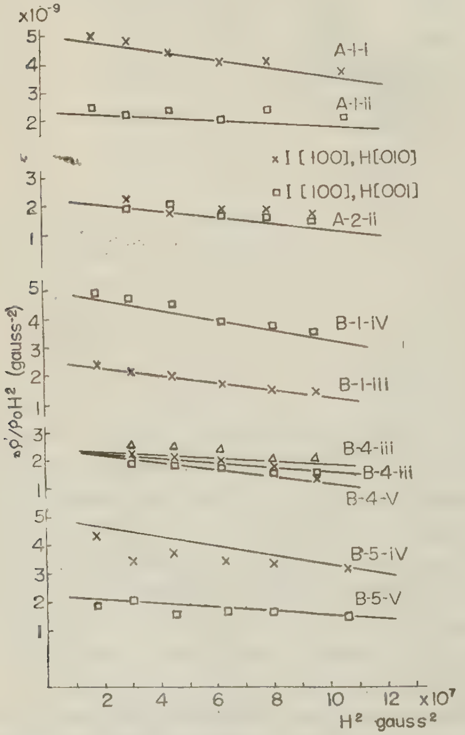

Fig. 7 (a). Field dependence of magnetoresistance. $\Delta\rho/\rho_0 H^2$ as a function of H^2.

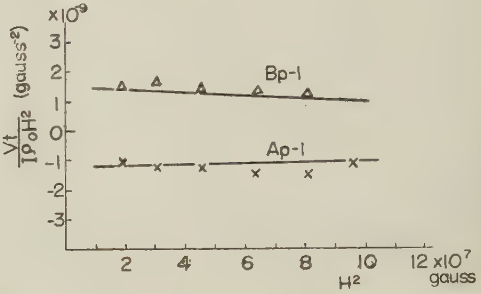

Fig. 7 (b). Field dependence of planar Hall effect. The dimension of the ordinate is the same as that of Fig. 7 (a).

Table III. Experimental values and theoretical formulas expressing the dependence of the galvanomagnetic effects upon the magnetic field.

Curve	π/ρ_0		Z/ρ_0	Exponen n of H^n
	Experimental value $\times 10^9$ (gauss^{-2})	Theoretical expression	Experimental value $\times 10^{18}$ (gauss^{-4})	Experimental value
A-1-i	5.2	$b+c+d$	−16	1.6
A-1-ii	2.6	b	− 6	1.8
A-2-ii	2.3		− 7	1.4
B-1-iii	2.6	$b+c+(d/2)$	−13	1.3
B-4-iii	2.2		− 8	1.3
B-1-iv	5.3	$b+(d/2)$	−18	1.5
B-5-iv	4.3		−12	1.5
B-4-v	2.3	b	− 8	1.3
B-5-v	2.2		− 8	1.5
B-4-vi	2.8	$b+(c/2)+(d/4)$	− 8	1.4
Ap-1-vii	2.5	$c/2$	− 1	1.8
Bp-1-viii	3.6	$(c+d)/2$	− 2	1.6

The straight lines shown in Fig. 7 are calculated by using Eqs. (i)~(viii) and the constants indicated in table IV. It must be noted that the constants listed in Table III are not used in the calculation of these lines. The solid curves of Figs. 2~5 are also obtained by calculating Eqs. (A-1), (A-2),⋯ and (Bp-1) with the constants shown in Table IV. It is known, from these figures, that the constants obtained from the field dependence of galvanomagnetic effects can also

Table IV. Values of the coefficient of galvanomagnetic effects.

		ζ^{442}/ρ_0	1×10^{-18} 〃

represent their angular dependence tolerably well. From the consistency shown in Table III and Figs. 2∼7, we think that these constants are reliable enough to be worthy of qualitative or partially quantitative discussions.

§ 5. Analysis

The constants of the galvanomagnetic effects derived in the preceding section can be considered to represent the characteristic values of the crystal as described before. Thus their values are used here in order to discuss the electronic band structure of the crystal. The fact that the longitudinal magnetoresistance, in general, is not zero but has a larger value shows that the band is far from that given by the simple spherical energy surface model.

The coefficients of H^2 are examined first. The relations between the coefficients expressed by Eq. (3–1) become, using Table IV, as follows:

$$\beta+\gamma+\delta=-2.7\times10^{-5}\,,$$
$$\beta+\gamma-\delta=+2.9\times10^{-5}\,,$$
$$\beta+\gamma=+1\times10^{-6}$$

and $\delta<0$. Therefore this crystal corresponds to (case **c**), *i.e.*; the band structure is approximated by energy spheroids having {111} axes as symmetrical axes. The mass ratio r is obtained by solving

$$\frac{\beta}{\delta}=\frac{(r+2)(2r+1)}{2(r-1)^2}\,. \tag{5–1}$$

The solution is: $r=3.5$ or $r=0.3$. The carrier density N is calculated by Eqs. (34), (35) and (23) of Shibuya's paper:

$$N=\begin{cases}2.36\times10^{18} & \text{for } r=3.5\\ 2.70\times10^{18} & \text{for } r=0.3\end{cases} \tag{5–2}$$

Moreover using $\sigma_0=NeA(r+2)/3$ and Eq. (7) of Shibuya's paper, we obtain

$$B=\begin{cases}9.9\times10^{-5} & \text{for } r=3.5\\ 2.1\times10^{-4} & \text{for } r=0.3\end{cases} \tag{5–3}$$

By combining the equations given in Table I of Shibuya's paper, we can also calculate the value of B. The value thus obtained is nearly equal to the value given by (5–3).

Saturation values of magnetoresistance are required in order to determine which value of r should be used. Unfortunately we could not produce a field strong enough to obtain saturation values. Therefore only a few comments will be given on the choice of values for r's by referring to the coefficients of H^4 determined in section 4. We have calculated the coefficients of H^4 by Eqs. (3–14) and (3–18) as shown in Table III. The coefficients obtained however are not constant but contain a factor Ei$(-X)$ whose argument includes the magnetic field. Unfortunately this factor varies by a fairly large amount within the range of magnetic fields used. Nevertheless, we compare the experimental values with the calculated ones. The coefficients of the fourth power of **H** must always be negative, because the equations, from which the coefficients are calculated, include the factor Ei$(-X)$ whose value is always negative. This requirement is, of course, realized in our experiments as shown in the figures and tables.

Let us examine the ratio of ζ_{111} to Z, referring to Eqs. (3–14) and (3–18) neglecting the slight difference between the arguments of the two equations. This ratio becomes 2.9 for $r=3.5$; or 1.4 for $r=0.3$, while corresponding value obtained experimentally is seen to be 1.5 from Table IV and Eqs. (i), (iii), (3–15) and (3–18). Therefore $r=0.3$, *i.e.*, prolate, seems more reasonable, although we must not jump to conclusions. The ratio of coefficients π_{11}/Π becomes, referring to Eqs. (3–12), (3–13), (3–14), (3–16), (3–17) and (3–18), as follows: 0 for (case **a**); 4/3 for (case **b**); 2 for (case **c**); these values being true regardless of the value of r. The corresponding experimental value is 2.0 which is deduced using Eqs. (i), (iii), (3–15) and Table IV. This value supports our conclusion that the crystal belongs to (case **c**).

§ 6. Discussions of the Results

The results of the calculation and analysis of this paper must be carefully examined. First of all a comment will be made on Eqs. (3–14) and (3–18). These equations are not considered simply to represent the coefficients of the fourth power of **H**. But it is believed that these equations have some relation to the coefficients, for example, proportional relation. On the basis of the assumption that expressions (3–14) and (3–18) are proportional to the coefficients, we have derived $r=0.3$ in the preceding section.

On the other hand Allgaier[13)] has recently published magnetoresistance data for PbS, PbSe and PbTe, and given a consideration on their band structure. Especially for PbTe he has obtained a definite conclusion and pointed out that his data and conclusion agree pretty well with our data and conclusion, which had been published previously in this journal.[19)] He has obtained $r=0.25\sim0.17$ by analyzing his data by means of Gold-Roth theory.[20)] His conclusion coincides with ours in that PbTe is to be represented by the {111} model and that the energy spheroids are prolate. Moreover his value of r is not much different from the value given in this paper.

Next it must be examined whether the assumptions on the basis of which Shibuya's calculation[16)] is made hold for these experiments or not. One of the questions is whether the holes of the crystal are degenerate or non-degenerate at the temperature of the measurements. The effective mass of the hole was given as $0.94\,m$ in our previous paper.[1)] Then the degenerate temperate of this crystal is calculated in the usual manner to be obout 80°K. The effective mass given in the previous paper is, however, the inertial mass; and the '*density-of-states*' mass is four times as large as the inertial mass if the crystal is expressed by the {111} eight-valley model. Therefore the degenerate temperature becomes lower by a factor of four. The holes in the crystal at the temperature of the measurements are not degenerate and Shibuya's theory can be applied to the crystal from this point of view.

The relaxation time for scattering used in Shibuya's calculation is inversely proportional to the square root of the carrier energy, which corresponds to the acoustical mode of lattice vibration. PbTe crystal is, however, thought to be an ionic or partial ionic crystal and, as pointed out in our previous paper,[1)] it is possible that the carriers are scattered mainly by the optical mode of lattice vibration. The relaxation time corresponding to the optical mode is independent of the carrier energy. One may doubt whether Shibuya's theory can be applied to this crystal.

The calculated expressions for the galvanomagnetic effects generally consist of the product of two factors, one of which is a function of the dependence of the relaxation time on the energy and also a function of the applied statistics, while the other is a function only of the shape of the energy band.[6)15)16)17)] Therefore relations (3–1) still represent the characteristics of the band structure and the discussion of section 5 dealing with ratios of magnetoresistance coefficients is also adequate when the relaxation time is different from that used by Shibuya.[16)] Thus it is concluded that the main parts of our analyzed results need not be corrected if the optical mode of lattice vibration is the main source of scattering, and even if the holes are degenerate.

In finishing this paper we will sum up the results as follows: *i*) Phenomenological expressions for galvanomagnetic effects are derived as a function of the magnetic field. The expressions are power series of **H** which have been calculated up to the fourth power. *ii*) Expanding Shibuya's formula the coefficients of the above power series are calculated as a function of parameters which represent the shape of the band structure. *iii*) Magnetoresistance and planar Hall effect of p-type PbTe are measured as a function of the field strength and of the angle θ. *iv*) The constants for the galvanomagnetic effects are determined from the measurements as a function of the field strength. The constants determined are coefficients of H^2 and H^4, and they corresponds reasonably well with the values measured as a function of θ. *v*) Using the constants relating to H^2, the band structure is shown to be represented by {111} energy spheroids. *vi*) Using the constants relating to H^4, it is speculated that the spheroids may be prolate with the mass ratio of 0.3. *vii*) The above conclusions agree reasonably well with those ef Allgaier. *viii*) The applicability of Shibuya's theory to this crystal is examined and verified.

The writer wishes to express his sincere thanks to Professor Y. Sakaki, at whose laboratory in Nagoya University the main parts of this work were done, for his kind guidance and encouragement. He is very grateful to Professor A. Okazaki and Professor K. Ariyama, who gave kind and critical review of the original manuscript. He is indebted to Dr. S. Uchiyama, who helped him by preparing the experiments for this research, by making measurements during the preliminary phases of the work, and by his suggestion and discussion.

Magnetic Susceptibility of Liquid Alloys of Copper with Cobalt, Iron, Manganese, and Chromium

By Yasuaki NAKAGAWA*

Department of Physics, Faculty of Science, University of Tokyo

(Received June 6, 1959)

A systematic investigation has been made on the magnetic susceptibility of a series of transition metals dissolved in molten copper at temperatures up to 1600°C. These molten metals are miscible in all proportions except for the Cu-Cr system.

The susceptibilities of the Cu–Co and Cu–Fe alloys follow the Curie-Weiss law. The Curie constant is roughly proportional to the concentration of Co or Fe. The paramagnetic Curie temperature for the Cu-Co system rises monotonously with the concentration of Co, while that for the Cu-Fe system shows a maximum at an intermediate composition. In the Cu-Mn and Cu-Cr systems, only the Cu-rich alloys show the Curie-Weiss paramagnetism, while the alloys containing more than 50% Mn or more than 5% Cr show rather temperature-independent paramagnetism.

§ 1. Introduction

The magnetic properties of dilute alloys of transition metals in noble metals have fully been studied by many investigators. The more enriched alloys, however, have been ignored in most cases, because the solid solubility is in general restricted. A systematic investigation on the variation of the magnetic properties with the composition of the alloys is possible in the liquid state, since these metals are miscible in almost all proportions. As reported previously by the present author,[1][2] the magnetic properties of the transition metals and alloys in the liquid state are not essentially different from those in the solid state. Accordingly, the magnetic properties in the solid state can be inferred to a certain extent from the measurements in the liquid state. In 1941 Weil[3] measured the magnetic susceptibilities of various transition metals dissolved in molten non-magnetic metals. Since his measurements were carried out below 1400°C, only the alloys having lower liquidus temperatures were studied.

The present work has been made at higher temperatures up to 1600°C. Specimens investigated are of the alloys of 3*d*-transition metals, such as Co, Fe, Mn and Cr, with a noble metal, Cu. The temperature dependence of the susceptibility can well be determined, because the liquidus temperatures for these alloys are fairly below 1600°C, except for the Cu-Cr alloys.

§ 2. Experimental Method

The measurements of magnetic susceptibility were made by Faraday's method using Sucksmith's ring balance. A silicon-carbide resistance furnace was used for the measurements at high temperatures, as described in our previous paper.[1] Each alloy specimen, weighing about 400 mg, was prepared by using this apparatus. The procedure was as follows: the two component metals of the alloy were contained together in a small alumina crucible fixed to the balance, and were heated by the furnace under a purified argon atmosphere. After the specimen had completely been melted and homogenized, its susceptibility was measured at various temperatures during successive cooling and heating cycles. The temperature was controlled step by step, the average cooling or heating rate being about 5°C/min.

During the first melting process, the magnetic susceptibility was measured to confirm the complete melting and mixing of the metals. Among the metals investigated, only chromium has the melting point higher than 1600°C. Because diffusion of the atoms in the liquid state is very rapid, the homogeneous liquid alloys could be formed in ten or twenty minutes at 1600°C, except for the Cu-Cr alloys. In the latter case, dissolution of solid chromium in molten copper is so sluggish that it took over an hour for the Cu-Cr specimens to reach thermal equilibrium.

---

* Present address: Department of Physics and Chemistry, Gakushuin University, Mejiro, Tokyo.

Temperatures were measured by Pt-PtRh thermocouple situated close to the specimen, calibrated *in situ* at the four transition temperatures of pure iron: ferromagnetic Curie point (770°C), α-γ transformation point on heating (910°C), γ-δ transformation point (1400°C), and melting point (1535°C); at these temperatures the magnetic susceptibility showed abrupt changes. The transition temperatures mentioned above are mainly based on a recent work of Pattison and Willows[4], being somewhat different from those described in our previous paper[1].

The metals used for the specimens were of very high purity. Electrolytic copper, cobalt, iron and manganese were used after being melted in a high vacuum induction furnace. The principal impurities determined by chemical analysis were carbon and silicon, the concentrations of which were as follows: C—0.006% in Cu, 0.008% in Co, 0.008% in Fe, and 0.010% in Mn; Si—0.001% in Cu, 0.060% in Co, 0.004% in Fe, and 0.010% in Mn. Chromium was spectroscopically pure obtained from Johnson, Matthey & Co.; the 'electrolytic flakes deoxidized' were used without the vacuum melting treatment. The compositions of the alloy specimens were not determined by chemical analysis but calculated from the mixing ratios. In this paper the compositions are hereafter expressed by atomic percent.

§ 3. Experimental Results

Cu-Co and Cu-Fe. Phase diagrams for the Cu-Co and Cu-Fe systems are similar to each other, showing very restricted solid solubility and nearly flat liquidus curve in the intermediate composition range.[5]

The susceptibility vs. temperature curves obtained for these alloys are shown in Fig. 1 and Fig. 2. Both Cu-Co and Cu-Fe alloys exhibit extensive supercooling of the liquid phase. The susceptibility curve measured during cooling is smooth at the liquidus temperature, T_L, and shows a large dis-

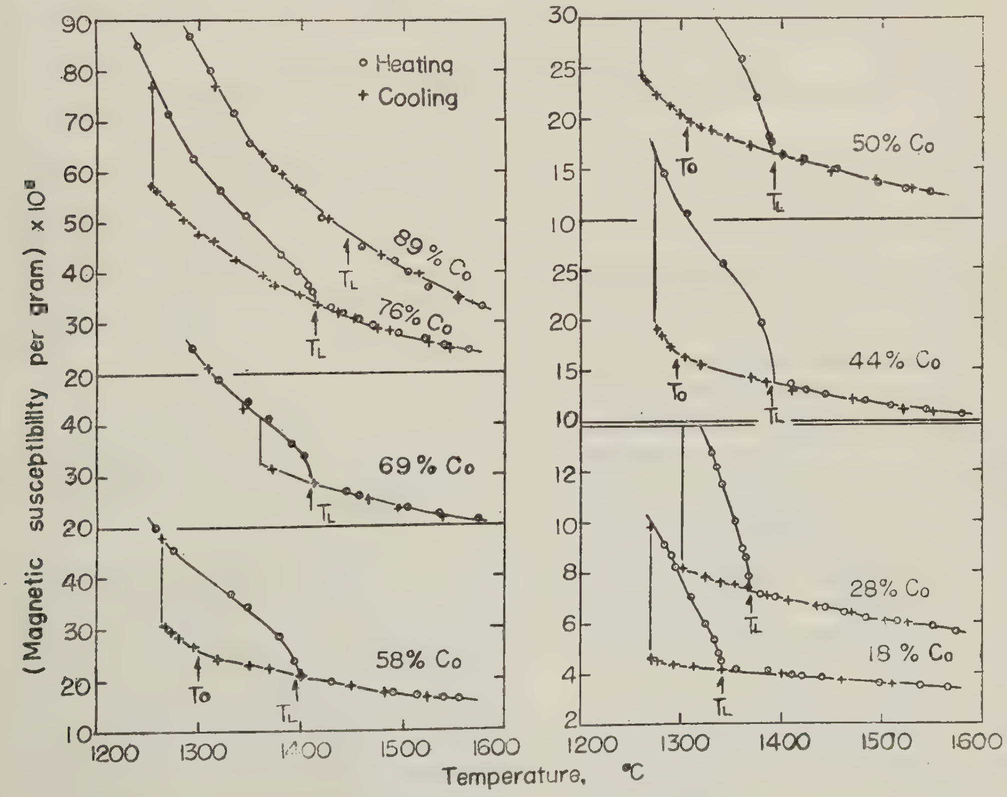

Fig. 1. Susceptibility curves for Cu-Co alloys.
T_L is the liquidus temperature; T_0 is the limit of liquid immiscibility.

T_L is the liquidus temperature; T_0 is the limit of liquid immiscibility.

continuity at the temperature about 100°C below T_L, where the solid phase is precipitated abruptly from the supercooled liquid solution. The precipitation of the solid phase causes an increase in susceptibility for the Cu-Co alloys wheras a decrease for the Cu-Fe alloys.

It is found in some cases that the susceptibility curve exhibits anomalous behaviour in the supercooled region; the curve has an angular point at a certain temperature denoted as T_0 in the figures. At this temperature the supercooled liquid solution breaks up into two liquid phases. This is confirmed by the microscopic examination of the quenched specimens. A detailed report on this subject has already been published elsewhere.[6]

Cu-Mn. Copper and manganese form a continuous series of solid solutions having a face-centred cubic structure. The liquidus temperatures reported by many investigators agree fairly well, while there are remarkable discrepancies for the solidus temperatures of the manganese-rich alloys.*

The results of the susceptibility measurements are shown in Fig. 3. The susceptibility shows a maximum at the liquidus temperature, T_L. Below T_L, the susceptibility measured during cooling deviates appreciably from that measured during heating, although the supercooling of the liquid phase in these alloys is not extensive. The deviation is mainly due to the segregation which takes place upon solidification. The segregation is confirmed by the microscopic examination of the quenched specimens. By annealing at

---

* According to Hansen[5], the most reliable solidus curve for the Cu-Mn system is that obtained by Dean *et al.*[7], which is based on incipient melting studies by means of micrographic investigation. Also the present author has studied the solidus curve by the similar method. The results will be published elsewhere. It is to be noted here that the solidus curve determined by the present author is in disagreement with that obtained by Dean *et al.*, being rather close to an earlier work of Grube *et al.*[8]

850°C for several hours, the segregated specimens are not completely homogenized, and so the susceptibility curves below T_L, shown in Fig. 3, do not represent the values for the equilibrium state. At temperatures above T_L, the susceptibility curves are well reproducible, because of rapid diffusion in the liquid state. For the manganese-rich alloys, the susceptibility in the liquid state is nearly independent of both temperature and the composition of the alloys.

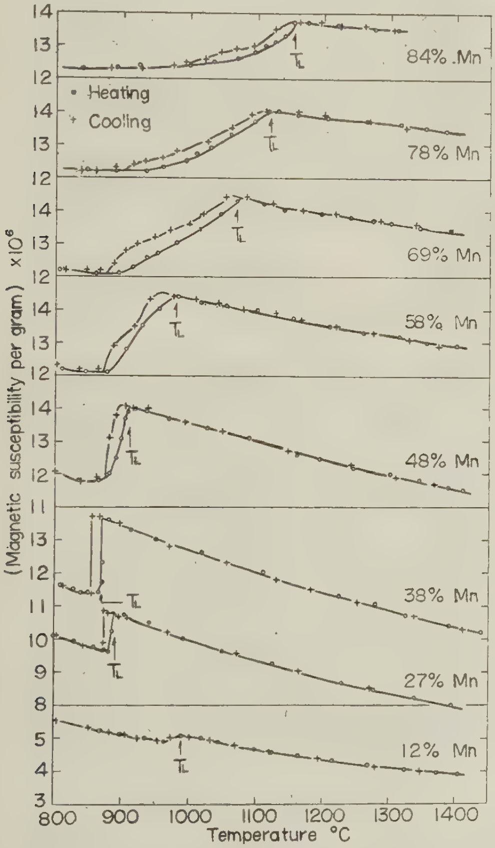

Fig. 3. Susceptibility curves for Cu-Mn alloys. T_L is the liquidus temperature.

Cu-Cr. Since the solubility of chromium in molten copper is fairly restricted, only the copper-rich alloys are investigated. The susceptibility curves obtained for these alloys and for pure copper are shown in Fig. 4. It is confirmed by the microscopic examination of the quenched specimen that an angular point on the susceptibility curve corresponds certainly to the liquidus temperature, T_L. According to Hansen,[5] there have been no reliable data on the liquidus curve for the Cu-Cr system. The liquidus curve obtained in the present work is shown in Fig. 5, together with that determined by Siedschlag[9] using fairly impure chromium. The liquid immiscibility is not found in the range up to 15% Cr.

The susceptibility curves for various Cu-Cr alloys show discontinuity at the same temperature, T_E, which must be a eutectic temperature of this system. The susceptibility shows a gradual change between T_L and T_E. Contrary to the Cu-Mn system, the temperature hysteresis is not found in this system. This is certainly due to the fact that the solid phases precipitated are of almost pure chromium and copper. The susceptibilities of these solid phases can be

estimated from the data shown in Fig. 4; the susceptibility per gram of chromium-rich phase is 5.8×10^{-6}, being independent of temperature, and that of copper-rich phase is 0.15×10^{-6} at 1050°C, its temperature dependence being not determined.

§ 4. Analysis of the Results on Homogeneous Liquid Alloys

It is shown that the magnetic susceptibilities of these alloys above the liquidus temperatures follow in general the Curie-Weiss law:

$$\chi=C/(T-\theta)\,, \tag{1}$$

where χ is the susceptibility per gram and T the temperature. The two parameters, C and θ, are the Curie constant per gram and the paramagnetic Curie temperature, respectively. As shown in Fig. 6, the reciprocal of susceptibility plotted against temperature lies on a straight line, from which C and θ are determined. For the Cu-Co and Cu-Fe alloys, the susceptibility in the supercooled liquid state also fits Eq. (1), as far as the separation into two liquid phases does not occur.

It is expected that the Curie-Weiss paramagnetism of these alloys is only due to the atoms of transition elements. Therefore, the measured values of susceptibility are corrected by taking into account the diamagnetic contribution of copper. The susceptibility per gram of molten copper is -0.13×10^{-6}, being independent of temperature, as shown in Fig. 4. For the alloys containing more than 30% transition metals, this correction becomes ineffective. The diamagnetic contribution of the closed-shell electrons of the transition elements is completely ignored. In Fig. 7 (a) the Curie constants per mole, C_M, are plotted against the atomic concentration of the transition metals. C_M is related to C in Eq. (1) as

$$C_M=C[xM_A+(1-x)M_B]\,, \tag{2}$$

where M_A and M_B are the atomic weights of A and B, and x is the atomic concentration of A. Fig. 7 (b) shows the values of θ in absolute temperature unit.

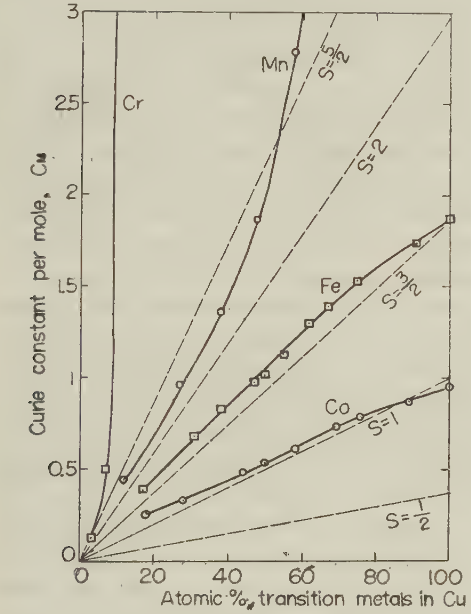
The Curie-Weiss law is derived from a theory based on the Heitler-London model.* According to the theory, C_M is given as

$$C_M=\frac{xN\mu^2}{3k}4S(S+1)\,, \tag{3}$$

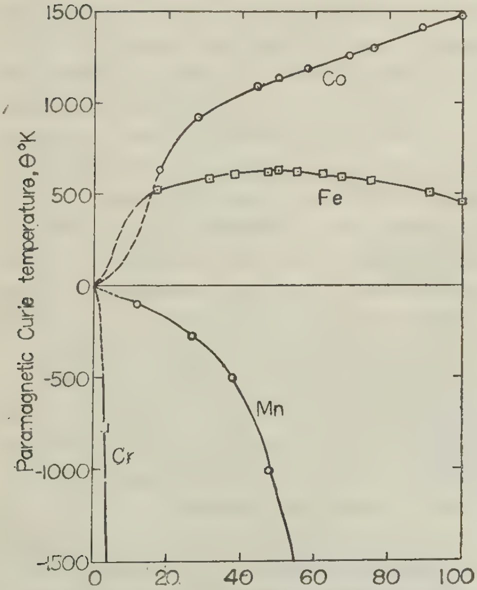
---

* The Curie-Weiss law can also be derived from Stoner's collective electron theory. However, a detailed analysis based on this theory requires a knowledge about the ferromagnetic state at low temperatures, which is lacking in the present case.

provided that the atoms of the transition elements have the resultant spin S, and the copper atoms have no magnetic moment. In Eq. (3), x is the atomic concentration of the transition element, N is Avogadro's number, k is Boltzmann's constant, and μ is the Bohr magneton. The theoretical curves for C_M are also shown in Fig. 7 (a) for various values of S. The experimental curves of C_M for the Cu-Co and Cu-Fe systems do not show marked deviations from the theoretical curves for $S=1$ and $S=3/2$, respectively.* The electronic configurations of cobalt and iron are thus considered to be $(3d)^8(4s)^1$ and $(3d)^7(4s)^1$, respectively. If the concentrations of cobalt and iron are sufficiently low, the measured values of C_M approach the theoretical values for $S=3/2$ and $S=2$, respectively, corresponding to the electronic configurations $(3d)^7(4s)^2$ and $(3d)^6(4s)^2$.



(a) Curie constant



(b) Paramagnetic Curie temperature

Fig. 7. Curie constant and paramagnetic Curie temperature vs. composition of alloys.

The values of θ are always positive in both Cu-Co and Cu-Fe alloys. The θ vs. composition curve for the Cu-Fe system has a flat maximum at an intermediate composition, while that for the Cu-Co system rises monotonously with the concentration of cobalt.

The results on the copper-rich alloys of Cu-Mn are similar to those on the Cu-Co and Cu-Fe alloys. In the range up to 50% Mn, the C_M vs. composition curve lies between the two theoretical curves for $S=2$ and $S=5/2$. The electronic configuration of the manganese atoms in these alloys is thus considered to be $(3d)^6(4s)^1$ or $(3d)^5(4s)^2$. For the alloys containing more than 50% Mn, C_M becomes extremely large, and θ tends to negative infinity. The Curie-Weiss law has no physical significance in this case, since the susceptibility is nearly independent of temperature.

In the Cu-Cr system, even the copper-rich alloys show the temperature-independent paramagnetism. The Curie-Weiss law is applicable only to the most dilute alloy, in which the electronic configuration of the chromium atoms is probably $(3d)^5(4s)^1$.

§ 5. Discussion

As mentioned above, the electronic configurations of the atoms of the transition elements are determined from the temperature dependence of the susceptibilities. The configurations of cobalt and iron determined here are quite consistent with those determined from the data on Ni-Fe, Ni-Co and

---

* The values of C_M and θ for pure iron and cobalt are calculated from the data reported in our previous paper[1]. The data are slightly modified by taking into account the alteration of the standard temperatures, upon which the calibration of thermocouple was based. (see §2)

Co-Fe alloys.[1][2]

The magnetic interactions between the atoms of the transition elements are estimated from the values of θ, being ferromagnetic in the Cu-Co and Cu-Fe systems whereas antiferromagnetic in the Cu-Mn and Cu-Cr systems. However, the dependence of θ on the concentration of the alloys cannot be explained by any simple theory. In the Cu-Co and Cu-Fe systems, if only a direct exchange interaction between the cobalt or iron atoms is effective, θ should decrease very rapidly with addition of copper to cobalt or iron. The effect of short-range ordering may to some extent account for the discrepancy between the above theory and the experimental fact. As reported elsewhere,[6] both the Cu-Co and Cu-Fe systems have the pronounced tendency towards liquid immiscibility. Thus the number of pairs of cobalt or iron atoms are laraer than that for the perfectly random distribution of the atoms, and consequently the magnetic interaction becomes stronger. However, the maximum in θ vs. composition curve for the Cu-Fe system cannot be accounted for by this effect. It is likely that there exist other kinds of magnetic interaction, for example, a superexchange interaction through the non-magnetic copper atoms.

Previously, Weil[3] has measured the susceptibilities of cobalt and iron dissolved in molten gold and antimony. The results on Au-Co and Au-Fe are very similar to those on Cu-Co and Cu-Fe investigated here, while the results on Sb-Co and Sb-Fe are fairly different. Weil has also measured the susceptibilities of liquid Cu-Mn alloys in the range up to 68% Mn. The results are in good agreement with the present results. With respect to chromium, Weil has studied only Sb-Cr alloys.

The susceptibilities of these alloys in the solid state have been studied by many investigators. For the Cu-Co and Cu-Fe systems, only the very dilute alloys have been investigated.[10][11][12] A continuous series of solid solution in the Cu-Mn system has been studied by Myers[13]. The results are similar to those obtained for the liquid state, but the Curie-Weiss law is applicable only to the alloys containing less than 25% Mn in the solid state, while it is applicable up to 50% Mn in the liquid state. For the Cu-Cr system, there has been only a room temperature measurement of the susceptibility of the quenched specimen[14].

Manganese and chromium show the Curie-Weiss paramagnetism in the dilute alloys whereas the temperature-independent paramagnetism in the enriched alloys. Although the temperature-independent paramagnetism is usually explained by the band theory of metals, the Heitler-London theory is also applicable to it. If the antiferromagnetic interaction between the atoms of transition elements becomes extremely large, it may depend very sensitively on the interatomic distance, as expected from the Bethe-Slater curve. In this case even a small change in interatomic distance due to thermal expansion can produce an appreciable change in magnetic interaction. As reported in detail in our previous paper,[2] this effect results in an apparent large value of the Curie constant. The temperature-independent paramagnetism corresponds to the case where the apparent Curie constant becomes infinitely large.

It is shown by the experimental results that the Cu-Cr alloys show the temperature-independent paramagnetism even in rather dilute alloys, while the Cu-Mn alloys show the ordinary Curie-Weiss paramagnetism even in fairly enriched alloys. These results are accounted for by the following two facts. Firstly, the antiferromagnetic interaction may be stronger in chromium than in manganese, since the diameter of $3d$-shell is larger. Secondly, as can be expected from the phase diagrams, the short-range ordering in the Cu-Cr alloys may increase the number of pairs of the same kinds of atoms, while that in the Cu-Mn alloys may decrease it; thus the antiferromagnetic interaction is enlarged in Cu-Cr, while it is reduced in Cu-Mn.

In conclusion, the author emphasizes that the magnetic properties of a series of transition metals vary continuously with the atomic number, at least in the liquid state. Cobalt and iron behave very similarly, though the former is more ferromagnetic. Manganese is less antiferromagnetic than chromium. These results are consistent with the Bethe-Slater curve. The atomic magnetic moments of these transition metals in the liquid state vary systematically with the atomic number, and the electronic configurations are close to $(3d)^n(4s)^1$. In the solid state, there may be a discontinuous change in electronic configuration between high-d and low-d elements, namely Ni and Co on the one hand and Fe, Mn and Cr on the other hand, which has been suggested by Lomer and Marshall15) on the basis of recent X-ray measurement by Weiss and DeMarco16). However, it is possible to suppose that the discontinuous change in d-electron density observed by X-ray is only due to the difference in crystal structure. It should be mentioned here that the magnetic properties of the liquid phase are similar to those of the face-centred cubic phase, as described in our previous paper1).

Acknowledgments

The author wishes to express his sincere gratitude to Professor S. Kaya for his encouragement and interest in the present work. The author is also indebted to Dr. Y. Tomono, Dr. S. Iida, and Dr. H. Sekizawa for their helpful discussions.

On the Viscosity of Irradiated Polymers, II

By Mitio INOKUTI and Kanji KATSUURA

Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received July 1, 1959)

The intrinsic viscosity of a polymeric substance crosslinked as well as degraded by irradiation with high-energy radiations is discussed for various types of initial molecular size distributions. The intrinsic viscosity as a function of radiation dose is shown to behave in a great variety of ways depending on the relative importance of crosslinking and degradation, and in particular, on the shape of the initial distribution. The effect of endlinking instead of crosslinking is also examined.

§1. Introduction

The intrinsic viscosity of a polymeric substance exposed to high-energy radiations is one of the most important quantities in the study of the effects of radiation on polymers. Gradual accumulation of reliable experimental data in recent years1) seems to require a careful theoretical analysis of the intrinsic viscosity of an irradiated polymeric substance.

In a previous paper2) (hereafter referred to as I), one of the authors (M.I.) examined the quantity for various types of initial molecular size distributions according to a formalism recently developed by Saito[3)–5)] and concluded that there exists a remarkable relationship between the initial distribution and the radiation-induced change of the intrinsic viscosity. The discussions in I are, however, confined to the coefficient $A_1(\lambda, \alpha)$ in the expansion of the intrinsic viscosity $\eta(R)$ at radiation dose R

$$\eta(R)/\eta(0)=1+A_1(\lambda, \alpha)R+A_2(\lambda, \alpha)R^2+\cdots, \tag{1}$$

where α stands for the viscosity exponent in Staudinger's law ($1/2\leq\alpha<1$) and λ for the ratio of the probability $\dot{r}$ of degradation per monomer unit per unit radiation dose to the probability $\dot{c}$ of crosslinking per monomer unit per unit radiation dose.

It is now the main purpose of the present paper to extend the discussions in I to the coefficient $A_2(\lambda, \alpha)$ in (1), so as to clarify more delicate and subtle features of the relationship between the initial distribution and the change of the intrinsic viscosity. Further we will examine the intrinsic viscosity of a polymeric substance into which endlinking instead of crosslinking is introduced by irradiation. Then the relationship in which we are interested exhibits a tendency qualitatively similar to the case of crosslinking, although the correlation is more pronounced in comparison with the latter case.

Another purpose is to give a detailed numerical analysis of $A_1(\lambda, \alpha)$ for a type of initial distribution, which is not only flexible in the sense that it covers a great variety with variation of a parameter involved but also experimentally interesting in the sense that it can approximately represent an actual distribution in an ordinary sample of polymers.

§ 2. General Formulation

As in I, we define the molecular size distribution $m(p, R)dp$ of a polymeric system as the fraction of polymers whose degree of polymerization lies between p and $p+dp$ when the system has been irradiated up to radiation dose R. The constancy of the total number of monomers imposes a normalization condition upon $m(p, R)$, namely,

$$\int_0^\infty pm(p, R)dp=1\ . \tag{2}$$

By the procedure described in I, we calculate $m(p, R)$ as a power series in R and we gave there the result up to the first order. The next term which is of the second order can be similarly obtained, although the calculation is rather complicated. Thus we have

$$\begin{aligned} m(p, R)&=e^{-(\lambda+2)pt}\{m(p, 0)+\psi_1(p)t \\ &\quad+\psi_2(p)t^2+O(t^3)\} \\ &=m(p, 0)+\{\psi_1(p)-(\lambda+2)pm(p, 0\}t \\ &\quad+\{\psi_2(p)-(\lambda+2)p\psi_1(p) \\ &\quad+\tfrac{1}{2}(\lambda+2)^2p^2m(p, 0)\}t^2+O(t^3)\ , \end{aligned} \tag{3}$$

where $t=\dot{c}R$, $\lambda=\dot{r}/\dot{c}$, and $m(p, 0)$ stands for the initial distribution and $\psi_1(p)$ and $\psi_2(p)$ are defined as follows:

$$\psi_1(p)=2\lambda F(p)+\int_0^p dll(p-l)m(l, 0)m(p-l, 0)\ , \tag{4}$$

$$\begin{aligned} \psi_2(p)=\lambda^2\int_p^\infty dlF(l) &\\ +4\lambda\int_0^p dll(p-l)F(l)m(p-l, 0) &\\ +\int_0^\infty dll(p-l)m(p-l, 0) &\\ \times\int_0^l dkk(l-k)m(k, 0)m(l-k, 0)\ , & \end{aligned} \tag{5}$$

where

$$F(p)=\int_p^\infty m(l, 0)dl\ . \tag{6}$$

According to the Staudinger's law the intrinsic viscosity $\eta(R)$ at dose R is

$$\eta(R)/\eta(0)=f_{\alpha+1}(R)/f_{\alpha+1}(0)\ , \tag{7}$$

where we have used the following notation:

$$f_\beta(R)=\int_0^\infty m(p, R)p^\beta dp\ . \tag{8}$$

Now we substitute (3) into the right-hand side of (7), rearrange the terms and compare the result with (1) to arrive at the following expressions for $A_1(\lambda, \alpha)$ and $A_2(\lambda, \alpha)$, the former of which has already been given in I. Namely,

$$\begin{aligned} A_1(\lambda, \alpha)&=-\left(\frac{\dot{c}\,\alpha}{\alpha+2}\right)\frac{f_{\alpha+2}(0)}{f_{\alpha+1}(0)}\{\lambda-\lambda_0(\alpha)\} \\ &=\left(\frac{\dot{r}\,\alpha}{\alpha+2}\right)\frac{f_{\alpha+2}(0)}{f_{\alpha+1}(0)}\left\{\frac{\lambda_0(\alpha)}{\lambda}-1\right\}\ , \end{aligned} \tag{9}$$

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{\frac{I(\alpha)}{f_{\alpha+2}(0)}-2\right\}\ , \tag{10}$$

and

$$A_2(\lambda,\alpha)=\frac{\dot{c}^2 f_{\alpha+3}(0)}{f_{\alpha+1}(0)}\{P(\alpha)\lambda^2-2Q(\alpha)\lambda+R(\alpha)\}\,, \tag{11}$$

$$P(\alpha)=\frac{\alpha(\alpha+1)}{2(\alpha+2)(\alpha+3)}\,, \tag{12}$$

$$Q(\alpha)=\frac{I(\alpha+1)-4J_1}{2f_{\alpha+3}(0)}-\frac{\alpha+1}{\alpha+3}\,, \tag{13}$$

$$R(\alpha)=2+\frac{J_2-2I(\alpha+1)}{f_{\alpha+3}(0)}\,, \tag{14}$$

where $I(\beta)$, J_1 and J_2 are repeated integrals defined as follows:

$$I(\beta)=\int_0^\infty dp p^{\beta+1}\int_0^p dl l(p-l)m(l,0)m(p-l,0)$$
$$(\beta=\alpha \text{ or } \alpha+1)\,, \tag{15}$$

$$J_1=\int_0^\infty dp p^{\alpha+1}\int_0^p dl l(p-l)F(l)m(p-l,0)\,, \tag{16}$$

$$J_2=\int_0^\infty dp p^{\alpha+1}\int_0^p dl l(p-l)m(p-l,0)$$
$$\times\int_0^l dk k(l-k)m(k,0)m(l-k,0)\,. \tag{17}$$

It should be noted that by interchanging orders of integrations we can rewrite the integrals in the following way:

$$I(\beta)=\int_0^\infty dl l m(l,0)\int_0^\infty dp(p+l)^{\alpha+1}p m(p,0)\,, \tag{18}$$

$$J_1=\frac{1}{(\alpha+2)(\alpha+3)}\Big\{(\alpha+2)I(\alpha+1)+f_{\alpha+4}(0)f_0(0)$$
$$-\int_0^\infty dp p^2 m(p,0)\int_0^\infty dk(p+k)^{\alpha+2}m(k,0)\Big\}\,, \tag{19}$$

$$J_2=\int_0^\infty dk k m(k,0)\int_0^\infty dl l(l+k)m(l,0)$$
$$\times\int_0^\infty dp p(p+l+k)^{\alpha+1}m(p,0)\,. \tag{20}$$

Now we will evaluate $A_2(\lambda,\alpha)$ for some types of initial molecular size distributions and discuss the result together with those obtained in I, so that we may clarify the relationship between the initial distribution and the radiation-induced change of the intrinsic viscosity more closely than in I. For this purpose it will be helpful to quote a theorem that gelation is possible if and only if $\lambda<4$ irrespective of the initial distribution.[2),3)]

§ 3. Application to Some Types of Initial Molecular Size Distributions

1) *Poisson distribution*

When the initial distribution is Poisson-like, namely,

$$m(p,0)=u^{-2}\exp(-p/u)\,, \tag{21}$$

where u is the initial number-average degree of polymerization, we have by (8), (15), (16) and (17)

$$f_\beta(0)=u^{\beta-1}\Gamma(\beta+1)\,,$$
$$I(\beta)=u^{\beta+1}\Gamma(\beta+5)/6\,,$$
$$J_1\ =u^{\alpha+2}\Gamma(\alpha+5)/6\,,$$
$$J_2\ =u^{\alpha+2}\Gamma(\alpha+8)/180\,.$$

Then we obtain $A_1(\lambda,\alpha)$ and $A_2(\lambda,\alpha)$ by (9)-(14), namely,

$$A_1(\lambda,\alpha)=-\dot{c}u\alpha\{\lambda-\lambda_0(\alpha)\}\,, \tag{22}$$

$$\lambda_0(\alpha)\ =(\alpha+2)(\alpha+7)/6\,, \tag{23}$$

$$A_2(\lambda,\alpha)=\frac{(\dot{c}u)^2\alpha(\alpha+1)}{2}\Big\{\lambda^2-\frac{(\alpha+2)(\alpha+7)}{3}\lambda$$
$$+\frac{(\alpha+2)(\alpha+3)(\alpha+7)(\alpha+14)}{90}\Big\}$$
$$=\frac{(\dot{c}u)^2\alpha(\alpha+1)}{2}\Big[\Big\{\lambda-\frac{(\alpha+2)(\alpha+7)}{6}\Big\}^2$$
$$+\frac{(1-\alpha)(\alpha+2)(\alpha+7)(3\alpha+14)}{180}\Big]\,. \tag{24}$$

It is worth noting that $A_2(\lambda,\alpha)$ is positive definite for any λ for $1/2\leq\alpha<1$, while $A_1(\lambda,\alpha)$ may be either positive or negative. This situation seems to be characteristic of a sufficiently broad initial distribution. For, as will be shown later, it is in a striking contrast with the case where the initial distribution is uniform or nearly uniform.

Consequently, we can distinguish the behavior of the intrinsic viscosity as a function

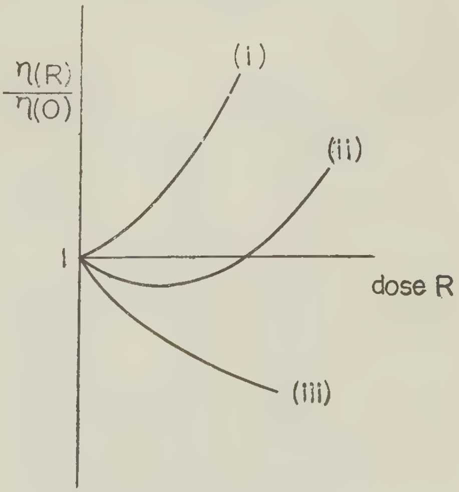

Fig. 1. Schematic representation of the behavior of the intrinsic viscosity when the initial distribution is Poisson-like.

of dose in the following way.

(i) $\lambda_0(\alpha)>\lambda$

$A_1>0$, $A_2>0$, gelation possible.

(ii) $4>\lambda>\lambda_0(\alpha)$

$A_1<0$, $A_2>0$, gelation possible.

(iii) $\lambda>4$

$A_1<0$, $A_2>0$, gelation impossible.

We give a typical viscosity-dose curve for each of the three cases in Fig. 1.

2) *Uniform distribution*

When the initial distribution is uniform and every polymer has degree of polymerization u, namely,

$$m(p,\,0)=u^{-2}\delta(p/u-1)\,, \tag{25}$$

we have

$$f_\beta(0)=u^{\beta-1}\,,$$
$$I(\beta)=(2u)^{\beta+1}\,,$$
$$J_1\;=u^{\alpha+2}\left\{\frac{2^{\alpha+2}(\alpha+1)-1}{(\alpha+2)(\alpha+3)}\right\}\,,$$
$$J_2=2\cdot 3^{\alpha+1}u^{\alpha+2}\,.$$

In the evaluation of these integrals, it is more convenient to make use of (18)-(20) rather than (15)-(17).

Then $A_1(\lambda,\alpha)$ and $A_2(\lambda,\alpha)$ is given as follows.

$$A_1(\lambda,\,\alpha)=-\left(\frac{\dot{c}u\alpha}{\alpha+2}\right)\{\lambda-\lambda_0(\alpha)\}\,, \tag{26}$$

$$\lambda_0(\alpha)=2(\alpha+2)(2^\alpha-1)/\alpha\,, \tag{27}$$

$$A_2(\lambda,\,\alpha)=(\dot{c}u)^2\{P(\alpha)\lambda^2-2Q(\alpha)\lambda+R(\alpha)\}\,, \tag{28}$$

$$Q(\alpha)=\frac{2^{\alpha+1}(\alpha^2+\alpha+2)-(\alpha^2+3\alpha+4)}{(\alpha+2)(\alpha+3)}\,, \tag{29}$$

$$R(\alpha)=2(3^{\alpha+1}+1-2^{\alpha+2})\,. \tag{30}$$

Table I. Values of $\lambda_0(\alpha)$, $\lambda_1(\alpha)$ and $\lambda_2(\alpha)$ for the uniform distribution

α	$\lambda_0(\alpha)$	$\lambda_1(\alpha)$	$\lambda_2(\alpha)$
0.50	4.1422	3.3874	7.4296
0.55	4.3033	3.4380	7.8234
0.60	4.4695	3.4910	8.2300
0.65	4.6409	3.5466	8.6494
0.70	4.8176	3.6050	9.0819
0.75	4.9998	3.6656	9.5286
0.80	5.1877	3.7284	9.9904
0.85	5.3815	3.7933	10.4678
0.90	5.5813	3.8602	10.9613
0.95	5.7874	3.9291	11.4719
1.00	6.0000	4.0000	12.0000

A simple analysis shows that $A_2(\lambda,\alpha)$ has two real, positive zeros with respect to λ, so that we rewrite it as

$$A_2(\lambda,\,\alpha)=(\dot{c}u)^2P(\alpha)\{\lambda-\lambda_1(\alpha)\}\{\lambda-\lambda_2(\alpha)\}\,,$$
$$(\lambda_2(\alpha)>\lambda_1(\alpha))\,. \tag{31}$$

We give numerical values of $\lambda_1(\alpha)$, $\lambda_2(\alpha)$ and $\lambda_0(\alpha)$ in Table I and Fig. 2.

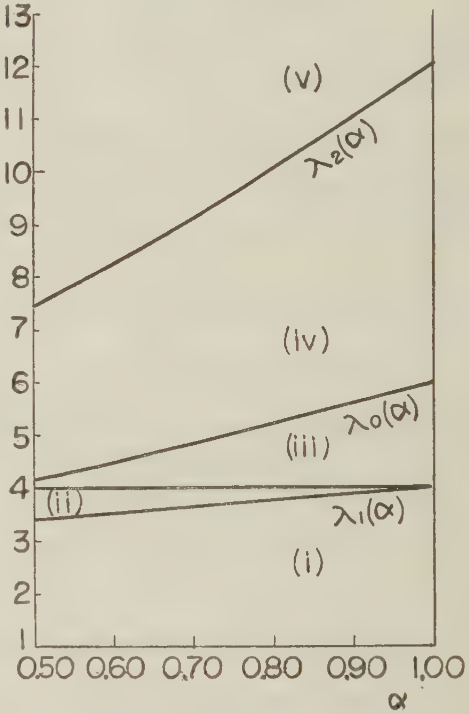

Fig. 2. Values of $\lambda_1(\alpha)$, $\lambda_2(\alpha)$ and $\lambda_0(\alpha)$ plotted against α when the initial distribution is uniform.

According to the values of λ and α, we classify the behavior of the intrinsic viscosity as follows.

(i) $\lambda_1(\alpha)>\lambda$

$A_1>0$, $A_2>0$, gelation possible.

(ii) $4>\lambda>\lambda_1(\alpha)$

$A_1>0$, $A_2<0$, gelation possible.

(iii) $\lambda_0(\alpha)>\lambda>4$

$A_1>0$, $A_2<0$, gelation impossible.

(iv) $\lambda_2(\alpha)>\lambda>\lambda_0(\alpha)$

$A_1<0$, $A_2<0$, gelation impossible.

(v) $\lambda>\lambda_2(\alpha)$

$A_1<0$, $A_2<0$, gelation impossible.

In Fig. 3 we give a typical viscosity-dose curve for each of the domains indicated in Fig. 2.

The possibility of a viscocity-dose curve with a maximum (case (iii)) for a nearly uniform initial distribution has already been predicted in I. In this connection, it is very interesting that Pearson[6] observed such a viscosity-dose curve for poly-(ethylene oxides), whose molecular size distribution were reportedly nearly uniform.

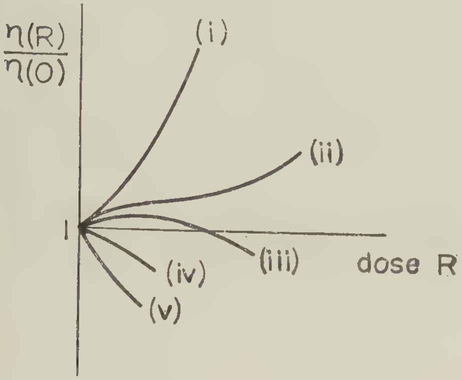

Fig. 3. Schematic representation of the behavior of the intrinsic viscosity when the initial distribution is uniform.

3) *Rectangular distribution*

We will examine the rectangular distribution defined in I, namely,

$$m(p,\,0)=\begin{cases}(2\xi u^2)^{-1} & (1-\xi<p/u<1+\xi)\\ 0 & \text{(otherwise)}\,,\end{cases} \tag{32}$$

where u stands for the number-average degree of polymerization. We regard the dimensionless parameter ξ as small compared with unity; therefore we have now to do with a sharp or nearly uniform initial distribution. In this case we have

$$A_1(\lambda,\,\alpha)=-\left(\frac{\dot{c}u\alpha}{\alpha+2}\right)\left\{1+\frac{\alpha+1}{3}\xi^2+\cdots\right\}\times\{\lambda-\lambda_0(\alpha)\}\,, \tag{33}$$

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{2(2^\alpha-1)-\frac{2^\alpha\alpha(\alpha+1)}{6}\xi^2+\cdots\right\}, \tag{34}$$

$$A_2(\lambda,\,\alpha)=(\dot{c}u)^2\left\{1+\frac{(2\alpha+3)}{3}\xi^2+\cdots\right\}\times\{P(\alpha)\lambda^2-2Q(\alpha)\lambda+R(\alpha)\}\,, \tag{35}$$

$$Q(\alpha)=\frac{2^{\alpha+1}(\alpha^2+\alpha+2)-(\alpha^2+3\alpha+4)}{(\alpha+2)(\alpha+3)}-\frac{2^{\alpha-1}(\alpha^3+\alpha^2+4\alpha-4)+2}{3(\alpha+2)}\xi^2+\cdots\,, \tag{36}$$

$$R(\alpha)=2(3^{\alpha+1}+1-2^{\alpha+2})-(2/3)(3^\alpha-2^\alpha)(\alpha+1)(\alpha+2)\xi^2+\cdots\,, \tag{37}$$

after laborious calculations.

As far as ξ is sufficiently small, $A_2(\lambda,\,\alpha)$ given by (35) has two positive zeros with respect to λ and it can be written in the form (31). To examine the dependence of the zeros $\lambda_1(\alpha)$ and $\lambda_2(\alpha)$ on ξ, or the broadness of the initial distribution, we have to resort to numerical computation since the expressions (36) and (37) are rather complicated. Then we find that both $\lambda_1(\alpha)$ and $\lambda_2(\alpha)$ decrease with increase of ξ at least for small ξ. It means that the regions $4>\lambda>\lambda_1(\alpha)$ and $\lambda>\lambda_2(\alpha)$ become wider and the region $\lambda_0(\alpha)>\lambda>4$ narrower as the initial distribution attains broadness.

In experiments the initial distribution cannot be exactly uniform, but has some broadness, even if advanced fractionation techniques are employed. A rectangular distribution with small ξ must be rather more realistic in a so-called "fractionated" sample of a polymeric substance. In view of this fact, observation of a viscosity-dose curve with an inflection point (case (ii)) is highly probable for a nearly uniform initial distribution, although, to the best of the authors, knowledge, it has never been reported. On the other hand, a viscosity-dose curve with a maximum (case (iii)) can be observed practically only if α is sufficiently large.

4) *Superposition of two uniform distributions*

In order to confirm the conclusion concerning the rectangular distribution, we consider a superposition of two uniform distributions

$$m(p,\,0)=(2u^2)^{-1}\{\delta(p/u-1-\zeta)+\delta(p/u-1+\zeta)\}\,, \tag{38}$$

where u is the number-average degree of polymerization and ζ will be regarded as small. We calculate $A_1(\lambda,\,\alpha)$ and $A_2(\lambda.\,\alpha)$ as

$$A_1(\lambda,\,\alpha)=-\left(\frac{\dot{c}u\alpha}{\alpha+2}\right)\{1+(\alpha+1)\zeta^2+\cdots\}\times\{\lambda-\lambda_0(\alpha)\}\,, \tag{39}$$

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{2(2^\alpha-1)-\frac{2^\alpha\alpha(\alpha+1)}{2}\zeta^2+\cdots\right\}, \tag{40}$$

$$A_2(\lambda,\,\alpha)=(\dot{c}u)^2\{1+(2\alpha+3)\zeta^2+\cdots\}\times\{P(\alpha)\lambda^2-2Q(\alpha)\lambda+R(\alpha)\}\,, \tag{41}$$

$$Q(\alpha)=\frac{2^{\alpha+1}(\alpha^2+\alpha+2)-(\alpha^2+3\alpha+4)}{(\alpha+2)(\alpha+3)}-\frac{2^{\alpha-1}(\alpha^3+\alpha^2+4\alpha-4)+2}{(\alpha+2)}\zeta^2+\cdots\,, \tag{42}$$

$$R(\alpha)=2(3^{\alpha+1}+1-2^{\alpha+2})$$
$$-2(3^{\alpha}-2^{\alpha})(\alpha+1)(\alpha+2)\zeta^2+\cdots\ . \qquad (43)$$

Thus we see that the expressions (39)–(43) are very similar to (33)–(37) so that the situation is qualitatively similar to the case where the initial distribution is rectangular.

§ 4. Generalized Poisson Distribution

The initial distributions which we have so far dealt with are either nearly uniform or Poisson-like. Although main features of the relationship between the initial distribution and the viscosity-dose curve have been understood, detailed analysis is necessary for an initial distribution which covers a wide range of a parameter involved. For such a purpose it is convenient to consider the distribution[7]

$$m(p,\ 0)=\frac{b^{b+1}}{u^2\Gamma(b+1)}\left(\frac{p}{u}\right)^{b-1}e^{-bp/u}\ , \qquad (44)$$

where u is the number-average degree of polymerization and $b(\geqq 1)$ is a parameter specifying the shape. We call (44) as the generalized Poisson distribution. It is normalized as (2). The βth moment turns out to be

$$f_\beta(0)=(u/b)^{\beta-1}\Gamma(\beta+b)/\Gamma(1+b)\ , \qquad (45)$$

where $\beta\geqq 0$. The parameter b is connected with the ratio of the weight-average $P_w(0)$ to the number-average $P_n(0)$ degree of polymerization in the following way:

$$P_w(0)/P_n(0)=\{f_2(0)/f_1(0)\}/\{f_1(0)/f_0(0)\}=1+1/b\ . \qquad (46)$$

If $b=1$, (44) reduces to the Poisson distribution; and if $b=\infty$, to the uniform distribution.

When we want to approximate the actual distribution of a polymer sample, we can determine the value of b by the relation (46), since the quantity on the left-hand side of (46) is obtained by measurements of light scattering and the osmotic pressure.

For this initial distribution, $A_1(\lambda,\ \alpha)$ is given as

$$A_1(\lambda,\ \alpha)=-\left(\frac{\dot{c}\,\alpha u}{\alpha+2}\right)\left(1+\frac{\alpha+1}{b}\right)\{\lambda-\lambda_0(\alpha)\}\ , \qquad (47)$$

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{\frac{\Gamma(2b+3+\alpha)\Gamma(b+1)}{\Gamma(b+2+\alpha)\Gamma(2b+2)}-2\right\}\ , \qquad (48)$$

The results of numerical computation given in Table II and Fig. 4 confirm quantitatively the very conclusion of I that $\lambda_0(\alpha)$ is larger or smaller than 4 according as the initial discribution is narrow or broad. Further these numerical values can be profitably used in analysis of experimental data, as will be reported elsewhere

Table II. Values of $\lambda_0(\alpha)$ for the generalized Poisson distribution.

§ 5. Endlinking

Let us consider the change of the intrinsic viscosity of a polymeric substance into which endlinking instead of crosslinking is introduced by irradiation. A treatment quite analogous to the case of crosslinking can be performed by employing Saito's theory.[4)] We will evaluate the coefficient B_1 in the expansion

$$\eta(R)/\eta(0)=1+B_1R+B_2R^2+\cdots\,. \tag{49}$$

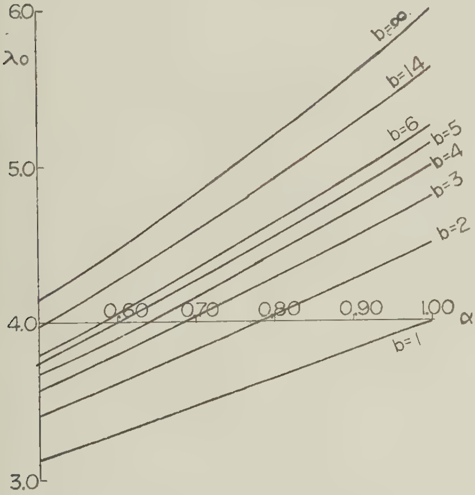

Fig. 4. Value of $\lambda_0(\alpha)$ plotted against α for various values of b.

To discuss the effect of endlinking, we have to classify polymers according to the number of ends involved in a polymer. Thus we define $m_k(p, R)dp$ as the fraction of polymers whose degree of polymerization lies between p and $p+dp$ and whose number of ends is k when the substance has been irradiated up to dose R. By a procedure used in the paper I we calculate $m_k(p, R)$ as a power series in R. Now we regard the polymeric substance initially contains only linear polymers with molecular size distribution $m(p, 0)$ and the number-average degree of polymerization u. Let $\dot{r}$ be the probability of degradation per monomer unit per unit dose and σ the probability of endlinking per degraded monomer, then $m_k(p, R)$ is

$$\begin{aligned} m_k(p, R)=\delta_{k2}m(p, 0)+\dot{r}R[2F(p)\delta_{k2} \\ -\{2\sigma u+(2\sigma+1)p\}\delta_{k2}m(p, 0) \\ +2\sigma u\delta_{k3}G(p)]+O(R^2)\,, \end{aligned} \tag{50}$$

where

$$F(p)=\int_p^\infty dlm(l, 0)\,,$$

$$G(p)=\int_0^p dllm(l, 0)m(p-l, 0)\,,$$

and δ_{kj} is the Kronecker symbol.

Substituting (50) into

$$\frac{\eta(R)}{\eta(0)}=\sum_{k=2}^{\infty}\int_0^\infty dpp^{\alpha+1}m_k(p, R)\Big/\int_0^\infty dpp^{\alpha+1}m(p, 0)\,, \tag{51}$$

and comparing the result with (49), we obtain the following formula for $B_1(\sigma, \alpha)$, namely,

$$B_1(\sigma, \alpha)=\left(\frac{\dot{r}\alpha}{\alpha+2}\right)\frac{f_{\alpha+2}(0)}{f_{\alpha+1}(0)}\{\theta(\alpha)\sigma-1\}\,, \tag{52}$$

where

$$\theta(\alpha)\equiv\frac{2(\alpha+2)}{\alpha}\left\{\frac{uI^*(\alpha)-uf_{\alpha+1}(0)}{f_{\alpha+2}(0)}-1\right\}\,, \tag{53}$$

$$I^*(\alpha)\equiv\int_0^\infty dpp^{\alpha+1}\int_0^p dllm(l, 0)m(p-l, 0)\,, \tag{54}$$

$$f_\beta(0)\equiv\int_0^\infty dpp^\beta m(p, 0)\,. \tag{55}$$

Remembering the fact that gelation occurs as a result of endlinking if and only if $\sigma>1/4$ for any initial molecular size distribution,[4)] we can predict the behavior of $\eta(R)/\eta(0)$ as follows. If $1/\theta(\alpha)>\sigma>1/4$, the viscosity-dose curve has a minimum. On the other hand, if $1/4>\sigma>1/\theta(\alpha)$, the intrinsic viscosity increases in the beginning and reaches a maximum, though it falls off for large dose. As will be shown later, $1/\theta(\alpha)>1/4$ holds when the initial distribution is sufficiently broad; and $1/\theta(\alpha)<1/4$ when it is sufficiently narrow.

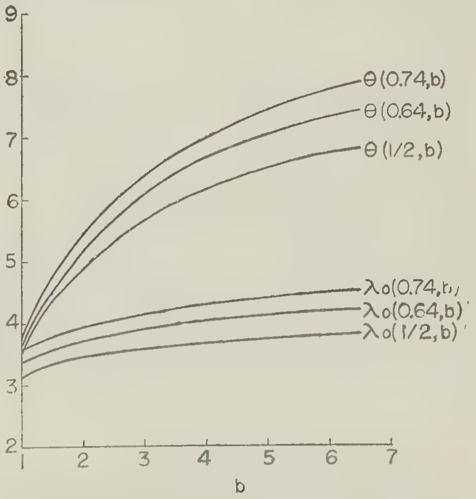

Fig. 5. Dependence of $\lambda_0(\alpha)$ and $\theta(\alpha)$ on b.

Thus we find a parallelism between crosslinking and endlinking, which can be easily visualized when we note the parameter $1/\lambda$ in crosslinking corresponds to the parameter σ in endlinking and compare (52) and (53) with (9) and (10) respectively.

To examine the dependence of $B_1(\sigma, \alpha)$ on the shape of the initial distribution, we carry out calculation of $B_1(\sigma, \alpha)$ when $m(p, 0)$ is the generalized Poisson distribution (44). The result is

$$B_1(\sigma, \alpha)=u\dot{r}\left(1+\frac{\alpha+1}{b}\right)\left(\frac{\alpha}{\alpha+2}\right)\{\theta(\alpha)\sigma-1\}\,, \tag{56}$$

$$\theta(\alpha)=\frac{2(\alpha+2)}{\alpha}\left\{\frac{\Gamma(b+1)\Gamma(2b+\alpha+2)}{\Gamma(2b+1)\Gamma(b+\alpha+2)}-\frac{2b+\alpha+1}{\alpha}\right\}. \tag{57}$$

In Fig. 5 we give $\theta(\alpha)$ and $\lambda_0(\alpha)$ as functions of b for a few values of α. The both curves bear qualitative resemblance to each other, but $\theta(\alpha)$ depends on b, or the shape of the initial distribution, more strongly than $\lambda_0(\alpha)$. This implies that the correlation between the initial distribution and the viscosity-dose curve is more emphasized in endlinking than in crosslinking. It is mathematically a consequence of the difference between $I(\alpha)$ and $I^*(\alpha)$ appearing in $A_1(\lambda, \alpha)$ and $B_1(\sigma, \alpha)$ respectively. (See (15) and (54).)

§ 6. Discussions

We will summarize the results obtained here. Generally the viscosity-dose curve shows a great deal of variety depending on the shape of the initial molecular size distribution.

If the initial distribution is sufficiently sharp, we may expect that the viscosity-dose curve with a maximum or an inflection point should be observed for a proper value of λ. And the curve can be concave either upward or downward near $R=0$. Further it cannot have a minimum. To get a rough idea of the sharpness necessary for such a situation, or for $\lambda_0(\alpha)>4$, we may set $\alpha=1$ in (10), since $\lambda_0(\alpha)$ is an increasing function of α for $1/2\leq\alpha<1$. Thus by simple manipulation, we have

$$\lambda_0(1)=6f_2^{\,2}(0)/f_3(0)\,.$$

Therefore, requiring $\lambda_0(1)>4$, we arrive at the following inequality:

$$P_z(0)/P_w(0)=\{f_3(0)/f_2(0)\}/\{f_2(0)/f_1(0)\}<3/2\,, \tag{58}$$

where $P_z(0)$ and $P_w(0)$ are the z- and the weight-average degree of polymerization at $R=0$. The condition (58) may be understood as a criterion for a " sufficiently sharp " initial distribution.

If the initial distribution is broad, the viscosity-dose curve may have a minimum for a proper value of λ, but never a maximum. The curve is definitely concave upward near $R=0$.

When high-energy radiation causes endlinking instead of crosslinking the situation is qualitatively the same, although the viscosity-dose curve is more sensitive to the shape of the initial distribution.

A few words about an assumption involved in Saito's formalism as well as in our treatment should be needed to avoid misunderstanding. Namely, we assume that crosslinking and degradation should take place under irradiation with constant probabilities $\dot{c}$ and $\dot{r}$, or that reactions leading to crosslinking and degradation should proceed uniformly under irradiation. And it is in the scope of this assumption that we can expect rather complicated behaviors of the intrinsic viscosity depending on the types of initial molecular size distributions. Sometimes we have to do with the case where $\dot{c}$ and $\dot{r}$ depend on time. Such a non-uniform process, as it may be called, is encountered, for instance, when diffusion plays a significant role in the reaction mechanism[8], or when the amount or additives or impurities which react as radical scavengers changes appreciably during irradiation.[9] If necessary, the time dependence of $\dot{c}$ and $\dot{r}$ can be taken into account by a procedure similar to that adopted by Watanabe[8] and Saito[9] in discussions of such non-uniform processes.

We have neglected the effect of branching resulting from crosslinking on the intrinsic viscosity and used the simple Staudinger's law (7) or (51). We believe, however, that our conclusion would not be seriously modified, if we would consider the effect, because our treatment is concerned exclusively with the initial stage of irradiation where the number of branching is presumably very small. In fact, the number of branching is estimated to be order of unity per number-average molecule according to Saito.[4)]

Although Shultz et al[10)] attempted to calculate the intrinsic viscosity of crosslinked polystyrene considering the effect of branching, their result was not satisfactory. According to our view, their calculation involves at least two ambiguities. Firstly, their approximation $\eta(R) \propto P_w^{\alpha}(R)$ is not reasonable, since the molecular size distribution becomes essentially modified by crosslinking, endlinking and degradation. Secondly, the correction due to branching they obtained is appreciable even in the neighborhood of $R=0$, where it is physically expected to be small. In any way, it seems to be very difficult to evaluate the effect of branching.

In conclusion we emphasize that precise measurement of the intrinsic viscosity of an irradiated polymeric substance offers a powerful clue to the determination of the initial molecular size distribution.

Acknowledgements

The authors are very grateful to Professor A. Amemiya of the University of Tokyo and Professor O. Saito of the Chuō University for their discussions and encouragements throughout the work. Further the authors highly appreciate invaluable suggestions and comments of Dr. M. Matsumoto of the Kurashiki Rayon Co., Ltd. Thanks are also due to the members of the Electronic Computer Laboratory of the Faculty of Engineering, University of Tokyo, who kindly gave the authors facilities for numerical calculations by means of the TAC (Tokyo Automatic Computer). The authors are indebted to the Ministry of Education for the Scientific Research Fund.

Determination of Molecular Weight Distributions of High Polymers by Fractionation

By Hiroshi OKAMOTO

The Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino, Japan

(Received July 3, 1959)

There are several impudent assumptions in the determination of molecular weight distributions of high polymers by fractionation. Therefore the reliability of the molecular weight distribution is very problematical. We reconsider the theoretical basis of two fractionation methods, the one is Spencer's method and the other is the successive precipitation method (SPM). Solving simultaneous integral equations, a modified Spencer's method is proposed. Though it necessitates to measure the ratio of the volume of the solution phase to that of the precipitated phase, the results are more accurate than Spencer's method. A modified SPM is also proposed. The results are also compared with the numerical calculation made by other authors and found to be in accord with them.

Molecular weights of high polymers may be established from appropriate physical measurements on dilute solutions, such as light scattering or osmotic method etc. These methods are all absolute, that is, if the experiments were carried out ideally, no error would be introduced in the results.

In the case of determination of molecular weight distributions of high polymers by fractionation, such a situation is not satisfied. Because many impudent assumptions are postulated in the procedure of the fractionation, there must be unavoidable errors in the resultant distribution curves.

Billmeyer and Stockmeyer[1] had studied about Spencer's fractionation method[2] and from many experimental resuls they had rather negative conclusion about this method. Other study [3][4][5][6] about the above mentioned problem were made only by numerical calculations. It seems to be difficult to obtain the general conclusions from them.

Under these circumstances, we try to reconsider the theoretical basis of the two fractionation method, one is Spencer's method and the other is the successive fractionation. Thus we can find a modified method to determine the distribution curves and a fractionation condition to reduce the errors as small as possible.

Recently, Broda, Niwińska, Potowiński[7] discussed the so called summative fractionation method. The auther considers that the first order approximation of their method is nothing but Spencer's method and a further analytical treatment is needed.

CHAPTER I

§ 1.1. Introduction

The procedure of Spencer's method is as follows. A series of polymer solutions is prepared. Each solution is separated into two phases by successive variation of its solvent power. This can be established by successive variation of the content of the non-solvent or of the temperature of each solution. The quantities actually measured are the weight fraction of the precipitated polymer $W(s)$ and the weight-average molecular weight of it $m(s)$. To simplify the problem, Spencer proposed an artificial assumption, namely, that all of the polymer above a certain molecular weight $x(s)$ is in the precipitate and that all bellow $x(s)$ is in the solution phase. Where we use "s" as a parameter which represents the solvent power of the solution, that is, "s" have a one to one correspondence to the non-solvent content or the temperature of the solution.

According to this assumption, if $f(x)$ is the distribution function of the molecular weight,

$$W(s)=\int_{x(s)}^{\infty} f(x)dx \qquad (1.1)$$

$$M(s)=m(s)W(s)=\int_{x(s)}^{\infty} xf(x)dx\ , \qquad (1.2)$$

From Eq. (1.1) and (1.2)

$$\frac{dM}{dw}=x(s) \tag{1.3}$$

The procedure is, then, to plot $m(s)W(s)$ versus $W(s)$ and draw a smooth curve through the points. The curve is differentiated to give the corresponding values of $x(s)$ and $W(s)$. A plot of $1-W(s)$ versus $x(s)$ is the integral distribution curve.

It is an obvious fact, however, that Eq. (1.1) and Eq. (1.2) are not exact. There must be a continuous function $K(s, x)$ which determines the phase separation of the solution.

$$W(s)=\int_0^{\infty}K(s, x)f(x)dx \tag{1.4}$$

$$M(s)=\int_0^{\infty}K(s, x)xf(x)dx \tag{1.5}$$

To treat the problem exactly, solving integral equations (1.4) and (1.5) we must find an unknown function $f(x)$ from the two functions of variable "s", $W(s)$ and $M(s)$ which are able to be obtained from the experiments.

Following the theory of Flory,[8] Sott[9] and Münster,[10] $K(s, x)$ is given by

$$K(s, x)=\frac{1}{1+R(s)\exp\left[-\sigma(s)x\right]} \tag{1.6}$$

Where $R(s)$ is the ratio of the volume of the solution phase to that of the precipitated phase and $\sigma(s)$ is a complicated function of several interaction parameters and the composition of the solution.

For example, for a single solvent solution,

$$\sigma=v\left(1-\frac{1}{r_n}\right)-v'\left(1-\frac{1}{r_n'}\right)+\chi\{(1-v)^2-(1-v')^2\} \tag{1.7}$$

where, v and v' are the volume concentrations of the polymer in the solution and the precipitated phase, r_n and r_n' are the number average molecular weights of each phase and χ is the interaction parameter between the solvent molecule and the polymer segment. Takenaka and his co-workers[11] had already proposed to solve the integral equation (1.4) with Eq. (1.7) by numerical calculation using the electronic computor. Though their method is rigorous, it necessitates the knowledge of many quantities R, v, v', r_n, r_n' and χ. In practice this must be a quite inconvenient task.

We propose to solve the problem as a simultaneous integral equation regarding $f(x)$ and $\sigma(s)$ as two unknown functions, and $W(s)$, $M(s)$ and $R(s)$ as three known functions of s which are able to be obtained from the experiments.

§ 1.2. Mathematical Calculation of the Problem

We write down again the fundamental equation as

$$W(s)=\int_0^{\infty}\frac{1}{1+R(s)\exp\left[-\sigma(s)x\right]}f(x)dx \tag{1.8}$$

$$M(s)=m(s)W(s)=\int_0^{\infty}\frac{1}{1+R(s)\exp\left[-\sigma(s)x\right]}x^{\alpha}f(x)dx \tag{1.9}$$

When $\alpha=1$, $m(s)$ is the weight-average molecular weight, when $\alpha=-1$, $1/m(s)$ is the number average molecular weight and if the distribution curve is plotted against the intrinsic viscocity, α is idential with that encountered in the intrinsic viscocity molecular weight relationship

$$[\eta]=KM^{\alpha}\,.$$

And $m(s)$ is given by

$$m(s)=\frac{1}{K}[\eta]\,.$$

We define $x(s)$ by the following equation,

$$W(s)=\int_{x(s)}^{\infty}f(x)dx \tag{1.10}$$

$\varDelta(s)$ is also defined as,

$$M(s)=\int_{x(s)}^{\infty}x^{\alpha}f(x)dx+\varDelta(s) \tag{1.11}$$

and the shifts diminish as $\log R$ becomes large. We can also recognize that the conditions I and II are nearly satisfied with $f(x)=-1/2(\log 0.996)^3\times 0.996^x x^2$. Matsumoto also calculated for the box type and the two peaks type distributions. For the box type distribution, his calculated curves seemed to lie on the right side of the true curve. We tried similar and more detailed numerical calculation for the box type distribution and found that the calculated curve increases rapidly and moves from the right to the left side of the true curve near the end of the distribution at the higher molecular weight side (Fig. 2).

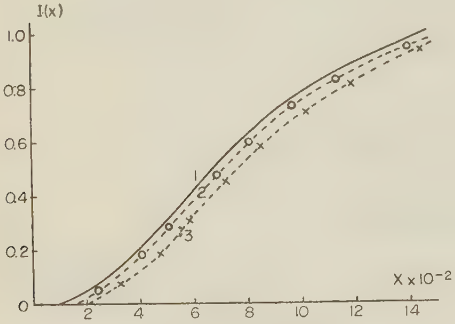

Fig. 1. Comparison of the true integral distribution curve (1) and the curves calculated following Spencer's methods (2) and (3). R is 1000 for the curve (2) and is 500 for the curve (3). $f(x)$ is $-1/2(\log 0.996)^3 0.996^x x^2$. This figure is copied from Matsumoto's work[6].

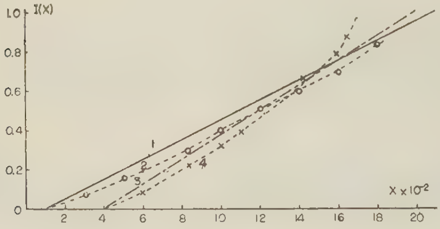

Fig. 2. Comparison of the true integral distribution curves (1) and (3) and the curves calculated following Spencer's methods (2) and (3) for the box type distribution. Curves (1) and (2) are copied from Matsumoto's work[6]. The curve (2) are calculated for the curve (1) under the condition $R=100$, the curve (3) are calculated for the curve (2).

This irregularity arises from the fact that the conditions I and II do not hold in this region. $f(x)$ has two discontinuous points at both ends of the distribution.

From the statistical analysis of their experiments, Billmeyer and Sockmeyer[1] concluded that Spencer's method cannot yield a very detailed description of the molecular weight distribution. They considered three types of the distribution curves, a rectanglar box, a triangle and a parabola.

According to our consideration, all of such distribution curves do not satisfy the conditions I and II, because they all have two or three discontinous points.

The application of Spencer's method is questionable for these cases. This must be one of the important reason of the failure of Spencer's method.

An important question arises, how can we know that $f(x)$ does satisfy the conditions I and II or not. At the start point of the experiment, we know nothing about $f(x)$ and we cannot determine R properly to satisfy the condition II. To answer the question, it must be one of the possible way that we check that the zeroth or the first order approximate function are satisfied by the conditions I and II or not. If they are satisfied, we can almost safely conclude (strictly, not always) that the true distribution curve also satisfies the conditions. If the approximated function does not satisfy the conditions, we can strictly say that the obtained distribution functions never represent the true function. And we are obliged to recommence the fractionation under larger R.

We must add a short remark for the measurement of the average molecular weight. It must be avoided to use Z or higher order average molecular weight. Because for these averages the theory developed in § 1.2 does not hold and we cannot use the final result Eq. (1.25).

CHAPTER II

§ 2.1. Introduction

We have reconsidered the theoretical basis of Spencer's method heretofore and proposed a more reliable method. However, the author considers that the method which is most widely employed now is the successive fractionation method, especially the successive precipitation method (SPM).

There are several impudent assumptions in the usual procedure of the SPM, which is as follows.

The polymer sample of which molecular weight distribution is to be determined is dissolved by an appropriate solvent or solvent mixture. By means of lowering the temperature or adding the precipitant its solvent power is lowered slowly until two phase separation occurs. Then the precipitated phase is taken out of the apparatus. The ratio of the weight of the precipitated polymer to that of the whole polymer W_1 and the average molecular weight of the precipitated polymer m_1 are measured. The supernatant phase remained is again separated into two phases by further lowering the solvent power and W_2 and m_2 are measured, the similar procedures are repeated $n-1$ times. Finally W_n and m_n are also measured for the remaining solution. Usually, the integral molecular weight distribution curve is assumed to be

$$I(m_i)=\sum_{\lambda=0}^{n-\lambda=i+1} W_n{}^{-\lambda}+\frac{1}{2}W_i\,. \tag{2.1}$$

As Schulz[3] had already pointed out, the actual molecular weight distribution of each fraction is considerably overlapped each other. Because this overlapping is apparently neglected in Eq. (2.1), the reliability of the obtained distribution curve is very doubtful. The influence of these neglections upon the results have only been numerically calculated by G. V. Schulz,[3] Matsumoto and Ohyanagi,[6] however, the general conclusion cannot be drawn by the numerical calculation.

The questions, how does this neglection affect the result and how should we perform the experiments to minimize the errors due to this, have not yet been answered.

We try to answer such questions in the following along the similar treatment described in Chapter I.

§ 2.2. Mathematical Calculation of the Problem

There are $n-1$ separation functions for each fractionation step.

$$K_i(x)=\frac{1}{1+R_i\exp[-\sigma_i x]} \tag{2.2}$$

$$i=1,\,2,\,\cdots\,n-1$$

W_i is written as

$$W_i=\int K_i\prod_{\lambda=1}^{i-1}(1-K_\lambda)f dx \tag{2.3}$$

The average molecular weight is measured as the number average or the weight average and in many cases the intrinsic viscocity is used instead of the molecular weight. So that,

$$M_i=m_i W_i=\int K_i\prod_{\lambda=1}^{i-1}(1-K_\lambda)x^\alpha f dx \tag{2.4}$$

The relation between m_i and α is the same as those described in Chapter I.

W_n and M_n are written as

$$W_n=\int\prod_{\lambda=1}^{n-1}\{1-K_\lambda(x)\}f(x)dx \tag{2.5}$$

$$M_n=\int\prod_{\lambda=1}^{n-1}\{1-K_\lambda(x)\}x^\alpha f(x)dx \tag{2.6}$$

And we can find the following relations

$$\sum_{\lambda=0}^{n-\lambda=i+1} W_{n-\lambda}=\int\prod_{\lambda=1}^{i}\{1-K_\lambda(x)\}f(x)dx \tag{2.7}$$

$$\sum_{\lambda=0}^{n-\lambda=i+1} M_{n-\lambda}=\int\prod_{\lambda=1}^{i}\{1-K_\lambda(x)\}x^\alpha f(x)dx \tag{2.8}$$

We defined y_i as the inflection point of K_i and $y_i-\delta y_i$ is defined by the following relation

$$\sum_{\lambda=0}^{n-\lambda=i+1} W_{n-\lambda}=\int_0^{i-\delta i} f(x)dx \tag{2.9}$$

$$\int_{i-\delta i}^{i} f dx = \int_0^i \left\{1-\prod_{\lambda=1}^{i-1}(1-K_\lambda)\right\} f dx + \int_0^i K_i \prod_{\lambda=1}^{i-1}(1-K_\lambda) f dx - \int_i^\infty (1-K_i)\prod_{\lambda=1}^{i-1}(1-K_\lambda) f dx\,. \tag{2.10}$$

Where the intergration limits i and $i-\delta i$ are used in places of y_i and $y_i-\delta y_i$. Using these abbreviations, the following relation is obtained.

$$W_i = \int_{i-\delta i}^{i-1-\delta(i-1)} f(x)dx \tag{2.11}$$

We call the integration range of Eq. (11) $[y_{i-1}-\delta y_{i-1}, y_i-\delta y_i]$ as d_i hereafter.

Next, Δ_i is defined as

$$\Delta_i = M_i - \int_{i-\delta i}^{i-1-\delta(i-1)} x^\alpha f(x)dx \tag{2.12}$$

It is important to notice the following consideration.

If

$$\Delta_i \ll \int_{i-\delta i}^{i-1-\delta(i-1)} x^\alpha f(x)dx\,, \tag{III}$$

then m_i is in the range

$$y_i-\delta y_i \leqq m_i^{1/\alpha} \leqq y_{i-1}-\delta y_{i-1}\,. \tag{2.13}$$

When d_i is so small that $f(x)$ can be seen to be constant in d_i and α is equal to 1, the following relations stand.

$$m_i = \frac{1}{2}(y_{i-1}-\delta y_{i-1}+y_i-\delta y_i) \tag{2.14}$$

$$\int_0^{m_i} f(x)dx = \sum_{\lambda=0}^{n-\lambda=i+1} W_{n-\lambda} + \frac{1}{2}W_i \tag{2.15}$$

Eq. (2.14) is the same as Eq. (2.1). The usual assumptions are found to be adequate in this case. But this is only an ideal case. If the condition III does not hold, however small d_i may be, Eq. (2.13), (2.14) do not stand.

Therefore, there are two important factors in the fractionation, the one is to make d_i as small as possible and the other is to make Δ_i satisfy the condition III. The former corresponds to the analyzability of the fractionation. To clarify these situations, we proceed to calculate Eq. (2.9) and Eq. (2.11). We can prove the following relations by the analogous process which was used to derive Eq. (1.14) from Eq. (1.15)

$$\int_0^i \left\{1-\prod_{\lambda=1}^{i-1}(1-K_\lambda)\right\} f dx \cong \int_0^i K_{i-1} f dx \cong \sum_{n\geqq 0}(-)^n E_{n+1,i}\left(\frac{d^n f}{dx^n}\right)_i \left(\frac{y_{i-1}}{\log R_{i-1}}\right)^{n+1} \tag{2.16}$$

where,

$$E_{n,i} = \sum_{\nu\geqq 0}(-)^\nu \frac{1}{(\nu+1)^n}\left(\frac{1}{R_{i-1}}\right)^{\nu+1} \exp\left[(\nu+1)\sigma_{i-1}y_i\right]$$

and

$$\int_0^i K_i \prod_{\lambda=1}^{i-1}(1-K_\lambda) f dx - \int_i^\infty (1-K_i)\prod_{\lambda-1}^{i-1}(1-K_\lambda) f dx \cong -2\sum_{\nu\geqq 0} C_{2\nu+2}\frac{d^{2\nu+1}}{dx^{2\nu+2}}\left\{\prod_{\lambda=1}^{i-1}(1-K_\lambda) f\right\}_i \left(\frac{y_i}{\log R_i}\right)^{2\nu+2}. \tag{2.17}$$

Then Eq. (2.9) reduces to

$$\int_{i-\delta i}^{i} f dx \simeq \left[E_{1,i}\left(\frac{y_{i-1}}{\log R_{i-1}}\right) - 2C_2\frac{d}{dx}\left\{\prod_{\lambda=1}^{i-1}(1-K_\lambda)\right\}_i \left(\frac{y_i}{\log R_i}\right)^2\right] f(x_i) +$$
$$+\left[-E_{2,i}\left(\frac{y_{i-1}}{\log R_{i-1}}\right)^2 - 2C_2\prod_{\lambda-1}^{i-1}(1-K_\lambda)_i\left(\frac{y_i}{\log R_i}\right)^2\right]\left(\frac{df}{dx}\right)_i + \cdots \tag{2.18}$$

As δy_i is defined for $\sum_{\lambda=0}^{n-\lambda=i+1} W_{n-\lambda}$ so $\delta y_i'$ is defined for $\sum_{\lambda=0}^{n-\lambda=i+1} M_{n-\lambda}$.

$$\int_{i-\delta'i}^{i} x^{\alpha} f dx = \int_{0}^{i} \left\{ 1 - \prod_{\lambda-1}^{i-1} (1-K_{\lambda}) \right\} x^{\alpha} f dx + \int_{0}^{i} K_i \prod_{\lambda=1}^{i-1} (1-K_{\lambda}) x^{\alpha} f dx - \int_{i}^{\infty} (1-K_i) \prod_{\lambda=1}^{i-1} (1-K_{\lambda}) x^{\alpha} f dx \tag{2.19}$$

The right hand side of Eq. (2.19) reduces to

$$\cong \sum_{n \geqq 0} (-)^n E_{n+1,i} \left. \frac{d^n(x^{\alpha} f)}{dx^n} \right)_i \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^{n+1} - 2 \sum_{\nu \geqq 0} C_{2\nu+2} \frac{d^{2\nu+1}}{dx^{2\nu+1}} \left\{ \prod_{\lambda=1}^{i-1} (1-K_{\lambda}) x^{\alpha} f \right\} \left(\frac{y_i}{\log R_i} \right)^{2\nu+2} \tag{2.20}$$

$$\begin{aligned} &\cong y_i^{\alpha} f(y_i) \left[E_{1,i} \frac{y_{i-1}}{\log R_{i-1}} - 2C_2 \frac{d}{dx} \left\{ \prod_{\lambda=1}^{i-1} (1-K_{\lambda}) \right\}_i \left(\frac{y_i}{\log R_i} \right)^2 \right] + y_i^{\alpha} \left. \frac{df}{dx} \right)_i \left[-E_{2,i} \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^2 \right. \\ &\left. -2C_2 \prod_{\lambda=1}^{i-1} (1-K_{\lambda})_i \left(\frac{y_i}{\log R_i} \right)^2 \right] + \alpha y_i^{\alpha-1} f(y_i) \left[-E_{2,i} \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^2 - 2C_2 \prod_{\lambda=1}^{i-1} (1-K_{\lambda})_i \left(\frac{y_i}{\log R_i} \right)^2 \right] + \cdots \end{aligned} \tag{2.21}$$

Comparing this equation with Eq. (2.17)

$$\cong \int_{i-\delta i}^{i} x^{\alpha} f(x) dx - \alpha y_i^{\alpha-1} f(y_i) \left[E_{2,i} \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^2 + 2C_2 \prod_{\lambda=1}^{i-1} (1-K_{\lambda})_i \left(\frac{y_i}{\log R_i} \right)^2 \right] + \cdots \tag{2.22}$$

Thus, from Eq. (2.11) $\varDelta_i$ is approximately equal to

$$\begin{aligned} \varDelta_i \cong \alpha y_{i-1}^{\alpha-1} f(y_{i-1}) &\left[E_{2,i-1} \left(\frac{y_{i-2}}{\log R_{i-2}} \right)^2 + 2C_2 \prod_{\lambda=1}^{i-2} (1-K_{\lambda})_{i-1} \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^2 \right] \\ - \alpha y_i^{\alpha-1} f(y_i) &\left[E_{2,i} \left(\frac{y_{i-1}}{\log R_{i-1}} \right)^2 + 2C_2 \prod_{\lambda=1}^{i-1} (1-K_{\lambda})_i \left(\frac{y_i}{\log R_i} \right)^2 \right] \end{aligned} \tag{2.23}$$

Considering that

$$\int_{i-\delta i}^{i-1-\delta(i-1)} x^{\alpha} f(x) dx = (x'_{i-1} - x_i') \xi_i^{\alpha} f(\xi_i) \tag{2.24}$$

$$x_i' < \xi_i < x'_{i-1} \qquad x_i' = y_i - \delta y_i \qquad x'_{i-1} = y_{i-1} - \delta y_{i-1}$$

To satisfy the condition III, it is sufficient that the following relation is satisfied.

$$\{E_{2,i-1} + 2C_2(1-K_{i-2})_{i-1}\} \frac{\alpha}{\{\log R\}^2} \ll \frac{x'_{i-1} - x_i'}{\eta} \tag{III$'$}$$

$$x_i' < \eta < x'_{i-1} \qquad R_{i-1} \leqq R \leqq R_{i-2}$$

where the approximation

$$\prod_{\lambda=1}^{i-2} (1-K_{\lambda})_{i-1} \cong (1-K_{i-2})_{i-1}$$

is used. The restrictions for $f(x)$ such as I and II in Chap. I should be also satisfied in the above discussions.

§ 2.3. Discussions

Among the two factors which are important in the SPM, the one to make d_i small is closely related to the number of the fractions. Roughly speaking, to make d_i small, the number of the fractions must be increased. But, however small d_i may be, if the conditions III or III′ is not satisfied, the value of m_i goes out of the range d_i and the reliability of the results become problematical. Conversely, however small $\varDelta_i$ may be, if d_i is large, the variation of $f(x)$ is smoothed out and the detailed knowledge of $f(x)$ can not be obtained.

The magnitude of $E_{2,i-1} + 2C_2(1-K_{i-2})_{i-1}$ is not known so far as the values of y_{i-1} and y_{i-2} are not given. They cannot be determined directly from the experiments but the magnitude of $E_{2,i-1} + 2C_2(1-K_{i-2})_{i-1}$ never exceeds $\log 2 + \pi^2/12$ and there will not occur appreciable errors when this factor is replaced by 1 so that

$$\frac{\alpha}{(\log R)^2} \ll \frac{x'_{i-1}-x_i'}{\eta} \qquad \text{III}$$

Though we have not the knowledge of x_i' etc., if the total range of the molecular weight is assumed to be equally divided into n fractions

$$\frac{x'_{i-1}-x_i'}{\eta} < \frac{1}{n-1}$$

so that

$$\frac{\alpha}{(\log R)^2} < \frac{1}{n-1}\ . \qquad \text{IV}$$

This is the most simplified from of the condition III. If we divide the sample into 10 fractions under the condition that R is comparable or greater than several hundreds, the results are probably satisfactory. Such fractionation can comparatively easily be attained without special intention.

Perhaps a more reliable estimation for the value of x_i' may be as follows

$$x_i' = \frac{W_{i+1}m_i^{1/2} + W_i m_{i+1}^{1/2}}{W_{i+1} + W_i}\ . \qquad (2.25)$$

When $\varDelta_i$ is found to be negligible, it may be a better approximation for $f(x)$ to assume it as a linear function of x in the range d_i. In this case

$$W_i = f_i(x'_{i-1}-x_i') + \frac{1}{2}(f_{i-1}-f_i)(x'_{i-1}+x_i') \qquad (2.26)$$

$$M_i = \frac{f_i}{\alpha+1}\left\{(x'_{i-1})^{\alpha+1}-(x_i')^{\alpha+1}\right\} + \frac{f_{i-1}-f_i}{\alpha+2}\,\frac{\{(x'_{i-1})^{\alpha+2}-(x_i')^{\alpha+2}\}}{x'_{i-1}-x_i'}$$

$$i=1, 2, \cdots n-1\ . \qquad (2.27)$$

$$W_n = \frac{1}{2} f_{n-1} x'_{n-1} \qquad (2.28)$$

$$M_n = \frac{1}{\alpha+2} f_{n-1}(x'_{n-1})^{\alpha+1} \qquad (2.29)$$

where

$$f_i = f(x_i') \qquad (2.30)$$

$$f(x) = f_i + (f_{i-1}-f_i)\frac{x-x_i'}{x'_{i-1}-x_i'} \quad x_i' \leqq x \leqq x'_{i-1} \qquad (2.31)$$

We must solve the above simultaneous equation with respect to f_i and x_i'.

Generally speaking, in the region $df/dx>0$, m_i is larger that $1/2(x'_{i-1}+x_i')$ and in the region $df/dx<0$, m_i is smaller than $1/2(x'_{i-1}+x_i')$. So the usual procedure will yield a more sharp distribution curve than the true one, this error will nearly be avoided with the assumption of linear from of $f(x)$.

Though the procedure becomes more complicated, higher order approximation may be possible. We estimate $\varDelta_i$ from Eq. (2.22) with the values of x_i' and $f(x)$ determined from the procedure usual or proposed in Eq. (2.26) to Eq. (2.28). Then, $M_i - \varDelta_i$ is used for the second approximation to $\int_{i'}^{(i-1)'} x^\alpha f(x)dx$.

Magnetohydrostatic Equilibrium for Plasma in a Torus Tube

By Taro KIHARA

Department of Physics, Faculty of Science, University of Tokyo

(Received May 20, 1959)

A solution of the magnetohydrostatic problem of finding the equilibrium configuration of a plasma in a slightly bending torus tube with circular cross section is reported. Both the plasma and the tube wall are assumed to be perfectly conducting. The ratio of the tube radius to the radius of curvature, R, of the tube axis is assumed to be so small that its square is negligible. The method is an application of a perturbed cylindrical coordinate sytsem, in which the line element ds is given by

$$ds^2=(1-\xi R^{-1}r\cos\theta)^2dr^2+(1-\eta R^{-1}r\cos\theta)^2r^2d\theta^2+(1+R^{-1}r\cos\theta)^2dz^2\ ,$$

ξ and η being functions of r satisfying $\xi=d(r\eta)/dr$. A result is the following. If an axially symmetric plasma cylinder with the material pressure monotonically decreasing towards the plasma surface is slightly bent into a torus, then two isobaric surfaces are closer in the more distant part from the torus axis than in the less distant part.

§1. Introduction

There are several magnetohydrodynamic investigations[1)2)] on the equilibrium configuration and its stability of a cylindrical plasma contained in a cylindrical tube. In the present paper is treated the case where the cylinder slightly bends into a torus with circular cross section. Plasma in a torus tube plays an important role in researches on controlled fusion.

Biermann et al.[3)] gave solutions to the problem assuming that the electric currents flow exclusively at the surface of the plasma; their method is exact but is restricted to this particular assumption. In the present paper the problem is solved without this restriction, although the solution is limited to small perturbations. Both the plasma and the tube wall are assumed to be perfectly conducting. The ratio of the tube radius to the radius of curvature of the tube axis is assumed to be so small that its square is negligible.

We consider a plasma in equilibrium, i.e. under the condition

$$\boldsymbol{J}\times\boldsymbol{B}=\mathrm{grad}\,P\ , \qquad (1)$$

which expresses balance between the electromagnetic and mechanical forces. Here $\boldsymbol{B}$ is the magnetic field satisfying $\mathrm{div}\,\boldsymbol{B}=0$; $\boldsymbol{J}$ is the current density, $\boldsymbol{J}=\mu^{-1}\,\mathrm{rot}\,\boldsymbol{B}$ with the constant permeability μ; P is the pressure assumed to be a scalar.

For a cylindrical plasma with axial symmetry an equilibrium configuration is given, in terms of the cylindrical coordinates r, θ, z, by

$$B_r=0\ ,\quad B_\theta=f(r)\ ,\quad B_z=g(r)\ , \qquad (2)$$

where $f(r)$ and $g(r)$ are arbitrary functions of r. The condition (1) is equivalent to

$$\frac{1}{2\mu}\frac{d}{dr}(f^2+g^2)+\frac{1}{\mu}\frac{f^2}{r}=-\frac{dP}{dr}\ . \qquad (3)$$

The cylindrical plasma is in equilibrium when it is surrounded by a cylindrical wall at $r=$constant.

Our aim is to discuss the perturbation to the equilibrium configuration (2) when the cylinder slightly bends into a torus. For this purpose we try to modify the cylindrical coordinates for which the line element ds is given by

$$ds^2=dr^2+r^2d\theta^2+dz^2\ .$$

Let R denote the radius of curvature of the tube axis. One might first expect to use an orthogonal curvilinear coordinates r, θ, z defined by

$$ds^2=dr^2+r^2d\theta^2+(1+R^{-1}r\cos\theta)^2dz^2\ , \qquad (4)$$

with the curved z-axis on the tube axis. Here positive and negative $\cos\theta$ correspond, respectively, the more and the less distant parts from the torus axis. This choice is not very convenient, since the field quantities are complicated in general in this coordinate system. One might then expect to use another orthogonal curvilinear coordinates defined by

$$ds^2=(1-\alpha R^{-1}r\cos\theta)(dr^2+r^2d\theta^2)+(1+R^{-1}r\cos\theta)^2dz^2\,, \tag{5}$$

with constant α. Here use has been made of the assumption that the square of the curvature of the z-axis can be neglected. This system, however, is not yet useful enough; and it will be generalized farther in the following.

§ 2. Solution

We introduce, neglecting the square of the curvature R^{-1}, a "perturbed cylindrical coordinate system" defined by

$$ds^2=\left(1-\frac{\xi}{R}r\cos\theta\right)^2dr^2+\left(1-\frac{\eta}{R}r\cos\theta\right)^2r^2d\theta^2+\left(1+\frac{1}{R}r\cos\theta\right)^2dz^2\,, \tag{6}$$

in which ξ and η are functions of r only. In order that r and θ defined by (6) with constant z indicate orthogonal curvilinear coordinates in a plane, it is necessary that the Gaussian curvature,

$$-\frac{1}{h_1h_2}\left[\frac{\partial}{\partial\theta}\left(\frac{1}{h_2}\frac{\partial h_1}{\partial\theta}\right)+\frac{\partial}{\partial r}\left(\frac{1}{h_1}\frac{\partial h_2}{\partial r}\right)\right],$$

in which

$h_1\equiv 1-R^{-1}\xi r\cos\theta$ and $h_2\equiv(1-R^{-1}\eta r\cos\theta)r$,

vanishes. The condition is calculated to be

$$\xi=\frac{d}{dr}(r\eta)\,. \tag{7}$$

This is also sufficient for (6) to be orthogonal curvilinear coordinate system in a Euclidian space. Equation (6) reduces to (5) when ξ is a constant.

With respect to this coordinate system we can prove, up to the first order of the curvature R^{-1}, the following. The vector $\boldsymbol{B}$ having the components

$$B_r=0\,,\quad B_\theta=\left(1+\frac{\xi-1}{R}r\cos\theta\right)f(r)\,,$$

$$B_z=\left(1-\frac{r}{R}\cos\theta\right)g(r) \tag{8}$$

is source-free,

$$\operatorname{div}\boldsymbol{B}=0\,,$$

and moreover the r-component of its curl vanishes:

$$(\operatorname{rot}\boldsymbol{B})_r=0\,.$$

The θ- and z-components are

$$(\operatorname{rot}\boldsymbol{B})_\theta=-\left(1+\frac{\xi-1}{R}r\cos\theta\right)\frac{dg}{dr}\,,$$

$$(\operatorname{rot}\boldsymbol{B})_z=\frac{1}{r}\frac{d}{dr}(rf)+\frac{1}{R}\cos\theta\left[(2\xi-1)\frac{d}{dr}(rf)+\left(r\frac{d\xi}{dr}-1\right)f\right],$$

where the condition (7) has been used. The current density, $\boldsymbol{J}$, is given by $\mu^{-1}\operatorname{rot}\boldsymbol{B}$.

Now, $\xi(r)$, and hence $\eta(r)$ also, can be determined in such a way that the magnetic field (8) satisfies the equilibrium condition (1). The condition is equivalent to $\operatorname{rot}(\boldsymbol{J}\times\boldsymbol{B})=0$, which is calculated to be

$$\frac{d}{dr}(r^2f^2\xi)=r^2\frac{d}{dr}(f^2+g^2)+3rf^2\,. \tag{9}$$

Hence

$$(\operatorname{rot}\boldsymbol{B})_z=\left(1+\frac{r}{R}\cos\theta\right)\frac{1}{r}\frac{d}{dr}(rf)+\frac{r}{Rf}\cos\theta\frac{d}{dr}g^2\,.$$

The electric current density vanishes where both $d(rf)/dr$ and dg/dr vanish. Integrating (9) we have

$$f^2\xi=\frac{1}{r^2}\int_0^r(f^2-2g^2)rdr+f^2+g^2\,; \tag{9a}$$

The pressure depends on r only and is determined by

$$\frac{1}{2\mu}\frac{d}{dr}(f^2+g^2)+\frac{1}{\mu}\frac{f^2}{r}=-\frac{dP}{dr}\,, \tag{10}$$

which has the same form as (3). Integrating we have

$$P=\text{const.}-\frac{1}{2\mu}(f^2+g^2)-\frac{1}{\mu}\int_0^r\frac{f^2}{r}dr\,, \tag{10a}$$

Thus we have generalized the cylindrical configuration (2) into a toroidal one (8) by use of a curvilinear coordinate system (6) with the conditions (7) and (9). This toroidal plasma is in equilibrium when it is surrounded by a tube wall at $r=$constant.

From (9) and (10) we obtain

$$\frac{d}{dr}(r^2f^2\xi)=-2\mu r^2\frac{dP}{dr}+rf^2\,.$$

Therefore, if the pressure is a monotonically decreasing function of r, ξ is always positive, and, by virtue of (7), η is also positive:

$$\xi>0\,,\quad \eta>0\quad\text{if}\quad dP/dr\leqq 0\quad\text{for all}\quad r\,.$$

For positive ξ we have from (6),

$$(ds\text{ at constant }\theta\text{ and }z)<dr\quad\text{for}\quad\cos\theta>0\,,$$

$(ds$ at constant θ and $z) > dr$ for $\cos\theta < 0$. Since an isobaric surface coincides with a surface of constant r, we can express one of our results as follows. *If an axially symmetric plasma cylinder with the material pressure monotonically decreasing towards the plasma surface is slightly bent into a torus, then two isobaric surfaces are closer in the more distant part from the torus axis than in the less distant part.* It is to be noted that this conclusion is not at all self-evident; if the numerical coefficient of the last term of (9) were less than 2 instead of being 3, then the conclusion would not hold.

§ 3. Example

As an example let us consider the case where

$$f(r)=\begin{cases} r^n & \text{for } r<1 \\ r^{-1} & \text{for } 1<r<r_1\,, \end{cases}$$

$$[g(r)]^2=\begin{cases} g_0^2(1-r^{2n}) & \text{for } r<1 \\ 0 & \text{for } 1<r<r_1\,, \end{cases}$$

$$P=0 \text{ and } \boldsymbol{J}=0 \quad \text{for } 1<r<r_1\,,$$

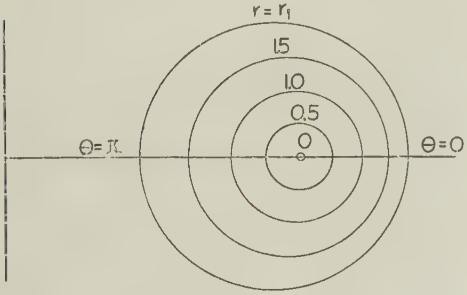

Fig. 1. Lines of constant r in the (r, θ)-plane for $\alpha=1/2$, $r_1=2$, $R=4$.

n and g_0^2 being positive constants. This indicates a plasma of unit radius in a tube of radius r_1 $(r_1 \ll R)$, the averaged B_θ at the plasma surface being taken as unity. Using (10a) we have

$$P=\frac{1}{2\mu}\left(1+\frac{1}{n}-g_0^2\right)(1-r^{2n}) \quad \text{for} \quad r<1\,,$$

from which follows $g_0^2<1+n^{-1}$. The ξ and η are calculated to be

$$\xi=\eta=\alpha \qquad \text{for} \quad r<1\,,$$

$$\xi=\alpha+\ln r, \quad \eta=\xi+r^{-1}-1 \quad \text{for} \quad 1<r<r_1\,,$$

where

$$\alpha=1+\frac{1}{2n+2}-\frac{n}{n+1}g_0^2>\frac{1}{2n+2}\,.$$

In this case the relation (6) for $r<1$ reduces to (5). Lines of constant r in the (r, θ)-plane are such as shown in Fig. 1; these lines are cross sections of isobaric surface fop $r<1$.

In the foregoing we did not consider the stability of the equilibrium, which is influenced only in the second power of the curvature. When the curvature is small at least, the equilibrium configuration discussed in the above example is stable when g_0^2 is sufficiently large and r_1 is sufficiently small.

F–M Conversion in Additively Colored KCl Crystals

By Masamitsu HIRAI

Department of Physics, The Faculty of Science,
University of Tohoku, Sendai

(Received May 22, 1959)

The photochemical reaction of F→M conversion in an additively colored KCl crystal was investigated as a function of the concentration of F centers, under the condition such as differently colored crystals absorb the equal number of incident photons.

The process of the F band bleaching is separated into two steps of the fast and slow bleaching. During earlier stages of F light irradiation the F band displayed the fast bleaching and its amount in each crystals was equal, and independent on the F center concentration, but the growth rate of the M band was proportional to the square root of the concentration of F center. An absorption band, which may be Petroff's A band, was induced on the red side of the F band, but the appearance of this band was dominant in the crystal lightly colored. These experimental results show that the mechanism of the optical F→M conversion depends on the F center concentration, and that the M center is converted from the F center through certain intermediate states.

In the case of the F centers converted from U centers, the growth of the M band was small as compared with that of additively colored crystals containing only F centers, and the growth of the A band was also negligibly small.

§1. Introduction

The optical bleaching of the F center in additively colored alkali halide crystals have been investigated by many authors and the following phenomena have been well known. When the additively colored KCl crystals were irradiated with F light, the F band bleaches, while the M band appeares on the red side of the F band and succesively, the enhancement of the R_1, R_2, N and K bands is observed. However, Petroff[1] observed that the A and B bands appear very close to the F band at the red and violet sides of it before the other bands grow up. These bands have been explained as follows.

The M band corresponds to the transition in the absorption center which has the symmetry of C_{2v} or D_{2h}, which was determined from the experiments of its dichroic property[2] and fluorecence[3]. As to the R_1 and R_2 bands, Seitz[4] states that they arise from transitions in F_2^+ and F_2 centers respectively, which consist of the two nearest adjacent negative ion vacancies and a traped electron for the former center, or two traped electrons for the latter center[5].

The Göttingen workers believe that A and B bands occupy an important genetic relationship in the formation of the other bands, however, Seitz[6] states that these bands are characteristic of Petroff's specimens rather than of the alkali halides in general, for these bands are not observed in the crystals of other labolatories. However, Harman et al. observed that the absorption on the red side of the F band increses, when the additively colored KCl crystals (Harshaw Chemical Co.) were irradiated with F light at room temperature, and measured at liquid air temperature. Furthermore, Markham and Konitzer[7] reported also on the B band in the additively colored KCl crystals. Then it seems still probable to consider that accompaning with the F light irradiation A and B bands will apear as characteristic of the alkali halide crystals in general. However, up to the present, the intrinsic properties of these bands or the relationship to the other bands are not particularly investigated.

As mentioned above, although many investigations on each band have been made, the information on the process, in which the F band is converted to the other bands are very few. In the present paper, in order to clarify this process the mechanism of F→M conversion was investigated, by observing how the growth of the M band depends on the density of the F centers, and how the A or B bands relate to the F→M conversion and also to the half width of the F band.

Furthermore, the bleaching of the F band in the crystals containing U centers was also investigated. When the additively colored alkali halide crystal is heated in the hydrogen gas, it displays a bell shaped absorption band in the ultra violet region. This band is called U band and arises from the electronic transition in the U center, which is considered to be a negatively charged hydrogen ion occupying halogen ion site substitutionally and its absorption maximum situates at 216 mμ in KCl crystal[8]. When this crystal is irradiated by the U light, U band is bleached and F band appeares again. There is no centers other than F center in this conversion process. On this process, Mott and Gurney[9] explained as follows. The excited level of the U center is metastable as a result of crossing of the crystalline Franck-Conson curves, then if the U center absorbes U light, the hydrogen atom escapes from the U center to the interstitial site in the crystal, leaving an F center. The paramagnetic reresonance[10] showed that these interstitial hydrogen atoms combine to form interstitial hydrogen molecules at room temperature.

When KCl+U→F crystal is irradiated with F light, the F band bleaches and the M, R_1, R_2, and N bands appear on the red side of the F band as in the case of additive coloration, however, the behavior of bleaching or growth of these bands are somewhat different. The mechanisms of F→M conversion in this crystal were also investigated, and compared with the cases of KCl+F crystal. KCl+U→F crystal means KCl+U crystal containing the F centers and the interstital hydrogen molecules, which are produced by U light irradiation. KCl+F and KCl+U crystals mean the crystals containing F or U centers only, respectively.

All measurments were made at room temperature.

§ 2. Experimental Procedures

KCl crystals grown by Kyropoulos method were heated with K metals in the Terex tube at 460°C∼550°C, then these crystals were quenched down to room temperature. Concentration of F centers in these crystals were $2.1\times10^{16}\sim6.9\times10^{17}/\text{cm}^3$ and the M band absorption in these crystals were only a trace. Table I shows the description of specimens, thickness, total number of F centers, density of F centers and growth rate of M band.

Table I. Description of used specimens in the present experiment.

Sample (No.)	Thickness d (mm)	Number of F centers [a]	Density of F centers (cm^{-3})	Growth rates of M band
1	0.17	1.17×10^{16}	6.9×10^{17}	0.47
2	0.28	1.08×10^{16}	3.9×10^{17}	0.29
3	0.84	1.04×10^{16}	1.3×10^{17}	0.18
4	1.57	1.23×10^{16}	7.9×10^{16}	0.13
5	4.22	0.91×10^{16}	2.1×10^{16}	0.07

[a]: The number of the F centers obtained by equation (2), which gives the number of the F centers contained in the specimen whose volume $d\times1\times1\,\text{cm}^{-3}$.

In order to compare the bleaching of the F band or the growth of the M band in several crystals colored additively with different concentration, the total number of F center in crystals must be made equal for each specimen. By cleaving the lightly colored crystals into thick slices, and cleaving the heavily colored crystals into thin slices, the total number of F centers in each specmen was made equal. Because, if the number of F centers in one specimen is larger than that in another one, it will be natural that the bleaching of the F band or the growth of the M band in the former specimen will occur in larger quantity and rapidly. Second column in Table I shows the thickness of each specimen and third column shows the number of F centers contained in such specimens of thickness shown in the second column. Using these specimens, it was investigated how much M centers will be produced from equal number of F centers, and how the growth of the M band depends on the density of F centers, when the crystals were illuminated in this same condition.

Using Smakula's equation[11] the number of F centers was obtained optically, i.e.,

$$n_F f_F = 1.31\times10^{17}\frac{n'}{(n'^2+2)^2}\cdot\alpha_m\cdot W_F \qquad (1)$$

where, n_F is the number of F centers per cubic centimenter, f_F is oscillator strength of the F center, n' and α_m are the refractive index and absorption coefficient at the absorption peak of the F band in the crystals, W_F is the half width of the F band in electron volts. Putting $n'=1.49$, $W_F=0.35$ e.v. and $f_F=0.81$ for KCl crystal, a simplified equation $n_F=1.09\times10^{16}\ (\log_{10} I_0/I)/d$ was used. I/I_0 is the transparency at the absorption peak of the F band, and d is thickness of the specimens in centimeter. Then the equation

$$n_F=1.09\times10^{16}\,(\log_{10} I_0/I)_F \qquad (2)$$

gives the number of F centers in the specimen whose volume is $d\times1\times1$ cm³.

The KCl+U crystals were obtained as follows: KCl crystals obtained from Harshaw Chemical Co. were colored with F centers, then these crystals were heated in the hydrogen gas of about 100 atomospheric pressure at 530°C for two hours. These cryrtals contain about 1×10^{18} U centers per cubic centimeter. This crystal was cleaved to a piece of 1 mm thickness, and was irradiated with ultraviolet light (containing U light) from the hydrogen discharge tube through the quartz window. Thus irradiated KCl+U crystal contains 1.3×10^{17} F centers per cubic centimeter, which were converted from U centers. The coloration of F centers converted with this method was not uniform, so that the number of F center is the average value.

F light irradiations were made with the monochromatic light of which wavelength and band width are 560 mμ and 40 mμ respectively. Number of the incident photons were measured by a thermopile as 5.2×10^{14} photons per cm² per sec. on the surface of specimen. Absorption measurements were made between the region from 400 mμ to 1000 mμ.

§ 3. Experimental Results

Fig. 1 shows a sequence of absorption measurements at successive stages of F light irradiation for the KCl+F crystal. This specimen was cleaved from the same colored block as the specimen of No. 5 represented in Table I and its thickness is 2.23 mm.

Curve (a) shows the absorption specta before the specimen is irradiated. In this curve, the half width of the F band is 0.35 e.v., and the M band adsorption is only a trace. Curve (b) shows the state attained after two minutes' irradiation. In spite of the considerable bleaching of the F band, the growth of the M band is very little, but instead of the small growth of the M band the absorption on the red side of the F band (may be A band) has increased and half width of the F band has also increased up to 0.41 e.v.. Curve (c) shows the state after 20 minutes' irradiation, in spite of a little bleaching of the F band during states from (b) to (c), the M band has grown rapidly. While the A band has decreased and the half width of the F band has also decreased down to 0.39 e.v.. Curve (e) shows the final state after 140 minutes' irradiation. The R_1, R_2 and N bands appeared and the peak of the F band shifted to the violet. During the irradiation the K band showed a monotonic increase.

The growth rate of the M band, the bleaching rate of the F band, the change of its half width and the change of the A band etc. depend on the density of F centers.

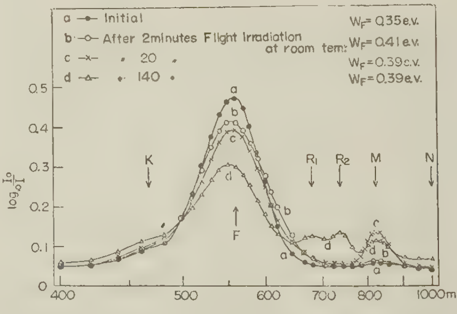

Fig. 1. A sequence of absorption measurements at succesive stages of F light irradiation for KCl+F crystals at room temperature.

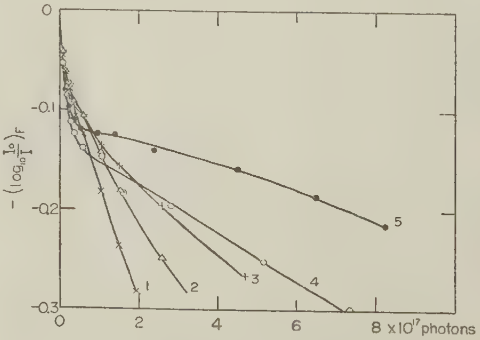

Fig. 2. Bleaching curves of the F band in KCl crystals colored additively with various concentration of F centers.

A. *Bleaching of the F band and Growth of the M band*

Fig. 2 shows the optical bleaching curves of the F bands in the specimens tabulated in Table I, as a function of absorbed F light quanta. $-(\log_{10} I_0/I)_F$ means the decrease of optical density at the absorption peak ($560\,\mathrm{m}\mu$) of the F band.

During earlier stages of irradiation, the F band bleaches by equal amount independently on the density of F centers (fast bleaching), but during later stages of prolonged irradiation, the F band in heavily colored specimens bleachs more rapidly, than that of lightly colored one (slow bleaching).

Fig. 3-A shows the growth curves of the M band, which are measured simultaneously with the measurements of the F band bleaching. $(\log_{10} I_0/I)_M$ represents the increment of optical density at the M band peak ($820\,\mathrm{m}\mu$). These curves show that the growth of the M band depends on the density of the F centers colored additively. In heavily colored specimens the growth rate of the M band is larger than that of lightly colored one, and the optical density at the peak of the M band in the former crystals reaches more rapidly to the maximum value than that in the latter crystal.

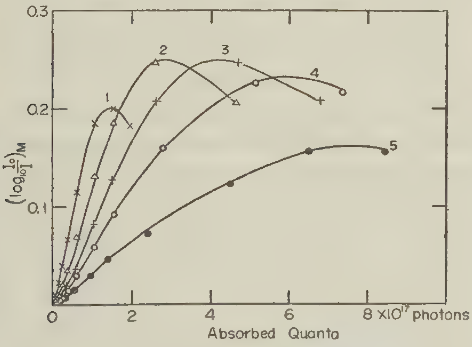

Fig. 3-A. Grow curves of the M band.

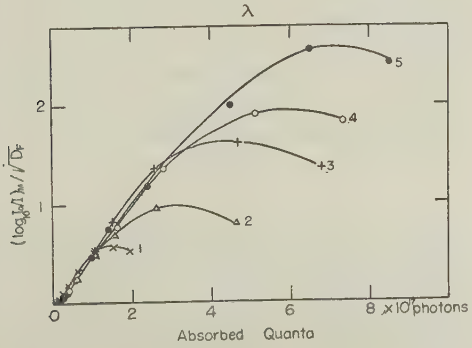

Fig. 3-B. Normalized grow curves of the M band.

The number of the F centers contained in each specimen were nearly equal, and all specimens were irradiated under the same condition, then it was expected that the bleaching of the F band and the growth of the M band will be the same in all specimens. However, Figs. 2 and 3-A show that F→M conversion take place more easily in heavily colored crystals. The fifth column in Table I shows the growth rates of M band, which are expresed as the tangent at the origin of the curves in Fig. 3-A. Comparing the F center concentration of each specimen shown in Table I, it will be cleared that the growth rate of the M band is proportional to the square root of the F center concentration. (See Fig. 3-B)

Figs. 4-A and 4-B show the bleaching

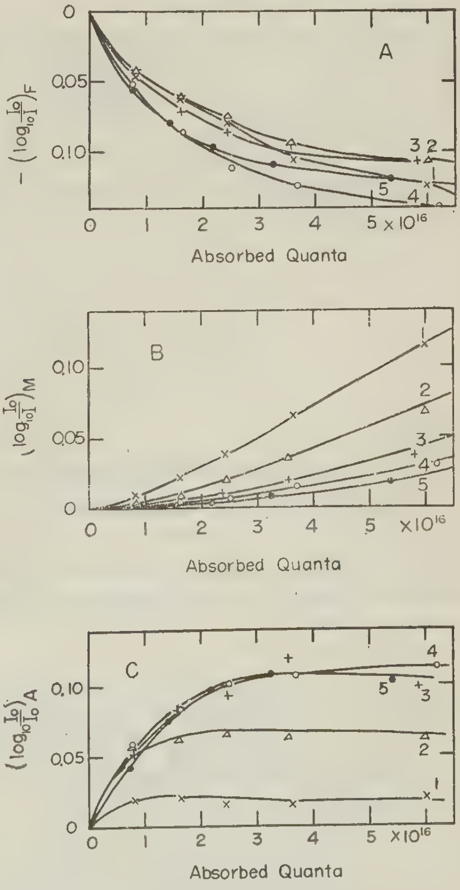

Fig. 4-A. Bleaching curves of the F band.
4-B. Grow curves of the M band.
4-C. Grow curves of the A band.

curves of the F band and the grow curves of the M band during about three minutes' irradiation. These figures suggest that in lightly colored crystals the F band may be converved to another absorption band rather than the M band. Relating with the variation of half width of the F band, this band will be examined in the next section.

B. *Relation between the A band and half width of the F band*

Curve (b) in Fig. 1 was the absorption spectrum at the state after two minutes' irradiation in the specimen of No. 5, of which growth of M band is small. As compared with curve (a) in this figure, it is clear that the absorption on the red side of the F band has increased and that the position of the half height in the red side (ε_r) of the F band has also shifted to the red. Then it is supposed that an absorption band overlaps on the red side of the F band.

Curve (c) in Fig. 5 shows this overlapping absorption band, which was analysed as follows. Curve (b) in Fig. 5 is identical with curve (b) in Fig. 1, and half width of the F band (in this curve) is 0.41 e.v.. Curve (a) is a reduced F band which are obtained as follows, and half width is 0.35 e.v.. The absorption intensity at the F peak of curve (a) in Fig. 1 was reduced to that at the F peak of curve (b) in Fig. 5, and next, the absorption intensities at other wave lengths of curve (a) in Fig. 1 were reduced to curve (a) in Fig. 5 with the ratio of two F-peaks. Shadowed area between curves (a) and (b) in Fig. 5 is the amount of absorption due to the band overlapping on the red side of the F band. Plotting the differences of the absorption curves (a) and (b) at each wave length, curve (c) was analysed. $\bar{A}$ shown in Fig. 5 represents the height of the absorption band, of which peak situates at 620 mμ (2.0 e.v.) and half width is 0.20 e.v. at room temperature. While the peak of Petroff's A band situates at 600 mμ (2.1 e.v.) at liquid air temperature, therefore it is supposed that the absorption band (c) shown in Fig. 5 is identical to Petroff's A band.

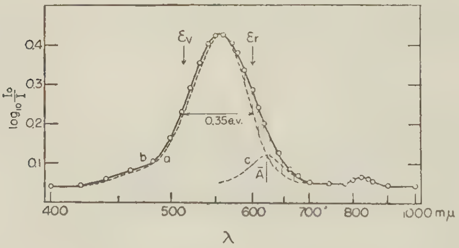

Fig. 5. Analysis of the A band, which is represented by curve (c) corresponding to the shadowed area.

Figs. 6–A and 6–B show the variation of $\bar{A}$ and ε_r in each specimen as a funclion of absorbed F light quanta. $\Delta\varepsilon_r$ is the shift of half height-position in the red side of the F band (ε_r). These figures show that the behavior of ε_r has a parallel rolation with $\bar{A}$, and that the A band in lightly colored crystals grows more largely and it bleaches gradually during prolonged irradiation.

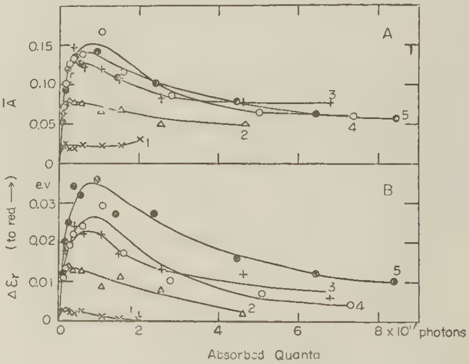

Fig. 6–A. Variation of the absorption intensities at the A band peak. $(\log_{10} I_0/I)_A$ reperesents the absorption intensity of the A band, i.e. $\bar{A}$ shown in Fig. 5.

Fig. 6–B. Shifts of the half height-position in the red side of the F band.

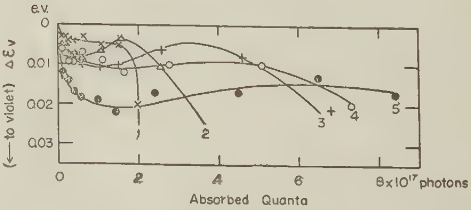

Fig. 7. Shifts of the half height-position in the violet side of the F band. (ε_v).

Fig. 7, shows the shift of the half height position in the violet side of the F band (ε_r). From the figure, it is proper to suppose that an absorption band overlaps on the violet side of the F band.

C. *Bleaching of the F band in KCl+U→F crystal.*

Fig. 8 shows a sequence of absorption spectra at successive stages of F light irradiation for KCl+U→F crystal. This specimen contains 1.3×10^{17} F centers per cubic centimeter, which are converted from U centers, and the density of F centers in this crystal corresponds to that of KCl+F specimen of No. 3. Curve (a) in Fig. 8 shows the absorption spectrum at initial state before the specimen is irradiated. Curves (b), (c) and (d) show the states after 1.5, 7 and 33 minutes' irradiation, respectively. Curve (e) shows the change when the specimen was kept in dark for about 20 hours at room temperature after the measurement of curve (d).

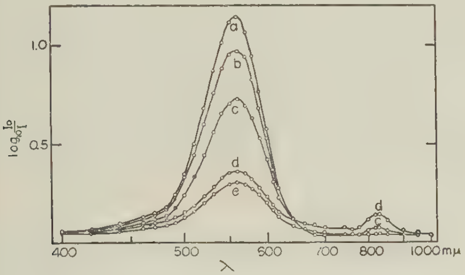

Fig. 8. A sequence of absorption spectra at successive stages of F light irradiation for KCl+U→F crystal.

This series of absorption spectra differ from that in Fig. 1 of additive coloration. Firstly, the M band grows slowly and slightly, secondly, the increment of the A band and the shift of ε_r are small, thirdly, in spite of considerable bleaching of the F band the growth of the M, R and N bands are very small, fourthly, the K band does not appear, and finally, when the specimen was kept in dark at room temperature after getting the state corresponding to curve (d) in Fig. 8, not only the R_1, R_2 and M bands are unstable but also the F band bleaches a little simultaneously. The last result agrees with the results reported previously[12].

§ 4. Discussion

A. *F→M Conversion in KCl+F Crystals.*

Oscillator strengths of the A and M centers were determined as follows: As shown in Fig. 7 ε_v shifts to the violet side, so that it is probable to consider that a certain absorption band, which may be Petroff's B band, overlaps on the violet side of the F band. Then it was assumed that at the end of t_i minutes' F light irradiation, the bleached F centers may be converted to the M, A or B centers as follows:

$$-n_F(t_i)=n_M(t_i)+n_A(t_i)+n_B(t_i) \tag{3}$$

where, $-n_F(t_i)$ is the number of optically bleached F centers, and $n_M(t_i)$, $n_A(t_i)$ or $n_B(t_i)$ are the number of the M, A or B center converted from F centers. Assuming that the number of the M and A centers may be expressed by Smakula's formula, $n_M(t_i)$ and $n_A(t_i)$ are expressed as follows;

$$n_M(t_i)=2.54\times10^{16}\frac{\alpha_M(t_i)W_M}{f_M} \quad \text{(for M center)} \tag{4}$$

$$n_A(t_i)=2.52\times10^{16}\frac{\alpha_A(t_i)W_A}{f_A} \quad \text{(for A center)} \tag{4'}$$

where, $\alpha_M(t_i)=(\log_{10} I_0/I)_M(t_i)$ and $\alpha_A(t_i)=(\log_{10} I_0/I)_A(t_i)$ and they represent the increment of optical density at the M and A band peaks, W_M and W_A are half widths of the M and A bands in electron volts, f_M and f_A are the oscillator strengths of the M and A centers, respectively. Then using equation (2) for $n_F(t_i)$, equation (3) is expressed as follows:

$$-1.09\times10^{16}\cdot\alpha_F(t_i) =2.54\times10^{16}\frac{\alpha_M(t_i)W_M}{f_M} +2.52\times10^{16}\frac{\alpha_A(t_i)W_A}{f_A}+n_B(t_i)$$

where $\alpha_F(t_i)=(\log_{10} I_0/I)_F(t_i)$ and it represents the decrease of optical density at the F band peak. Putting $W_M=0.13$ e.v. and $W_A=0.20$ e.v. (which are determined from the present absorption measurement on each band), and substituting the observed values of $\alpha_F(t_i)$,

Table II. Oscillator strengths of the A and M bands.

Sample (No.)	f_M	f_A
1	0.23	0.78
2	0.24	0.83
3	0.28	0.77
4	0.29	0.59
5	0.34	0.69
average	0.28±0.02	0.73±0.04

$\alpha_M(t_i)$ and $\alpha_A(t_i)$ into the above equation, the oscillator strengths f_A and f_M were obtained as tabulated in Table II. Average values of them were determined as 0.73 ± 0.04 and 0.28 ± 0.02, respectively. In the above calculation it was assumed that n_B for each specimen are unknown constants because the ε_v, of which shift may be proportional to the number of B centers, are nearly constant at earlier successive stages of irradiation, as compared with the changes of the F, A or M bands. Furthermore, the change of the K or R bands were not taken into consideration in the above calculation, because they were also negligibly small as compared with the change of the F, A or M bands up to the end of three minutes' irradiation.

In equation (4) and (4′), putting $f_M=0.28$ and $f_A=0.73$, we can determine the number of M and A centers converted from F centers. Namely,

$$n_M(t_i)=1.18\times10^{16}\cdot\alpha_M(t_i) \qquad \text{(for M center)}$$
$$n_A(t_i)=0.69\times10^{16}\cdot\alpha_A(t_i) \qquad \text{(for A center)}$$

Fig. 9B shows the summation of $n_M(t_i)$ and $n_A(t_i)$ at successive stages of irradiation, and shows that $n_M(t_i)+n_A(t_i)$ for all specimens are nearly equal, independently of F center concentration. Fig. 9A shows the number of bleached F centers in each specimen, and shows that the number of bleached F center is nearly equal to the summation of $n_M(t_i)$ and $n_A(t_i)$ for all specimens. Then, from these results one may suppose as follows; the fast bleaching of F band is independent on the concentration of F centers, and although the ionized electrons from F centers may be almost captured as the A or M centers, in the heavily colored crystals they are captured as M centers, whereas in lightly colored crystals they are captured as A centers. Thus the M center increases proportionally to the square root of F center concentration.

As mentioned previously in this section, it is probable to consider that a part of the ionized electrons from F centers are captured as the B centers. Because, there is slight difference between the summation of A and M centers and the number of bleached F centers, that is, this difference will be due to the B centers. However, it is difficult to determine the half width or the oscillator strength of the B center quantitatively, then at the present one can not state quantitatively on the B center.

As shown in Fig. 6, in stead of small growth of M band in lightly colored crystals the A band grew largely and it bleached gradually during prolonged irradiation. This results suggest that the F center will be converted to M center through the intermediate states, which are represented by A or B centers. However, the models of these intermediate states are not clear.

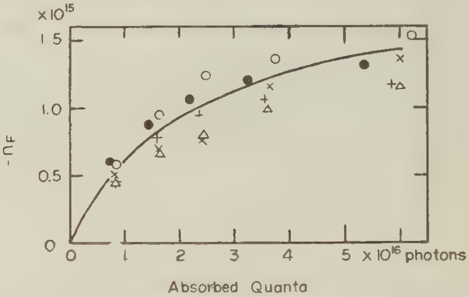

Fig. 9-A. The number of the bleached F cecters at the end of t_i minutes' F light irradiation for each specimen.

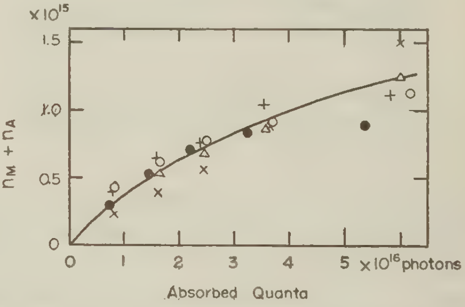

Fig. 9-B. The summation of the number of the A and M center optically converted from F centers at the end of t_i minutes' F light irradiation for each specimen.

Although a cause for the dependence on F center concentration of the slow bleaching of F band will be tentatively explained as follows; in heavily colored crystals a number of the vacancies, which act as the electron trapping center, has been introduced automatically into the crystals, because these crystals were quenched down very quickly from higher temperature to room temperature, then in the heavily colored crystals the ionized electrons from F center will be captured by these traps more than in the lightly colored crystals. But more detailed experiments are needed to conclude this.

B. *F→M Conversion in KCl+U→F Crystals.*

As shown in Fig. 6 for the bleaching of F band in KCl+U→F crystal the increment of the A band and the shift of ε_r are very small as compared with the case of KCl+F crystal. Furthermore, the growth of the M band was also small. Then in the case of this crystal, it is supposed that the behavior of the optically ionized electrons from F centers differ from that of KCl+F crystal. It is probable to consider as follows; as mentioned in the section of introduction, in this crystal considerable amount of hydrogen molecules present at the interstitial sites, so that the electrons from F centers will be captured by these hydrogen molecules before they are captured as M centers or as intermediate states (A or B centers). Therefore it may be a reason for the small growth of A, B or M bands. A process, which the electrons will be captured by hydrogen molecules, are explained as follows:

$$F+H_2 \rightarrow V_- + e + H_2 \rightarrow V_- + H^- + H \rightarrow U + H$$
$$F + H \rightarrow U$$

where, F, V_-, e, H^-, H and H_2 mean the F center, negative ion vacancy, electron, hydrogen ion, hydrogen atom and hydrogen molecule, respectively.

As shown in Fig. 9, the decrease of the K band in KCl+U→F crystal is contrast with the increase of the K band in KCl+F crystal, then these facts will be a clue to research the K band.

§ 5. Conclusion

Seitz stated that the A and B bands are not the characteristic of alkali halide crystals. However, from the present experimental results, it seems proper to conclude that the A and B bands appear as the characteristic of alkali halide crystals attending upon photochemical reaction of F→M conversion in additively colored crystals, and relate with the formation of other bands.

When the F centers, of which total number are equal in all specimens but the density are different, are bleached by the F light, it was observed that the M centers increase proportionally to the square root of the F center concentration. However, this result has not been explained by the present experiment only.

Optical Studies on Thallium-activated Alkali-iodide Crystals

By Yoichi UCHIDA and Riso KATO

Department of Physics, Kyoto University

(Received May 23, 1959)

Absorption and emission spectra of KI–Tl and NaI–Tl phosphors have been investigated at both room and liquid air temperatures. In order to perform optical measurements on NaI-Tl, special caution was given to prevent the crystal surface from being clouded by moisture. In the absorption spectra of NaI–Tl, new bands due to the presence of thallium were found. Their maximum absorption coefficients seemed to vary with the square of the thallium concentrations. The similar fact has already been found by Yuster and Delbecq in their investigation on KI–Tl. In emission, both KI and NaI crystals containing high concentrations of thallium showed a subsidiary band overlapping the short wavelength tail of the hitherto observed main band. The relations between these absorption and emission bands were investigated and discussions were given in terms of an extended model proposed by Seitz.

§ 1. Introduction

Based upon the various experimental works[1] available at that time, a theoretical explanation of the properties of thallium-activated alkalihalide phosphors was first given by Seitz[2]. He postulated that the absorptions and emissions observed in the phosphors are due to transitions in thallous ions which occupy the normal positive ion sites. The observed bands were interpreted in terms of the states of thallous ion perturbed by the crystalline interactions. Utilizing this approach and with the idea of the simplified configuration coordinates Williams[3] computed with fairly good agreement the positions of the absorption band, called *A* by Seitz, and of the associated emission band in KCl-Tl. Then a series of systematic works[4] performed by Johnson, Williams and their coworkers succeeded fairly well in the interpretation of the absorption and emission spectra, their temperature dependence and recently of the problem on the oscillator strength[5],[6] of absorption bands. In their quantitative treatments of the problem, however, the single isolated thallium center was mainly considered. Yuster and Delbecq[7] studied the absorption spectra of KI-Tl phosphors containing various concentrations of thallium. They found several new bands at high Tl concentration and assumed that these bands arose when two thallous ions occupy the neighbouring sites. The symmetry surrounding a thallous ion having another one as a nearest neighbour is no longer cubic but is reduced to D_{2h} symmetry. This symmetry permits nine absorption bands which may vary with the square of the concentration of thallium.

The present work was undertaken for the purpose of investigating the effects of the paired thallous ions on both absorption and emmission spectra in KI-Tl and NaI-Tl crystals containing high concentrations of thallium. In some of the absorption bands of NaI-Tl crystal it was found that their absorption coefficients vary with the square of the thallium concentrations, the fact having been already reported by Yuster and Delbecq on KI-Tl crystals. In emission, both KI-Tl and NaI-Tl crystals with high Tl concentrations showed a new emission band when they were excited by the light of the absorption on the long wavelength side of the *A* band. The relation between these absorption and emission were discussed in terms of an extended model used by Seitz.

§ 2. Experimental Procedure

Single crystals of KI-Tl and NaI-Tl were grown by the Kyropoulos method in our laboratory. Concentrations of thallium in the crystals of KI-Tl were measured spectroscopically and found to be nearly 10 per cent of those added to each melt. The NaI-Tl crystal is so hygroscopic that its surface was readily clouded by moisture in air. To keep the surface clear for the optical measurement the following processes were devised. The crystal of NaI-Tl was cleaved in a dry room and put into a small quartz cell (Fig. 1b), and the cell was connected to a pump system. The crystal was slowly warmed until its surface became clear. The cell was then evacuated and sealed off. If the cell is evacuated without warming, the surface of the crystal suddenly turns white and opaque. After these procedures the cell containing the NaI-Tl crystal was utilized for the measurement. Absorption spectra were measured using a Beckman Model D. U. Spectrophotometer and also a Shimazu Q. B.-50 type Spectrophotometer. A conventional cryostat was employed for the measurements at liquid air temperature. A Fuess Medium Dispersion Quartz Spectrograph in conjunction with a mercury lamp was adapted for a monochromator in order to produce monochromatic lights exciting the phosphors. The emission spectra were photographed by a Hilger small quartz spectrograph in the direction normal to the exciting light as shown schematically in Fig. 1a.

§ 3. Results

a) *Absorption Spectra*

In KI-Tl, Yuster and Delbecq found the eight absorption bands with peaks at 224, 233, 244, 250, 252, 282, 290 and 293 mμ by cooling the crystals down to liquid helium temperature as shown schematically in Fig. 12. In the present work the three crystals having thallium added to each melt at the varying concentration of 0.05, 0.5 and 5 mole per cent respectively were studied. Their absorption spectra at liquid air temperature are shown in Fig. 2. In these spectra the peaks are not resolved more sharply at this temperature than at liquid helium temperature, as observed by Yuster and Delbecq[7], because the bands

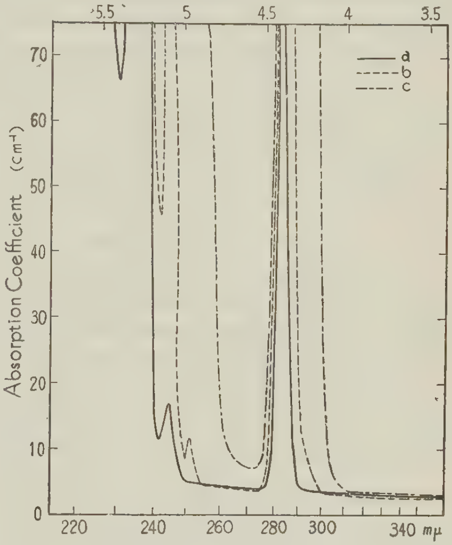

Fig. 2. Absorption spectra of KI-Tl crystals at liquid air temperature. The concentration of thallium added to the melt, a: 0.05 mole per cent; b: 0.5 mole per cent; c: 5 mole per cent.

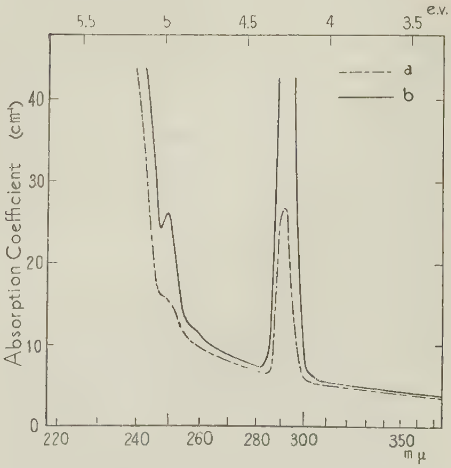

Fig. 3. Absorption spectra of NaI-Tl crystals at liquid air temperature. The concentration of thallium added to the melt, a: 0.005 mole per cent; b: 0.05 mole per cent.

become broader as temperature and concentration of thallium increase. Neverthless the band which covers the range from 280 to 300 mμ at our highest concentration of thallium may be concluded to consist of two bands: the single band at 282 mμ and the composite band at 290∼293 mμ as interpreted from the results of Yuster and Delbecq.

Similar results were obtained on the absorption spectra of NaI-Tl phosphors. The seven crystals of NaI-Tl having the concentration of thallium added to the melt of 0.005, 0.05, 0.2, 0.5, 2, 3 and 5 mole per cent respectively were studied. The absorption spectra at liquid air temperature of the NaI-Tl crystals containing lower concentrations of thallium are shown in Fig. 3. The band around 236 mμ is not sharply separated from the long wavelength tail of the fundamental absorption band of NaI. The absorption band at 250 mμ is fairly well resolved from the 244 mμ band in the case of 0.05 mole per cent of thallium content. The absorption spectra due to higher concentrations of thallium are shown in Fig. 4. At these concentrations two shoulders began to appear; the one at about 260 mμ superimposed on the long wavelength tail of the 250 mμ band, and the other at 305 mμ on the tail of a strong absorption at 290 mμ. The absorption spectra at still higher thallium concentrations are shown in Fig. 5. At these high thallium concentrations the peak heights of the bands at 236, 250 and 290 mμ were too high to be measured with our instruments, and thus the maximum absorption coefficient of the 250 mμ band was estimated in the region of low thallium concentrations ranging from 0.005 to 0.2 mole per cent, while that of the 305 mμ band was estimated up to the highest concentration. Although the resolution of the peaks was not complete, as stated above, the estimation was carried out by substracting

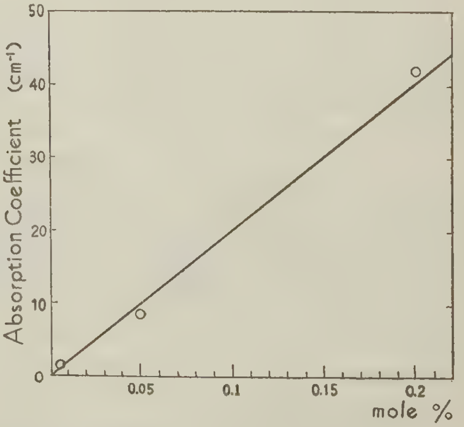

Fig. 6. Variation of maximum absorption coefficient, at liquid air temperature, as a function of thallium concentration for the band at 250 mμ.

the background from the measured absorption.

Figs. 6 and 7 show the variation of the maximum absorption coefficient of the band at 250 mμ and 305 mμ respectively at liquid air temperature as a function of thallium concentration. It is seen that the maximum absorption coefficient of the band at 250 mμ obviously varies linearly with the concentration of thallium, while that of the band at 305 mμ varies in some other fashion, most likely with the square of the concentration of thallium. The shoulder at 260 mμ appears to be proportional in height to the band at 305 mμ with the varied concentrations of thallium as seen in Fig. 4. So the band at 260 mμ should also be considered to vary with the square of the concentration of thallum. The results we obtained above on NaI-Tl remind us of the results obtained on KI-Tl by Yuster and Delbecq.

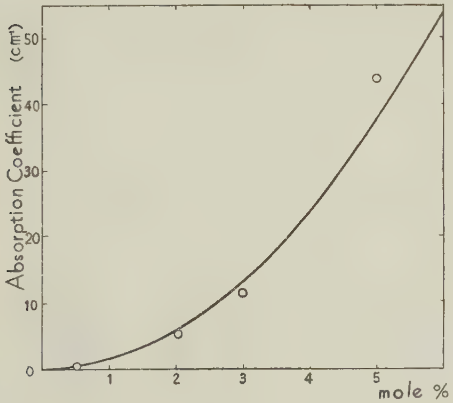

Fig. 7. Variation of maximum absorption coefficient, at liquid air temperature, as a function of thallium concentration for the band at 305 mμ.

b) *Emission Spectra*

Before presenting our results on KI-Tl, it seems convenient to refer to the results obtained by von Meyern1) and Yuster and Delbecq7). It has been described that the luminescence spectrum of KI-Tl, when excited by ultra-violet light, consists of a single band with its maximum at about 415 mμ. In the present investigation, however, a new band has appeared under some circumstances to be described below at about 332 mμ overlapping the short wavelength tail of the 415 mμ (Fig. 8a). In Fig. 8 the densitometer curves of typical emission spectra of KI-Tl phosphors are shown with their peak heights suitably normalized. The curve of type (a) was obtained at room temperature for the crystal containing the highest concentration of thallium when excited by the light at 296 or 302 mμ of a mercury lamp. Two peaks were observed at 332 and 415 mμ. But when the same crystal was excited by 280 mμ of mercury at room temperature, the curve of type (b) consisting of a single band (415 mμ) was obtained. Finally the curve of type (c) was given when excited by 253 mμ; here the shorter wavelength emission (332 mμ) appeared weak compared with the case when the crystal was excited by 296 or 302 mμ. The emission spectrum of type (b) was also given when the crystal with the lowest thallium concentration was excited by the light of any absorption band. However, it should be remarked that, when excited at liquid air temperature by any light, the emission spectrum always consisted of a single band of type (b) with the peak shifting slightly toward the longer wavelength side and the bandwidth becoming narrower.

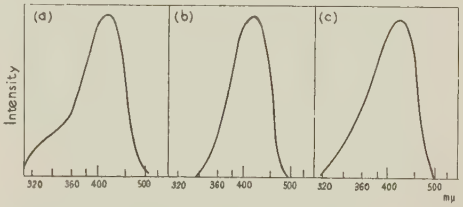

Fig. 8. Densitometer curves of emission spectra of KI-Tl crystals at room temperature. The concentration of thallium added to the melt is 5 mole per cent. (a): the spectrum excited by 296 mμ or 302 mμ; (b): by 280 mμ; (c): by 253 mμ light of mercury lamp.

Curve (c) also shows the emission spectrum of the crystals containing lower concentrations of thallium when excited by the light of any absorption band.

In the case of NaI-Tl, similar phenomena were observed except for the excitation at liquid air temperature. The emission spectra of NaI-Tl at room temperature are shown in Fig. 9. The concentration of thallium added to the melt was 2 mole per cent. The curve (a) is for the emission spectrum excited by 302 or 312 mμ of mercury, (b) by 289 mμ and (c) by 253 mμ of mercury. As is noticed in the figure, the curves (a) and (c) are composite, but (b) is single.

At liquid air temperature the same crystal, when excited by 302 mμ, gave rise to the emission spectrum which consisted of two bands at about 330 mμ and 425 mμ respectively, as shown in Fig. 10 (a). While by 289 mμ, a single band at 425 mμ was resulted as shown in Fig. 10 (b).

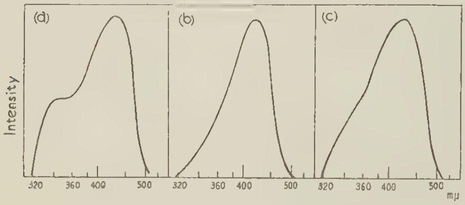

Fig. 9. Densitometor curves of emission spectra of NaI-Tl crystals at room temperature. The concentration of thallium added to the melt is 2 mole per cent. (a): the spectrum excited by 302 or 312 mμ; (b): by 289 mμ; (c): by 253 mμ.

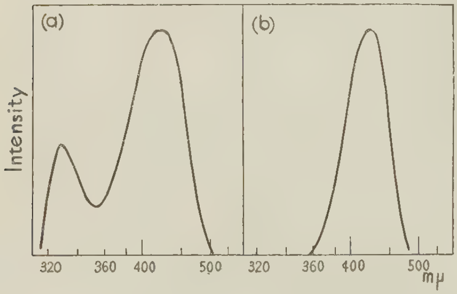

Fig. 10. Densitometer curves of emission spectra of the same crystal used in Fig. 9, but at liquid air temperature. (a): the spectrum excited by 302 or 312 mμ; (b): by 289 mμ.

By presuming an equivalent mechanism on the emission of type (a) the shorter wavelength bands were compared for KI-Tl and NaI-Tl crystals and it was found that the band remains still appreciable at lower concentration of thallium for NaI in comparison with that in KI. The intensity ratio of the two emissions, $I_{\text{short}}/I_{\text{long}}$, is slightly larger for NaI-Tl than KI-Tl, although it increased with concentration of thallium. The remarkable difference between the emission spectrum of NaI-Tl and that of KI-Tl is in that the short wavelength band of NaI-Tl does not vanish at liquid air temperature when excited by the light of absorption band at 305 mμ, while in the case of KI-Tl, it vanishes at liquid air temperature when excited by the light of corresponding absorption bands at 290∼293 mμ even at the highest concentration of thallium.

§ 4. Discussion

The observed absorption bands of NaI-Tl phosphors may be interpreted by the analogy with those[7)] of KI-Tl, considering the two types of the thallium center: the single thallous ion and the paired thallous ions in the crystal. The fact that the peak height of the absorption band at 250 mμ in NaI-Tl seems to vary linearly with the thallium concentration indicates that the absorption is caused by the single isolated thallous ions in the crystal. The shorter wavelength band at about 236 mμ was not sufficiently resolved from the background and the peak was not definitely confirmed. But the origins of this absorption and of the 290 mμ band might be ascribed to the single thallium center, since they were observed even at a low thallium concentration. Thus, considering the intensities of these three absorption bands respectively, they can be assigned to the transitions between the states of single thallous ions in the crystal as follows;

(1) the band at 290 mμ is associated with the transition ${}^1S_0 \to {}^3P_1$,

(2) the band at 250 mμ is ascribed to the transition ${}^1S_0 \to {}^3P_2$,

(3) the band at about 236 mμ may be due to the transition ${}^1S_0 \to {}^1P_1$.

Here, according to Seitz, the transition corresponding to the absorption at 250 mμ is considered to be allowed on account of the perturbation due to the littice vibration.

The bands at 305 and 260 mμ, which are observed at fairly high thallium concentrations, appear to vary with the square of the thallium concentration and, therefore, they are considered to be ascribed to the paired thallium center. Then considering the energies associated with these absorption, the band at 305 mμ is assumed to be ascribed to the transition corresponding to ${}^1S_0 \to {}^3P_1$ and the band at 260 mμ to ${}^1S_0 \to {}^3P_2$ both in the thallous ion perturbed by the neighbouring thallous ion. Some other absorptions which vary with the square of the thallium concentration, may be allowed from the symmetry consideration, but they would not be observed, being concealed under much stronger absorptions due to the single thallous ions.

The fact that the shorter wavelength emission bands (332 mμ for KI-Tl and 330 mμ for NaI-Tl) which are observed at fairly high thallium concentrations are preferentially excited by the light of absorption bands at 290～293 mμ for KI-Tl and 305 mμ for NaI-Tl, shows that these emission bands are associated with the paired thallous ions.

In the case of KI-Tl, the shorter wavelength emission band vanishes at liquid air temperature, although absorption at 290～293 mμ are appreciable. From this fact, the transition giving rise to the shorter wavelength emission is assumed to follow some thermal activation process. Assuming the contribution of the state $^3P_0$ of thallous ion which may become emitting when two toallous ions occupy the neighbouring sites in the crystal, a possible explanation of this emission process is given in Fig. 11.

(1) Through the excitation by the light of 290～293 mμ absorptions, the paired thallium centers in KI-Tl arrive at the perturbed state $(^3P_1)$ which corresponds to the $^3P_1$ state of the single thallous ion, the perturbed state in the paired center being denoted by the corresponding state of the single ion bracketted in ( ). The $(^3P_1)$ state of the paired thallium center is assumed to be connected to the underlying state $(^3P_0)$ of the same center perturbed but corresponding to the $^3P_0$ state of the single thallous ion through a potential barrier.

(2) Going over this potential barrier by

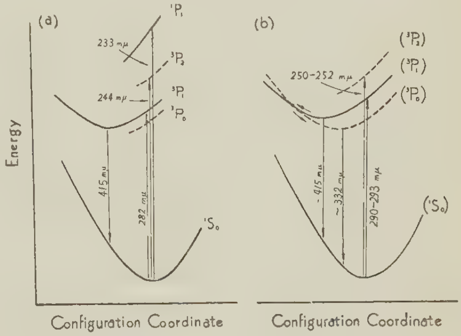

Fig. 11. Configuration coordinate curves of the luminescent centers in KI-Tl; (a) for the single thallium center and (b) for the paired thallium center.

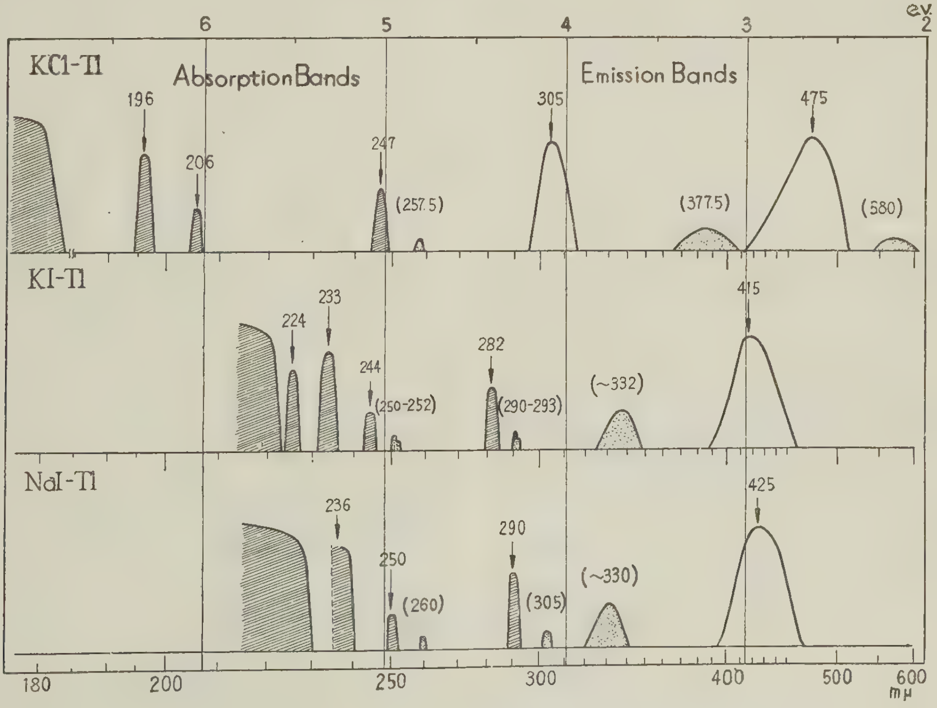

Fig. 12. Diagram schematically summarizing the distribution of absorption and emission bands in KCl-Tl, KI-Tl and NaI-Tl crystals respectively. Shaded bands are absorptions appearing at low concentrations of thallium, while dotted bands show absorptions or emissions at high concentrations. Blank bands are emissions at low concentrations of thallium.

thermal activation, the systems arrive at the minimum point of the ($^3P_0$) state.

(3) Then the systems return to the ground state ($^1S_0$) emitting the light of shorter wavelength band at 332 mμ.

In the paired thallium center, the state ($^3P_1$) also can make transition to the ground state. But the associated emission with this transition is assumed to be concealed under the main band at 415 mμ. Through the excitation by 290～293 mμ, the single thallium centers are also excited to the $^3P_1$ state by absorbing the light at the tail of strong absorption band at 282 mμ and gives rise to the main emission at 415 mμ. Only the single thallium centers are excited by 282 mμ and therefore a single emission band at 415 mμ is observed (Fig. 8b). At liquid air temperature, the paired thallium centers can be excited through the excitation by 290～293 mμ, but the process of going over the potential barrier is considered to be suppressed, so the only single emission band (415 mμ) is observed (Fig. 8b). Thus Fig. 11 shows schematically the configuration coordinate curves for the single and paired thallium centers in KI-T1 and illustrates the observed transitions which give rise to the two emission bands.

In the case of NaI-T1 phosphors, a similar interpretation is possible if one assumes that the potential barrier which connects the two states in the paired thallium center is rather low and can be passed over even at liquid air temperature. Anotner interpretation may be possible without assuming the contribution of the state $^3P_0$ which might become emitting in the paired thallium center. The transition from the state ($^3P_1$) to the ground state in paired thallium center may directly give rise to the shorter wavelength emission at about 330 mμ. But in the latter speculation the analogous relation to the KI-T1 is no longer maintained.

Concerning the emission when excited to much higher states by the lights of B or C absorption bands, so called by Seitz, or further by the light of the fundamental absorption band, both crystals showed more complicated phenomenon. Namely, the contributions of host sensitized luminescence seems to exist partly. About these emission processes the more detailed investigation is now in progress.

Fig. 12 illustrates schematically all the absorption and emission bands in KC1-T1, KI-T1 and NaI-T1 hitherto known including the results obtained in the present investigation.

Acknowledgments

The authors would like to acknowledge the contributions of Miss Toshiko Nakagawa, who grew several of the crystals and assisted in the spectral measurements. This research was supported in part by a grant-in-aid for promoting scientific researches sponsored by the Ministry of Education.

On the Preferential Bleaching of the M Band in KCl Crystal with Polarized Light

By Takehiko ISHII, Tetsuhiko TOMIKI
and Masayasu UETA

*Department of Physics, The Faculty of Science,
University of Tohoku, Sendai*

(Received June 24, 1959)

The temperature dependence of the dichroic properties of the M center in KCl crystal was investigated. At the temperatures above 60°C, the thermal reorientation of the M center in the *ground* state occurs. The measured value of the activation energy for it was 1.0 eV. It was suggested that vacancy clusters may trap free electrons to form new M centers in the course of the bleaching of the M band and this process may be responsible for the temperature dependence of dichroism of the M band.

§ 1. Introduction

When the additively colored alkali halide crystal is irradiated with light in the F band at room temperature, various absorption bands appear on the long wavelength side of the F band¹⁾. Except the A band observed by Petroff²⁾, the M band is the first one which is developed by F bleaching. The M band has been of interest for this reason and studied by many authors. However, the phenomena associated with the M center are so complex that the models³⁾ proposed so far are not conclusive. The R band composed of two bands, R_1 and R_2, is the second to appear in the course of F bleaching.

The behavior of the R band is so closely related to those of F and M bands. Therefore, it will be necessary to know the interrelation between these bands for the investigation of the M center. In KCl crystals, M, R_1 and R_2 bands appear at 820 mμ, 670 mμ, and 730 mμ, respectively at room temperature.

The preferential bleaching of the M band⁴⁾ and the luminescence of the M center⁵⁾ stimulated with polarized light have given some insights on the symmetry properties of the center. The investigations already carried out seem to show that the dipole matrix element of the center is oriented along the face diagonal of the crystal.

Previously, the behavior of the preferential bleaching of the M band in KCl has been reported⁶⁾ when the temperature of the specimen was altered. The main results seem to suggest two facts: (1) When the crystal containing M center is irradiated with light in its absorption band, which is polarized along the direction of the face diagonal, the number of the centers of which dipole matrix elements are normal to it increases; (2) the thermal reorientation of the M center may occur in the ground state. The experiments reported here were carried out to examine these affairs in detail, and it was suggested that one part of electrons ionized from M centers during light bleaching might be trapped by vacancy clusters to form new M centers. Furthermore, the value of 1.0 ev was obtained as the activation energy for the thermal reorientation of the M centers. Some investigations on the dichroism of other bands have been also described.

§ 2. Experimental Procedures

Hitachi Model EPBU spectrophotometer was employed for measurements of optical absorption. The polarizer was of a type of the Rochon prism made of calcite. It was placed just behind the exit slit of the monochromator as shown in Fig. 1 which indicates the optical arrangement. The condenser lens and cryostat windows made of glass did not affect the polarization state of light. To obtain high temperature, oil or water in the cryostat was heated by a nichrome coil inserted in it. Low temperature was obtained by either ice and rocksalt, dryice and methyl alcohol or liquid air. The measurement of temperature was made with copper-constantan thermocouple dipped into the copper block on which the specimen was mounted. The obtained constancy of temperature was within the order of 1°C.

KCl single crystals used in this experiment were grown from the melt by Kyropoulos method. Additive coloration was performed by heating the crystal with potassium metal at about 500°C, and successively quenching to room temperature. The concentration of the F centers in the sample was of the order of 2 or $4\times10^{17}\,\mathrm{cm}^{-3}$. In order to eliminate the reflection loss from the surface, the pure KCl crystal-plate was used as the reference for the measurement of optical absorption.

The M band was developed by illumination with F-absorption light at 560 mμ having a band pass of 80 or 40 mμ. Here the light fell normally upon the (100) surface and was polarized along the [100] direction of the specimen. The development and the bleaching of the M band were carried out with the same optical arrangement as that employed in the absorption measurements. In Fig. 2, the development of the M band by F bleaching was shown against the time of exposure to F light. Except some special cases, the developmedt of the M band was discontinued when its height reached the position of (a) in Fig. 2, because with further illumination, the R band is enhanced.

§ 3. Experimental Results

3.1 *Some observations of the dichroism of the F, M and R bands*

When the M band is preferentially bleached by exposure to M light polarized in the [011] direction, at room temperature, dichroism appears in the F and R bands as well as in the M band. However, it becomes quite difficult to induce dichroism by this procedure at −30°C. The preferential bleaching of the F band also induces dichroism in the F, M and R bands. These phenomena have already been reported and the assumption that the second absorption band of the M center overlaps on F absorption band has been proposed by van Doorn and Haven³⁾.

It was observed when the sample containing F, M and R centers was irradiated for about 4 hours at room temperature with R_2 light ($\lambda=730\,\mathrm{m}\mu$, band pass$\sim$30 m$\mu$, photon intensity$\sim2.4\times10^{14}\,\mathrm{cm}^{-2}\mathrm{sec}^{-1}$) polarized in the [011] direction, weak dichroism also appeared in the F, M and R bands. This fact may hardly be explained only by the model which requests the another absorption band of the M center overlapping with the F band, and it will be necessary to assume the existence of close coupling of R centers with F and M centers.

When dichroism was induced in the F and M bands by irradiating the specimen with M light polarized in the [011] direction, $\delta^{\mathrm{M}}>0$ and $\delta^{\mathrm{F}}<0$ were obtained, where δ^{M} and δ^{F} are defined by the following notation:

$$\delta^{\times}=\mathrm{A}^{\times}_{[0\bar{1}1]}-\mathrm{A}_{[011]}$$

here, × indicates the absorption band such as the F, M or R band and $\mathrm{A}^{\times}_{[ijk]}$ shows the logarithm of the inverse transmission at the peak of the × band measured with light polarized in the [*ijk*] direction.

The sample was illuminated with F light

polarized in the [011] direction after dichroism had been induced in the F, M and R bands by exposure to [011]-polarized M light. Then, the R and M bands developed as shown in Fig. 3. We can clearly see that δ^F, δ^M and δ^R reverse their signs simultaneously in the course of this F bleaching.

The reversal of the sign, however, did not occur when F bleaching was carried out in this turn with F light polarized along the [0$\bar{1}$1] direction, after the dichroism had been induced with [011]-polarized M light. Since the free electrons ionized by F light have not history, the fact that δ's reverse their signs or not depending on the state of polarization of light used in this F bleaching, seems to suggest the existence of some couplings between these centers.

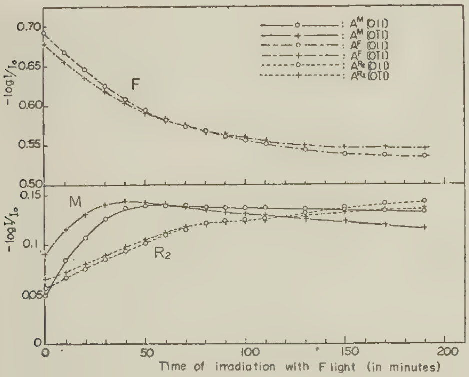

Fig. 3. Changes of the dichroism of F, M and R bands by the exposure to [011]-polarized F light. Dichroism had been initially induced in each band by illumination with [011]-polarized M light.

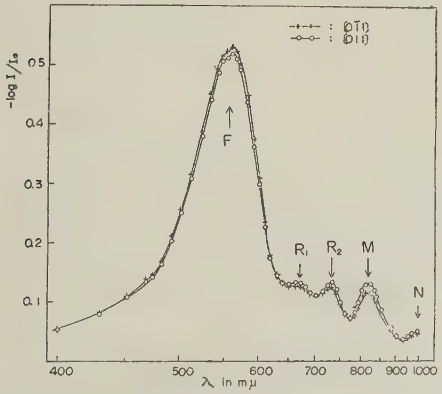

Fig. 4. The absorption spectrum showing a shoulder peak in the F band. The specimen were irradiated for 200 minutes with [011] polarized light of 560 mμ with a band pass of 8 mμ at room temperautre.

The prolonged irradiation with polarized F light induced a shoulder peak at the shorter wavelength side of the F band. Fig. 4 shows the absorption spectrum after 200 minutes' illumination at room temperature with light polarized in the [011] direction whose wavelength was 560 mμ and band pass was about 8 mμ.

This shoulder peak did not appear in the similar experiment at liquid air temperature, nor resolved when the specimen was quenched to that temperature after the peak had been induced at room temperature. This may be due to the shift of F absorption band to shorter wavelength side. The peak did not appear in the case of the irradiation with 560 mμ light polarized in the [011] direction with a broad band pass, say, of about 40 mμ. The origin of this shoulder peak is not clear.

3.2 *The temperature dependence of the preferential bleaching of the M band.*

Figs. 5(a)–(g) show the preferential bleaching of the M bands at various temperatures with [011] polarized light at the peak of the M band with a band pass of 40 mμ. The M

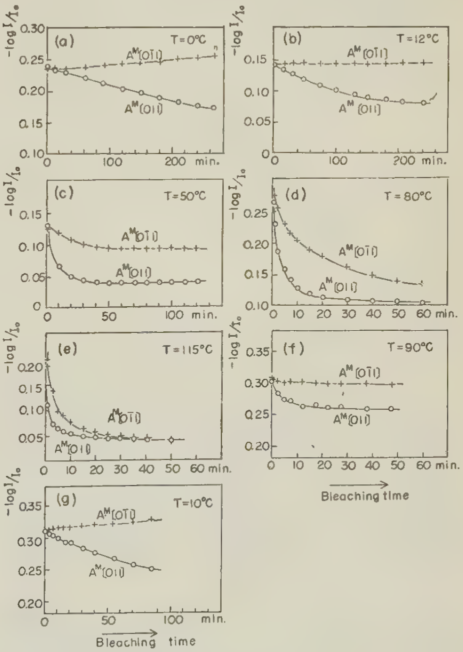

Fig. 5. Preferential bleaching of the M band with [011]-polarized M light at (a) 0°C, (b) 12°C, (c) 50°C, (d) 80°C, (e) 115°C, (f) 10°C, (g) 90°C. The M bands were developed at 12°C in samples (a)—(e), at 35°C in sample (f) and at 90°C in sample (g).

band was developed at 12°C in Figs. 6 (a)–(e), at 35°C in (f) and at 90°C in (g), respectively. In Fig. 5 (g), $A^{M}_{[0\bar{1}1]}$ remains almost constant, but in the similar experiment with other samples it decreased, although the amounts of decrease were not large.

F bleaching at 90°C makes a broad band enhance on the long wavelength side of the F band and it overlaps with the M band completely. This broad band is unstable thermally, and decreases slightly in the dark and then reaches a stationary state. The measurements were made after keeping the specimen in the dark for an hour or so until the broad band became stable both thermally and optically. Therefore, the change in absorption in Fig. 5 (g) can be considered to be due to M centers. From the measurements shown in Fig. 5 (a)–(g), the following results are derived: $A^{M}_{[0\bar{1}1]}$ increases with irradiation time if the M bleaching with polarized light is carried out at the temperature lower than that at which the M centers were created. On the other hand, $A^{M}_{[0\bar{1}1]}$ decreases remarkably if the preferential bleaching is made at the temperature higher than that at which the M centers were produced. If the M center has the dipole matrix element oriented along the face diagonal, the fact that $A^{M}_{[0\bar{1}1]}$ does not decrease in some cases may suggest the number of the M centers which contribute to $A^{M}_{[0\bar{1}1]}$ and have not dipole matrix elements in the $[0\bar{1}1]$ direction increases by irradiation with [011]-polarized M light. In Fig. 6 (d), both $A^{M}_{[011]}$ and $A^{M}_{[0\bar{1}1]}$ decrease rapidly at the initial stage of preferential bleaching, but the former becomes constant in the subsequent bleaching, whereas the latter continues to decrease. In Fig. 5 (e), the dichroism in the M band vanishes in the course of the preferential bleaching. These facts may imply the thermal reorientation of the M center in its ground state. The decrease in $A^{M}_{[0\bar{1}1]}$ in the region where $A^{M}_{[011]}$ is nearly constant may be attributed to the thermal reorientation of M centers, and the optical ionization of the correrponding increment may keep the resultant constancy of $A^{M}_{[011]}$. The thermal reorientation process will be described in the next section.

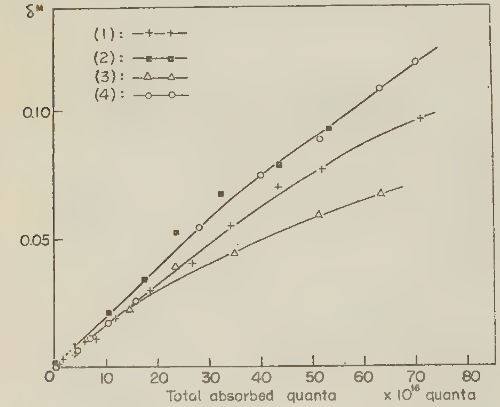

Fig. 6. δ^{M} plotted against total absorbed quanta in the preferential bleaching of the M band at 10°C. The M band was developed at 10°C until its height reached the position (a), (b) and (c) in Fig. 2, in the samples (1), (2) and (3), respectively. In the sample (4), the concentration of M centers is much higher.

The preferential bleaching of the M band at various temperatures is suitably described in terms of the quantum yield for inducing dichroism in the M band. We define the quantum yield as

$$\eta=(\partial\Delta/\partial q_{a})_{t=0}\ ,$$

here, q is the total absorbed quanta, Δ is the product of δ^{M} and the half width of the M band, and $t=0$ indicates the time at which the irradiation of M light starts. η corresponds to the difference between the relative number of the M centers with dipole matrix elements in the [011] direction and that in the $[0\bar{1}1]$ direction, induced per absorbed photon. As shown in Fig. 6, the experimental values of η were the same for the four specimens at 10°C. In the specimen of No. 1 M developing had been made until its height had arrived at the position (a) in Fig. 2, in No. 2 at (b) and in No. 3 at (c), respectively, and in No. 4 the concentration of the M centers was much larger. This means that the value of η is independent both of the number of M centers and the stage of M developing. Thus, it is possible to define η as a quantity characteristic of the M center only.

Fig. 7 shows the curve of $\log\eta$ versus reciprocal kT. The curve (a) corresponds to the case where the M band was bleached preferentially at the temperature at which the M band had been created. The curve (b) corresponds to the case where the M band was generated at 12°C. The curve (a) has a kink point which appears between 30°C and 20°C. It is interesting to note that a kink point appears also between 30°C and 20°C in the curve which shows a relation between log R and inverse kT[7], where R is the ratio of the number of M centers to that of F centers at the moment when the height of the M band reached its maximum in the process of F bleaching.

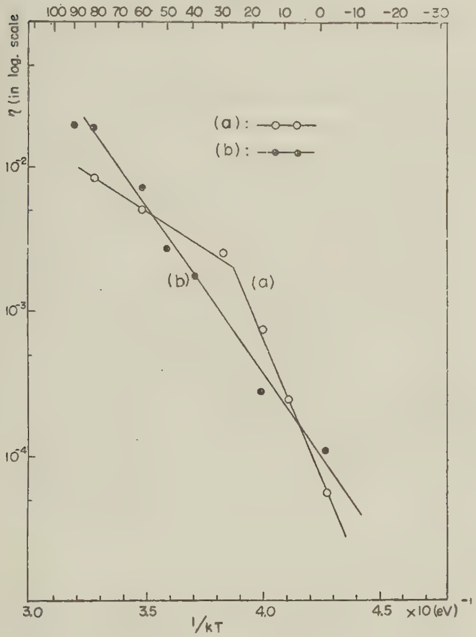

Fig. 7. log η plotted against $1/kT$.
For curve (a): the bleaching of the M band was carried out at the same temperature as that at which the band was developed.
For curve (b): the M band was developed at 12°C in all specimens and bleached at various temperatures.

3.3 *The thermal reorientation of the M center*

The thermal reorientation of the M center suggested in §3.2 was confirmed by the variations in $A^{M}_{[011]}$ and $A^{M}_{[0\bar{1}1]}$ when the sample was kept in the dark after dichroism had been induced in the M band at high temperature. Since photons were completely avoided, the changes in $A^{M}_{[011]}$ and $A^{M}_{[0\bar{1}1]}$ were attributed to the reorientation of the dipole matrix elements of M centers in the ground state caused by the ionic motions. Fig. 8 shows the curve of $A^{M}_{[011]}$, $A^{M}_{[0\bar{1}1]}$ and log δ^{M} versus the time of keeping in the dark at 87°C after dichroism was induced in the M band with [011]-polarized M light at the same temperature. The decrease in $A^{M}_{[0\bar{1}1]}$ was smaller than the increase in $A^{M}_{[011]}$. Under

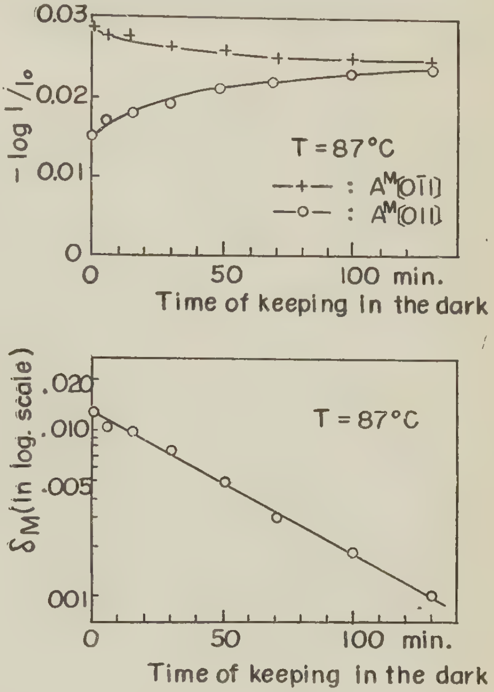

Fig. 8. Changes in $A^{M}{}_{[011]}$, $A^{M}{}_{[0\bar{1}1]}$ and log δ^{M} when the samples were kept in the dark at 87°C.

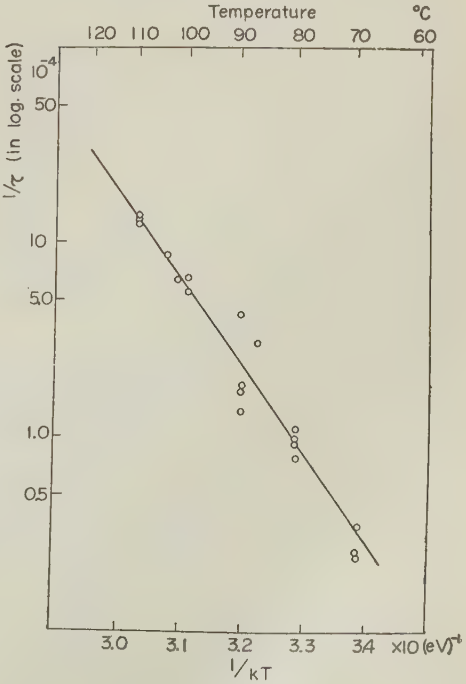

Fig. 9. $1/\tau$ plotted against $1/kT$.

the assumption that the dipole matrix elements of M centers are oriented along the face diagonals and their thermal reorientation occurrs with the same probability $1/\tau\,\mathrm{sec}^{-1}$ for the possible six orientations, it is calculated that δ^{M} varies as

$$\delta^{M}=\mathrm{const.}\times\exp(-6/5\cdot t/\tau)\ .$$

This is consistent with the result shown in Fig. 8. From Fig. 8 $1/\tau$ at 87°C is obtained. From the same measurements at various temperatures, the curve which shows the relation of $\log(1/\tau)$ against $1/kT$ was obtained as shown in Fig. 9. The measured values of τ differed slightly according to the thermal treatment of the sample. The data shown in Fig. 9 were obtained with the specimens cleaved at room temperature, and warmed slowly up to the temperature at which the measurment was done. As is well known, $1/\tau$ varies as $1/\tau=B_0\exp(-W/kT)$ and this relation is satisfied in Fig. 9. The gradient of the curve gives the activation energy W, for the reorientation of the M center in the ground state. We obtained the following values from the figure:

$$W=1.0\,\mathrm{ev},\quad B_0=3.5\cdot10^{10}\,\mathrm{sec}^{-1}.$$

§ 4. Discussion and Conclusions

An assumption to explain the dischroism exhibited by the F band is that the another absorption band of the M center is hidden under the F band. The fact that the preferential bleaching of the R band induces dichroism in both the F and the M bands may hardly be explained by such a simple assumption as described above. The dichroism in the F band seems to come partly from some interactions such as distortion of the crystalline field around the color center through the coexistence of F, M and R centers. The reversal of the sign of dichroism caused by irradiation with polarized F light described in § 3.1. may indicate the existence of such interactions. In respect to this point, it should be noted that when the crystal containing F, M and R centers is illuminated with light in the F absorption band, the emission of the R center and the M center is enhanced⁵⁾.

Now, let us consider the temperature dependence of the variations in $A^{M}_{[0\bar{1}1]}$, in the preferential bleaching with [011]-polarized M light. We assume here that the dipole matrix element of the M center is oriented along the face diagonal of the crystal. In § 3.2, it is described that the number of the M centers whose dipole matrix elements lie in the [0$\bar{1}$1] direction increases in some cases by irradiation with [011] polarized M light. The reason for this is as follows: In these cases, $A^{M}_{[0\bar{1}1]}$ does not decrease in spite of the fact that the number of the M centers which contribute to $A^{M}_{[0\bar{1}1]}$ and have the dipole matrix elements in the directions other than [0$\bar{1}$1] should be decreased by irradiation with [011]-polarized M light. It may be considered that there are two possibilities to cause the increase of the number of M centers of which dipole matrix elements are normal to the polarization direction of bleaching light, a) reorientation of the M centers in the excited state as a result of ionic motions, b) electron trapping by vacancy clusters to form new M centers. As described in § 3.2, the preferential bleaching of the M band was strongly dependent on the thermal history of the specimens in respect to the M center formation, and, moreover, the density of vacancy cluster may be influenced by the thermal history, too. Therefore, the electron trapping process will be predominant among two possibilities.

Another contribution to $A^{M}_{[0\bar{1}1]}$ in the preferential bleaching with [011]-polarized M light is the thermal reorientation of M centers in the ground state. This occurs at high temperature and decrease the number of the M center with dipole matrix elements in the [0$\bar{1}$1]. Thus, the temperature dependence of the preferential bleaching of the M band may be understood as the competing process of (a), (b) and (c) given below:

(a) Electron trapping of the vacancy clusters to form M centers,
(b) Ioninzation of M centers,
(c) Thermal reorientation of M centers in the ground state.

The processes (b) and (c) are predominant at high temperature and not so frequent to occur at lower temperature, in consistence with the observations.

Flow of a Visco-Elastic Liquid near a Stagnation Point

By S. K. SHARMA

Department of Mathematics,
Indian Institute of Technology, Kharagpur

(Received April 28, 1959)

The problem of viscous flow near a stagnation point has been exactly solved by Froessling.[1]

In this paper equations of motion for the flow of a visco-elastic liquid near a stagnation point, occurring when a stream of such a liquid impinges on a wall at right angles to it and flows away radially in all directions, have been set up and solved by the Karman-Pohlhausen method. The effect of elasticity is found to depend upon a non-dimensional parameter $\tau^*=\tau a$ (where τ is the flow parameter or the relaxation time constant and a is a constant of dimensions T^{-1} depending on the velocity in potential flow). Behaviour for small values of this parameter has been studied. It is observed that the boundary layer thickness and the shearing at the wall increase with an increase in τ^*, while the normal stress at the wall is independent of both elasticity and viscosity. The stream lines get closer to the wall with an increase in the parameter.

§ 1. Introduction

A number of approaches have been tried to investigate the rheological behaviour of the so-called Visco-elastic fluids, i.e. fluids which when sheared demonstrate elastic properties besides viscous ones. Oldroyd, Strawbridge and Toms[2] have shown that the behaviour of dilute (ca. 3 percent) solution of highly polymerized methyl methacrylate in an organic liquid in a simple shearing motion can be represented approximately, at sufficiently small rates of shear, by the stress-strain law proposed by Jeffreys[3]

$$S^i{}_j+\tau\dot{S}^i{}_j=2\mu(d^i{}_j+\lambda\dot{d}^i{}_j)\,, \qquad (1.1)$$

where $S^i{}_j$ is the deviatoric stress tensor, τ and λ are the relaxation and retardation time constants respectively of the fluid, and μ is the coefficient of viscosity as in Newtonian flow, $d^i{}_j$ is the rate of deformation tensor and dot denotes the rate of change.

In this paper we have discussed the problem of flow of a visco-elastic liquid near a stagnation point when only relaxation phenomenon of the liquid is considered and the stress strain law is taken in the form

$$S^i{}_j+\tau\tilde{S}^i{}_j=2\mu\, d^i{}_j\,, \qquad (1.2)$$

where $\tilde{S}^i{}_j$ denotes the rate of stress and is equal to the expression[4]

$$\frac{\partial}{\partial t}S^i{}_j+S^i{}_{j,k}\,v^k-S^i{}_k\,v^j{}_{,k}-S^k{}_j\,v^i{}_{,k}+S^i{}_j\,v^k{}_{,k}.$$

Some interesting results are obtained.

§ 2. Equations of Motion

The stress-strain relations given by (1.2), when transformed into cylindrical system of coordinates, take the form

$$t^{r}_{r}+\tau\left[\frac{\partial t^{r}_{r}}{\partial t}+u\frac{\partial t^{r}_{r}}{\partial r}+\frac{v}{r}\frac{\partial t^{r}_{r}}{\partial \theta}+w\frac{\partial t^{r}_{r}}{\partial z}-2\left(t^{r}_{r}\frac{\partial u}{\partial r}+\frac{t^{r}_{\theta}}{r}\frac{\partial u}{\partial \theta}+t^{r}_{z}\frac{\partial u}{\partial z}\right)\right]=2\mu\frac{\partial u}{\partial r}, \tag{2.1}$$

$$t^{r}_{\theta}+\tau\left[\frac{\partial t^{r}_{\theta}}{\partial t}+u\frac{\partial t^{r}_{\theta}}{\partial r}+\frac{v}{r}\frac{\partial t^{r}_{\theta}}{\partial \theta}+w\frac{\partial t^{r}_{\theta}}{\partial z}-t^{r}_{r}\left(\frac{\partial v}{\partial r}-\frac{v}{r}\right)-t^{r}_{\theta}\left(\frac{\partial u}{\partial r}+\frac{1}{r}\frac{\partial v}{\partial \theta}+\frac{u}{r}\right)-t^{r}_{z}\frac{\partial v}{\partial z}-\frac{t^{\theta}_{\theta}}{r}\frac{\partial u}{\partial \theta}-t^{\theta}_{z}\frac{\partial u}{\partial z}\right]=\mu\left(\frac{1}{r}\frac{\partial u}{\partial \theta}+\frac{\partial v}{\partial r}-\frac{v}{r}\right), \tag{2.2}$$

$$t^{r}_{z}+\tau\left[\frac{\partial t^{r}_{z}}{\partial t}+u\frac{\partial t^{r}_{z}}{\partial r}+\frac{v}{r}\frac{\partial t^{r}_{z}}{\partial \theta}+w\frac{\partial t^{r}_{z}}{\partial z}-t^{r}_{r}\frac{\partial w}{\partial r}-t^{z}_{z}\frac{\partial u}{\partial z}-\frac{t^{r}_{\theta}}{r}\frac{\partial w}{\partial \theta}-t^{r}_{z}\left(\frac{\partial w}{\partial z}+\frac{\partial u}{\partial r}\right)-\frac{t^{z}_{\theta}}{r}\frac{\partial u}{\partial \theta}\right]=\mu\left(\frac{\partial w}{\partial r}+\frac{\partial u}{\partial z}\right), \tag{2.3}$$

$$t^{\theta}_{\theta}+\tau\left[\frac{\partial t^{\theta}_{\theta}}{\partial t}+u\frac{\partial t^{\theta}_{\theta}}{\partial r}+\frac{v}{r}\frac{\partial t^{\theta}_{\theta}}{\partial \theta}+w\frac{\partial t^{\theta}_{\theta}}{\partial z}-2t^{r}_{\theta}\left(\frac{\partial v}{\partial r}-\frac{v}{r}\right)-2t^{\theta}_{\theta}\left(\frac{1}{r}\frac{\partial v}{\partial \theta}+\frac{u}{r}\right)-2t^{\theta}_{z}\frac{\partial v}{\partial z}\right]=2\mu\left(\frac{1}{r}\frac{\partial v}{\partial \theta}+\frac{u}{r}\right), \tag{2.4}$$

$$t^{\theta}_{z}+\tau\left[\frac{\partial t^{\theta}_{z}}{\partial t}+u\frac{\partial t^{\theta}_{z}}{\partial r}+\frac{v}{r}\frac{\partial t^{\theta}_{z}}{\partial \theta}+w\frac{\partial t^{\theta}_{z}}{\partial z}-t^{r}_{\theta}\frac{\partial w}{\partial r}-\frac{t^{\theta}_{\theta}}{r}\frac{\partial w}{\partial \theta}-t^{z}_{z}\frac{\partial v}{\partial z}-t^{\theta}_{z}\left(\frac{\partial w}{\partial z}+\frac{1}{r}\frac{\partial v}{\partial \theta}+\frac{u}{r}\right)-t^{r}_{z}\left(\frac{\partial v}{\partial r}-\frac{v}{r}\right)\right]=\mu\left(\frac{\partial v}{\partial z}+\frac{1}{r}\frac{\partial w}{\partial \theta}\right), \tag{2.5}$$

$$t^{z}_{z}+\tau\left[\frac{\partial t^{z}_{z}}{\partial t}+u\frac{\partial t^{z}_{z}}{\partial r}+\frac{v}{r}\frac{\partial t^{z}_{z}}{\partial \theta}+w\frac{\partial t^{z}_{z}}{\partial z}-2\left(t^{z}_{z}\frac{\partial w}{\partial z}+t^{r}_{z}\frac{\partial w}{\partial r}+\frac{t^{\theta}_{z}}{r}\frac{\partial w}{\partial \theta}\right)\right]=2\mu\frac{\partial w}{\partial z}. \tag{2.6}$$

Momentum equations are

$$\rho\left[\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial r}+\frac{v}{r}\frac{\partial u}{\partial \theta}+w\frac{\partial u}{\partial z}-\frac{v^2}{r}\right]=-\frac{\partial p}{\partial r}+\frac{\partial t^{r}_{r}}{\partial r}+\frac{1}{r}\frac{\partial t^{r}_{\theta}}{\partial \theta}+\frac{\partial t^{r}_{z}}{\partial z}+\frac{t^{r}_{r}-t^{\theta}_{\theta}}{r}, \tag{2.7}$$

$$\rho\left[\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial r}+\frac{v}{r}\frac{\partial v}{\partial \theta}+w\frac{\partial v}{\partial z}+\frac{uv}{r}\right]=-\frac{1}{r}\frac{\partial p}{\partial \theta}+\frac{\partial t^{r}_{\theta}}{\partial r}+\frac{1}{r}\frac{\partial t^{\theta}_{\theta}}{\partial \theta}+\frac{\partial t^{\theta}_{z}}{\partial z}+\frac{2t^{r}_{\theta}}{r}, \tag{2.8}$$

$$\rho\left[\frac{\partial w}{\partial t}+u\frac{\partial w}{\partial r}+\frac{v}{r}\frac{\partial w}{\partial \theta}+w\frac{\partial w}{\partial z}\right]=-\frac{\partial p}{\partial z}+\frac{\partial t^{r}_{z}}{\partial r}+\frac{1}{r}\frac{\partial t^{\theta}_{z}}{\partial \theta}+\frac{\partial t^{z}_{z}}{\partial z}+\frac{t^{r}_{z}}{r}, \tag{2.9}$$

and the equation of continuity is

$$\frac{\partial u}{\partial r}+\frac{u}{r}+\frac{1}{r}\frac{\partial v}{\partial \theta}+\frac{\partial w}{\partial z}=0. \tag{2.10}$$

§ 3. Solution of Equations

The flow under consideration is along the negative z-axis and is caused when a stream of visco-elastic liquid impinges perpendicularly on a wall $z=0$, and flows away radially in all directions. The stagnation point is at the origin.

Taking U and W to be the velocities in frictionless case, we have

$$U=ar,\quad W=-2az.$$

If stagnation pressure is denoted by p_0, the pressure in the ideal flow is given by

$$p-p_0=\frac{\rho}{2}(U^2+W^2)=\frac{\rho}{2}a^2(r^2+4z^2).$$

The frictionless case suggests that the velocity field in the boundary layer region may be taken to be

$$u=rf'(z),\quad w=-2f(z). \tag{3.1}$$

Substituting from (3.1) into equations (2.1) to (2.6), we get

$$t^{r}_{r}+\tau\left[rf'\frac{\partial t^{r}_{r}}{\partial r}-2f\frac{\partial t^{r}_{r}}{\partial z}-2(f't^{r}_{r}+rf''t^{r}_{z})\right]=2\mu f', \tag{3.2}$$

$$t^{r}_{\theta}+\tau\left[rf'\frac{\partial t^{r}_{z}}{\partial r}-2f'\,t^{r}_{\theta}-rf''\,t^{\theta}_{z}\right]=0, \tag{3.3}$$

$$t^{r}_{z}+\tau\left[rf'\frac{\partial t^{r}_{z}}{\partial r}-2f\frac{\partial t^{r}_{z}}{\partial z}-rf''\,t^{z}_{z}+f'\,t^{r}_{z}\right]=\mu rf'', \tag{3.4}$$

$$t^{\theta}_{\theta}+\tau\left[rf'\frac{\partial t^{\theta}_{\theta}}{\partial r}-2f\frac{\partial t^{\theta}_{\theta}}{\partial z}-2f'\,t^{\theta}_{\theta}\right]=2\mu f', \tag{3.5}$$

$$t^{\theta}_{z}+\tau\left[rf'\frac{\partial t^{\theta}_{z}}{\partial r}-2f\frac{\partial t^{\theta}_{z}}{\partial \theta}+f'\,t^{\theta}_{z}\right]=0, \tag{3.6}$$

$$t^{z}_{z}+\tau\left[rf'\frac{\partial t^{z}_{z}}{\partial r}-2f\frac{\partial t^{z}_{z}}{\partial z}+4f'\,t^{z}_{z}\right]=-4\mu f'. \tag{3.7}$$

From equations (3.1) to (3.7) the values of the deviatoric stresses correct to the orders of $(\mu\tau)$ and $(\tau)^2$ are found to be

$$\left.\begin{aligned}
t^r{}_r&=2\mu[f'+\tau(2ff''+2f'^2+r^2f''^2)],\\
t^r{}_\theta&=0,\\
t^r{}_z&=\mu r[f''-\tau(6f'f''-2ff''')],\\
t^\theta{}_\theta&=2\mu[f'+2\tau(ff''+f'^2)],\\
t^\theta{}_z&=0,\\
t^z{}_z&=-4\mu[f'+2\tau(ff''-2f'^2)].
\end{aligned}\right\}\tag{3.8}$$

On substitution of these values the momentum equations (2.8) and (2.9) take the form

$$-\frac{1}{\rho}\frac{\partial p}{\partial r}=r[f'^2-2ff''-\nu f''' +\nu\tau(4f'f'''-2ff^{\mathrm{IV}})],\tag{3.9}$$

and

$$-\frac{1}{\rho}\frac{\partial p}{\partial z}=4ff'+2\nu f''+6\nu\tau(ff'''-3f'f''),\tag{3.10}$$

where a prime denotes differentiation with respect to z.

Applying the condition of integrability to equations (3.9) and (3.10) we get

$$\frac{\partial}{\partial z}[f'^2-2ff''-\nu f''+\nu\tau(4f'f'''-2ff^{\mathrm{IV}})]=0,\tag{3.11}$$

which on integration gives

$$2ff''-f'^2+\nu f''-\nu\tau(4f'f'''-2ff^{\mathrm{IV}})=c,\tag{3.12}$$

where c is an integration constant.

Boundary conditions are

$$f'(\delta^*)=a,\ f''(\delta^*)=0,$$

and

$$f'''(\delta^*)=\tau[4f'''(\delta^*)a-2f(\delta^*)f^{\mathrm{IV}}(\delta^*)],\tag{3.13}$$

where δ^* is the boundary layer thickness. Equation (3.12), on application of boundary condition (3.13), gives

$$c=-a^2.\tag{3.14}$$

From equation (3.9) and (3.12), we get

$$\frac{1}{\rho}\frac{\partial p}{\partial r}=cr$$

or

$$p=-\frac{a^2\rho}{2}(r^2+4F(z)),\tag{3.15}$$

where $F(z)$ is to be determined from equation (3.10).

Equation (3.12) can be rewritten as

$$(2ff''-f'^2+\nu f''')-\nu\tau(4f'f'''-2ff^{\mathrm{IV}})+a^2=0.\tag{3.12.1}$$

The boundary conditions are

$$\left.\begin{aligned}f=f'&=0\\ F&=0\end{aligned}\right\}\ \text{at}\ z=0,$$
$$f'=a\qquad \text{at}\ z=\delta^*.$$

The constants a^2 and ν can be removed from equation (3.12.1) by a similarity transformation

$$\eta=\sqrt{\frac{a}{\nu}}\frac{z}{\delta},\quad f(z)=\sqrt{a\nu}\ \phi(\eta,\delta),\tag{3.16}$$

where

$$\delta=\sqrt{\frac{a}{\nu}}\delta^*.$$

Effecting the transformation (3.16), equation (3.12.1) takes the form

$$\delta(2\delta\phi\phi''-\delta\phi'^2+\phi'''+\delta^3) -\tau^*(4\phi'\phi'''-2\phi\phi^{\mathrm{IV}})=0,\tag{3.12.2}$$

where primes denote differentiation with respect to η and $\tau^*=\tau a$ is a non-dimensional parameter.

Equation (3.12.2) shows that the elasticity effect depends on a non-dimensional parameter τ^*, $\tau^*=0$ giving the non-elastic viscous case.

Boundary condition in terms of ϕ are

$$\begin{aligned}&\phi(0)=0=\phi'(0),\\ &\phi'(1)=\delta,\ \phi''(1)=0,\ \phi'''(0)=-\delta^3.\end{aligned}\tag{3.17}$$

Proceeding now to solve equation (3.12.2) by Karman-Pohlhausen method, we assume a quartic profile

$$\phi(\eta)=a_0+a_1\eta+a_2\eta^2+a_3\eta^3+a_4\eta^4.\tag{3.18}$$

Applying the boundary conditions (3.17), we get

$$\phi(\eta)=\frac{\delta^3+6\delta}{8}\eta^2-\frac{\delta^3}{6}\eta^3-\frac{2\delta-\delta^3}{16}\eta^4.\tag{3.18.1}$$

Integrating equation (3.12.2) with respect to η between the limits 0 to 1, we have

$$\delta\left[2\delta(\phi\phi')^1{}_0-3\delta\int_0^1\phi'^2d\eta+(\phi'')^1{}_0+\delta^3\right] -\tau^*\left[6\int_0^1\phi'\phi'''d\eta-2(\phi\phi''')^1{}_0\right]=0.\tag{3.12.3}$$

Substituting the value of ϕ from (3.18.1) and putting $\delta^2=x$, equation (3.12.3) reduces to

$$3x^4+(44+119\tau^*)x^3-(912+1344\tau^*)x^2 +(2520+5796\tau^*)=0.\tag{3.12.4}$$

Equation (3.12.4) gives either $x=0$, which is not possible, or

$$3x^3+(44+119\tau^*)x^2-(912+1344\tau^*)x$$
$$+(2520+5796\tau^*)=0\,. \qquad (3.12.5)$$

When the non-dimensional parameter $\tau^*=0$, which gives the effect of elasticity as taken to be zero, (3.12.5) reduces to the corresponding equation in the non-elastic viscous case, viz.

$$3x^3+44x^2-912x+2520=0\,. \qquad (3.12.6)$$

This equation has two positive and one negative roots. Negative root is, however, not admissible as δ can not be imaginary. Out of the two positive roots 3.491151 and 8.894263, the latter is to be discarded as it gives rise to an absurdity in that it renders $\dfrac{u}{U}>1$ within the boundary layer.

The velocity profile corresponding to $\delta^2=3.491151$ is found to agree closely with that given by Froessling.

The roots of the equation (3.12.5) nearest to 3.491151 corresponding to different values of τ^* are given by the table below. The values of $\phi''(0)$ have also been tabulated.

Table I.

τ^*	δ^2	δ	$\phi''(0)$
0.000	3.491151	1.86846	4.43346
0.001	3.496308	1.86984	4.43914
0.002	3.501464	1.87122	4.44485
0.004	3.511764	1.87397	4.45619
0.006	3.523059	1.87699	4.46867
0.008	3.532347	1.87945	4.47889
0.010	3.542617	1.88218	4.49023
0.020	3.592688	1.89543	4.54557

The table shows that the boundary layer thickness as well as $\phi''(0)$ increase with an increase in τ^*.

Integrating equation (3.10), we get

$$a^2F=f^2+\nu f'+3\nu\tau\,(ff''-2f'^2)+D\,, \qquad (3.10.1)$$

where D is a constant of integration.

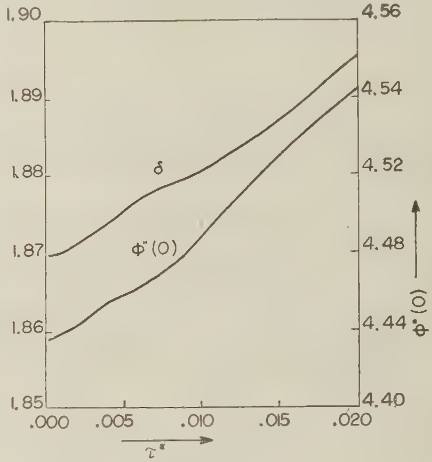

Fig. 1.

Applying the boundary conditions, $D=0$; or we get

$$a^2F=f^2+\nu f'+3\nu\tau\,(ff''-2f'^2). \qquad (3.10.2)$$

From (3.10.2) and (3.15), we get

$$p=-\frac{a^2\rho}{2}\left[r^2+\frac{4}{a^2}\{f^2+\nu f'\right.$$
$$\left.+3\nu\tau(ff''-2f'^2)\}\right]. \qquad (3.13)$$

The deviatoric normal stress component is

$$t^z_z=-4\mu\{f'+2\tau\,(ff''-2f'^2)\}\,. \qquad (3.14)$$

The value of the normal stress component at the wall, therefore, is

Table II.

η	$\tau^*=0.00$		$\tau^*=0.01$		$\tau^*=0.02$	
	ϕ	r	ϕ	r	ϕ	r
0.0	0.00000	∞	0.00000	∞	0.00000	∞
0.1	0.02110	6.8843	0.02136	6.8422	0.02162	6.8010
0.2	0.08026	3.5298	0.08120	3.5091	0.08213	3.4894
0.3	0.17158	2.4141	0.17353	2.4006	0.17544	2.3875
0.4	0.28958	1.8582	0.29274	1.8482	0.29583	1.8386
0.5	0.42921	1.5264	0.43371	1.5185	0.43811	1.5108
0.6	0.58582	1.3065	0.59172	1.3000	0.59750	1.2937
0.7	0.74517	1.1584	0.86093	1.0772	0.86996	1.0721
0.8	0.93248	1.0356	0.94222	1.0302	0.95076	1.0256
0.9	1.11735	0.9460	1.11423	0.9474	1.12360	0.9434
1.0	1.30381	0.8758	1.31528	0.8719	1.32650	0.8683

$$(T^z_z)_{z=0}=(t^z_z)_{z=0}-(p)_{z=0}$$
$$=\frac{\rho}{2}a^2r^2\,, \qquad (3.15)$$

which is independent of μ as well as τ.

The shearing at the wall is

$$(T^r_z)_{z=0}=(t^r_z)_{z=0}$$
$$=\mu r f''(0)$$
$$=\frac{\mu a^{3/2}}{\sqrt{\nu}}r\phi''(0)\,, \qquad (3.16)$$

which shows that shearing stress at the wall increases with τ^*.

Equation of stream line is

$$r^2\phi(\eta)=\text{constant}\,. \qquad (3.17)$$

Taking the constant to be unity, the stream lines have their equation as

$$r^2\phi(\eta)=1.$$

Table II gives the values of $\phi(\eta)$ and r for different values of η and τ^*. This table suggests that elasticity brings flow nearer to the wall. The pattern of flow is, however, the same as in Newtonian liquid.

§ 4. Conclusion

The results of this theoretical investigation may be summed up as follows:

1) The elastic effect in case of a single relaxation time visco-elastic model depends upon a non-dimensional parameter, an increase in the parameter causing an increase in the boundary layer thickness and also the shearing at the wall.

2) Normal stress at the wall is independent of elasticity as well as viscosity.

8) Stream lines get closer to the wall with an increase in the parameter.

The author is indebted to Prof. B. R. Seth for his guidance throughout this investigation.

The Flow of a Viscous Fluid past a Triangular Cylinder

By Mitutosi KAWAGUTI

Aeronautical Research Institute, University of Tokyo

(Received May 25, 1959)

The flow of a viscous fluid past an equilateral triangular cylinder has been studied using Imai's method of treating Oseen's approximation. The expression for the velocity in the flow field near the triangular cylinder is obtained correct to the order of R^2, and those for the frictional, pressure and total drag to the order of R. The drag of the triangular cylinder at high Reynolds numbers is estimated by use of Imai's new theory of drag and is compared with Asaka and Ôshima's experimental results.

§ 1. Introduction

It is well known that the steady two-dimensional flow of an incompressible viscous fluid past a fixed cylindrical obstacle at a small Reynolds number can be successfully dealt with on the basis of the Oseen approximation. However, investigations have hitherto been restricted to the cases of cylinders with rather simple cross-sectional shapes, such as circular and elliptic cylinders and a flat plate.

A few years ago, I. Imai put forward a

new method of solving Oseen's equations for arbitrary cylindrical obstacles,[4] which enables us to obtain the velocity distribution in the flow region near the cylinder and the lift and drag acting upon it in the form of power series in the Reynolds number R. Using this method, M. Hasegawa studied the flow past a thin symmetrical Joukowski aerofoil.[3]

In this paper, the flow past an equilateral triangular cylinder will be studied by use of Imai's method. The expression for the velocity in the region near the triangular cylinder is obtained correct to the order of R^2, the lowest order term being $O(1)$, and the expressions for the pressure, frictional and total drag to the order of R, the lowest order terms being $O(R^{-1})$. In §7, the drag at high Reynolds numbers are estimated according to Imai's new theory[4] by using our theoretical results at low Reynolds numbers, and compared with Asaka and Ôshima's experimental results at high Reynolds number.[1]

In the course of our study, it was found that the total drag remains invariant, within the accuracy of our approximation, when the cylinder is rotated by an angle π, whereas the pressure and frictional drags change their values in the second approximation i.e., $O(1)$. These results have been found to be valid for the cases of more general cross-sectional shapes. The discussion concerning this fact will be given in an accompanying paper.[8]

§2. Oseen's Equations of Motion and the Boundary Conditions.*

Oseen's approximate equations for the two-dimensional steady motion of an incompressible viscous fluid can be written as

$$U\frac{\partial u}{\partial x}+\frac{1}{\rho}\frac{\partial p}{\partial x}-\nu\Delta u=0\,, \tag{2.1}$$

$$U\frac{\partial v}{\partial x}+\frac{1}{\rho}\frac{\partial p}{\partial y}-\nu\Delta v=0\,, \tag{2.2}$$

where U is the velocity of uniform flow parallel to the x-axis, $\Delta=\partial^2/\partial x^2+\partial^2/\partial y^2$, (u, v) are the component velocities, p is the pressure, ρ the density, and ν the kinematic viscocity. The equation of continuity is satisfied by taking a stream function Ψ such that

$$u=\frac{\partial \Psi}{\partial y}\,,\quad v=-\frac{\partial \Psi}{\partial x}\,. \tag{2.3}$$

Eliminating p from (2.1) and (2.2), we have

$$\Delta\omega-2k\frac{\partial\omega}{\partial x}=0\,, \tag{2.4}$$

where ω is the vorticity defined as

$$\omega=\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}=-\Delta\Psi\,, \tag{2.5}$$

and $2k=U/\nu$.

Introducing complex variables

$$z=x+iy\,,\qquad \bar{z}=x-iy\,, \tag{2.6}$$

$$W=u-iv\,, \tag{2.7}$$

we obtain from (2.3)

$$W=2i\frac{\partial\Psi}{\partial z}\,, \tag{2.8}$$

and hence, by (2.5)

$$\frac{\partial W}{\partial \bar{z}}=2i\frac{\partial^2\Psi}{\partial z\partial\bar{z}}=\tfrac{1}{2}i\Delta\Psi=-\tfrac{1}{2}i\omega\,. \tag{2.9}$$

For the boundary conditions, we have

(a) $W\to U$, as $|z|\to\infty$, (2.10)

(b) $W\equiv 0$, on the surface of the cylinder, (2.11)

(c) ω and W are one-valued throughout the field of flow. (2.12)

§3. The General Expressions for ω and W

As is well known, the most general solution of (2.4) can be expressed as

$$\omega=\Re\sum_{n=0}^{\infty}C_n e^{kx}K_n(kr)e^{ni\theta}\,, \tag{3.1}$$

where (r, θ) are polar coordinates, K_n is the modified Bessel function and C_n's are complex constants. Here n must be integers and C_n should satisfy the relation

$$\Re\sum_{n=0}^{\infty}C_n=0\,, \tag{3.2}$$

in order that ω and W should be one-valued throughout the field of flow outside the cylinder (cf. (2.12)).

Substituting from (3.1) into (2.9) and integrating, we can find the general expression for W as

$$W=\frac{i}{2k}e^{kx}\Big\{A_1K_0(kr)+\sum_{n=1}^{\infty}(A_{n+1}e^{ni\theta}-\overline{A}^{n}e^{-ni\theta})K_n(kr)\Big\}+\frac{df}{dz}\,, \tag{3.3}$$

where

---

* As for the detail of this method, reference should be made to Imai's original paper.[4]

$$A_n=\sum_{i=n}^{\infty} C_i \qquad (n=1,2,\cdots), \tag{3.4}$$

and $f(z)$ is an arbitrary analytic function of z.

The arbitrary constants A_n as well as the analytic function $f(z)$ are to be determined from the appropriate boundary conditions.

§ 4. Transformation Function from Equilateral Triangle to Unit Circle

In this paper, we consider two cases of flow past an equilateral triangular cylinder:

a) the case where the forward stagnation point coincides with one of the vertices of the triangle (Fig. 1a),

and

b) the case where the forward stagnation point coincides with the middle point of a side of the triangle (Fig. 1b).

We shall refer to them as the case (a) and (b) respectively. It is to be noted that the case (b) will be obtained from the case (a) by rotating the cylinder by an angle π about an axis perpendicular to the plane of flow.

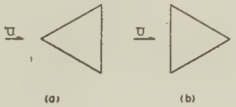

Fig. 1.

The transformation function from the equilateral triangle in the z-plane onto the unit circle in the Z-plane is given by

$$z=A\int_{-1}^{Z}(1+\varepsilon Z^{-3})^{2/3}dZ+B, \tag{4.1}$$

where A and B are constants which may be determined from the magnitude and the position of the triangle, and ε is 1 or -1 for the case (a) or (b) respectively.

Expanding the integrand of (4.1) in descending powers of Z and integrating, we have

$$z=Z-\tfrac{1}{3}\varepsilon Z^{-2}+\tfrac{1}{45}Z^{-5}-\tfrac{1}{162}\varepsilon Z^{-8}+\tfrac{7}{2673}Z^{-11}+\cdots, \tag{4.2}$$

where the constants have been determined by the conditions that centres of the triangle and the unit circle are the origins of the z- and Z-planes and that the coefficient of Z in (4.2) is unity. Thus the length of one side of the triangle becomes 2.371, but it does not mean any loss of generality of our solution.

Most of our calculation was performed by using very simple transformation function:

$$z=Z-\tfrac{1}{3}\varepsilon Z^{-2}, \tag{4.3}$$

but for the sake of checking, we have calculated the first approximation for the total drag by using more exact one:

$$z=Z-\tfrac{1}{3}\varepsilon Z^{-2}+\tfrac{1}{45}Z^{-5}-\tfrac{1}{162}\varepsilon Z^{-8}+\tfrac{7}{2673}Z^{-11}. \tag{4.4}$$

As is shown later, the transformation function (4.3) is sufficiently accurate for our purpose.

§ 5. Determination of A_n

For the convenience of our calculation, we make use of a function $g(z)$ defined as

$$\begin{aligned} g(z)=&\tfrac{1}{32}k^3A^1\{z^2\ln z-\tfrac{1}{2}z^2-(2S+1)z^2\}\\ &+\tfrac{1}{8}k^2\bar{A}_1z(\ln z-1)-\tfrac{1}{4}k\bar{A}_2\ln z\\ &+\tfrac{1}{4}k\sum_{n=3}^{\infty}(n-3)!\,\bar{A}_n(\tfrac{1}{2}kz)^{2-n}, \end{aligned} \tag{5.1}$$

where

$$S=\ln(2/k)-\gamma, \tag{5.2}$$

$\gamma=0.57721\cdots$ being Euler's constant.

In view of the form of W, it will be natural to suppose that A_n is in general $O(k^n)$, so that we put

$$\bar{A}_n=k_n(a_{n0}+ka_{n1}+k^2a_{n2}+\cdots), \tag{5.3a}$$

$$g(z)=k^3\{g_0(z)+kg_1(z)+k^2g_2(z)+\cdots\}, \tag{5.3b}$$

$$f(z)=k^{-1}\{f_0(z)+kf_1(z)+k^2f_2(z)+\cdots\}. \tag{5.3c}$$

Inserting (5.3) into (3.3), and expanding Bessel functions in increasing powers of k and equating to zero coefficients of powers of k in order to satisfy the boundary condition (2.11), we have a series of equations:

$$f_0'(z)=4ig_0''(z), \tag{5.4}$$

$$f_1'(z)=\tfrac{1}{2}(z+\bar{z})f_0'(z)+4ig_1''(z)+2i\bar{g}_0'(\bar{z}), \tag{5.5}$$

$$\begin{aligned} f_2'(z)=&\tfrac{1}{2}(z+\bar{z})f_1'(z)-\tfrac{1}{8}(z+\bar{z})^2f_0'(z)\\ &+i\{4g_2''(z)+2\bar{g}_1'(\bar{z})+\bar{z}g_0'(z)\}, \end{aligned} \tag{5.6}$$

$$\begin{aligned} f_3'(z)=&\tfrac{1}{2}(z+\bar{z})f_2'(z)-\tfrac{1}{8}(z+\bar{z})^2f_1'(z)\\ &+\tfrac{1}{48}(z+\bar{z})^3f_0'(z)+i\{4g_3''(z)+2\bar{g}_2'(\bar{z})\\ &+\bar{z}g_1'(z)+\tfrac{1}{2}z\bar{g}_0(\bar{z})-\tfrac{1}{8}\bar{a}_{20}z(\ln z-2S-1)\}, \end{aligned} \tag{5.7*}$$

on the profile.

---

* In Reference (4), there were misprints: the terms $(1/16)(z+\bar{z})^3f_0'(z)$ in Eqs. (5.6) and (8.4) should be read as $(1/48)(z+\bar{z})^3f_0'(z)$.

Using the transformation function (4.3), we can map the region outside the triangle onto the region outside a unit circle ($Z\bar{Z}=1$) in the Z-plane. Thus we can consider the equations (5.4)–(5.7) on the unit circle in the Z-plane.

On the other hand, it is known from Imai's investigation[5] that the exact solution of the Navier-Stokes equations for the viscous flow past an arbitrary cylinder has in general the asymptotic expression

$$f(z)=Uz+\frac{m+i\Gamma}{2\pi}\ln z-i\frac{k^{1/2}m^2}{4\pi^{1/2}U}\frac{1}{z^{1/2}}+O\left(\frac{1}{z}\right), \tag{5.8}$$

and that the drag and lift of the cylinder are given by

$$X=\rho Um, \qquad Y=\rho U\Gamma. \tag{5.9}$$

It may be noted that the third term on the right-hand side of (5.8) does not appear in the Oseen approximation.

§ 5.1 The First Approximation

In view of the above considerations, we can determine the first approximations: a_{10}, a_{20}, $f_0'(z)$, and $g_0'(z)$, from (5.4) and (5.5), as:

$$a_{10}=-\frac{18iU}{4+9S}, \tag{5.10}$$

$$a_{20}/a_{10}=\varepsilon/6, \tag{5.11}$$

$$f_0'(z)/a_{10}=\frac{i}{2}\frac{Z(3Z+\varepsilon)}{(3Z^3+2\varepsilon)}, \tag{5.12}$$

$$g_0'(z)/a_{10}=\tfrac{1}{8}\ln Z-\tfrac{1}{24}(\varepsilon/Z). \tag{5.13}$$

Using the more exact transformation function (4.4), we have

$$a_{10}=-\frac{2iU}{0.4357+S}. \tag{5.14}$$

for the value of a_{10}, instead of (5.10).

§ 5.2 The Second Approximations

We can determine the second approximations from (5.6) as

$$a_{11}/a_{10}=-(1/6)\varepsilon, \tag{5.15}$$

$$a_{21}/a_{10}=-(11+36S)/72, \tag{5.16}$$

$$\begin{aligned} f_1'(z)/a_{10}=&\frac{i}{18}(4+9S)+\frac{i}{48}\frac{\varepsilon}{Z}\\ &-\frac{i}{144}\frac{\{9\varepsilon Z^2-(66-216S)Z+32\varepsilon\}}{(3Z^3+2\varepsilon)}, \end{aligned} \tag{5.17}$$

$$\begin{aligned} g_1'(z)/a_{10}=&-\frac{1}{16}\left(Z-\frac{\varepsilon}{3Z^2}\right)(\ln Z-2S-1)\\ &-\frac{1}{48}\varepsilon\ln Z+\frac{11+36S}{288}\frac{1}{Z}\\ &+\frac{19}{864}\frac{\varepsilon}{Z^2}-\frac{1}{288}\frac{1}{Z^3}. \end{aligned} \tag{5.18}$$

---

§ 5.3 The Third Approximations

$$a_{12}/a_{10}=-\frac{1597-2187S}{1944(4+9S)}, \tag{5.19}$$

$$a_{22}/a_{10}=-\frac{109-829S-972S^2}{1296(4+9S)}\varepsilon, \tag{5.20}$$

$$\begin{aligned} f_2'(z)/a_{10}=&-\frac{i}{288}\frac{19-36S}{Z}+\frac{17}{1296}\frac{i\varepsilon}{Z^2}-\frac{i}{864Z^3}\\ &-i\frac{(3518+8019S+26244S^2)Z^2+(3870+4854S)\varepsilon Z-(3076+6057S-1944S^2)}{2592(4+9S)(3Z^3+2\varepsilon)}, \end{aligned} \tag{5.21}$$

$$\begin{aligned} g_2'(z)/a_{10}=&\frac{\varepsilon}{288}\left(3Z-\frac{\varepsilon}{Z^2}\right)(\ln Z-2S-1)-\frac{1597-2187S}{15552(4+9S)}\ln Z\\ &+\frac{109-829S-972S^2}{5184(4+9S)}\frac{\varepsilon}{Z}-\frac{407+1080S}{31104}\frac{1}{Z^2}-\frac{\varepsilon}{1728Z^3}-\frac{17+27S}{7776Z^4}-\frac{\varepsilon}{5184Z^5}. \end{aligned} \tag{5.22}$$

§ 6. Velocity and Drag

The complex velocity can be determined by (cf. ref. 4)

$$W=e^{kx}\sum_{n=0}^{\infty}k^n\{F_{n+1}(z)-G_n(z,\bar{z})\}, \tag{6.1}$$

where

$$F_n(z)=f_n'(z)-4ig_n''(z) \qquad (n=1, 2), \tag{6.2a}$$

$$F_3(z)=f_3'(z)-4ig_3''(z)+(i/8)\bar{a}_{20}z(\ln z-2S-1)\,, \tag{6.2b}$$

and

$$G_0(z)=\tfrac{1}{2}(z+\bar{z})f_0'(z)+2i\bar{g}_0'(\bar{z})\,, \tag{6.3a}$$

$$G_1(z)=\tfrac{1}{2}(z+\bar{z})f_1'(z)-\tfrac{1}{8}(z+\bar{z})^2f_0'(z)+2i\bar{g}_1'(\bar{z})+i\bar{z}g_0'(z)\,, \tag{6.3b}$$

$$\begin{aligned}G_2(z)=&\tfrac{1}{2}(z+\bar{z})f_2'(z)-\tfrac{1}{8}(z+\bar{z})^2f_1'(z)+\tfrac{1}{48}(z+\bar{z})^3f_0'(z)\\&+2i\bar{g}_2'(\bar{z})+i\bar{z}g_1'(z)+\tfrac{1}{2}iz\bar{g}_0(\bar{z})\,.\end{aligned} \tag{6.3c}$$

The total drag can be computed from (5.12), (5.17), and (5.21) using the above-mentioned relations (5.8) and (5.9):

$$D=\frac{18\pi U^2\rho}{k(4+9S)}\left\{1-k^2\frac{2785+4374S+8748S^2}{1944(4+9S)}+O(k^3)\right\}. \tag{6.4}$$

If we choose the length of a side of the triangle L as the characteristic length, and define the Reynolds number as $R=LU/\nu$, we have a formula for the total drag coefficient:

$$C_D=\frac{D}{\frac{1}{2}\rho U^2L}\frac{72\pi}{R(4+9S)}\left\{1-\left(\frac{R}{2L_0}\right)^2\frac{2785+4374S+8748S^2}{1944(4+9S)}+O(R^3)\right\}, \tag{6.5}$$

where

$$L_0=2.371\,, \tag{6.6}$$

$$S=1.672-\ln R\,. \tag{6.7}$$

The frictional drag D_f can be calculated by use of the formula:

$$D_f=-\eta\oint\left(\frac{\partial V_s}{\partial n}\right)\sin\alpha ds\,, \tag{6.8}$$

where the integration must be carried out over the entire surface, and (s, n) are the curvilinear orthogonal coordinates, $n=0$ corresponding to the surface, and where the positive directions of s and n are chosen as shown in Fig. 2, V_s is the component of the velocity in the positive direction of s, η the viscocity, and α is the angle between n and x-axis (cf. Fig. 2).

Performing the integration in (6.8), we have the frictional drag coefficient as

$$\begin{aligned}C_{Df}=&\frac{72\pi}{R(4+9S)}\\&\times\left[0.3889+\frac{\varepsilon R}{2L_0}(-0.1019+0.3333S)\right.\\&+\left(\frac{R}{2L_0}\right)^2\left\{0.0236-0.2500S-\frac{0.5139}{4+9S}\right\}\\&\left.+O(R^3)\right].\end{aligned} \tag{6.9}$$

The pressure drag coefficient can be easily obtained as the difference of the total and the frictional drag.

The drag coefficients thus obtained are given in Fig. 3, where the first approximation to the total drag coefficient obtained by using the transformation function (4.4) is also given to show the sufficient accuracy of the very simple transformation (4.3).

It is to be noted that the total drag for the cases (a) and (b) are the same to the

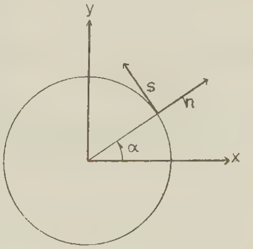

Fig. 2.

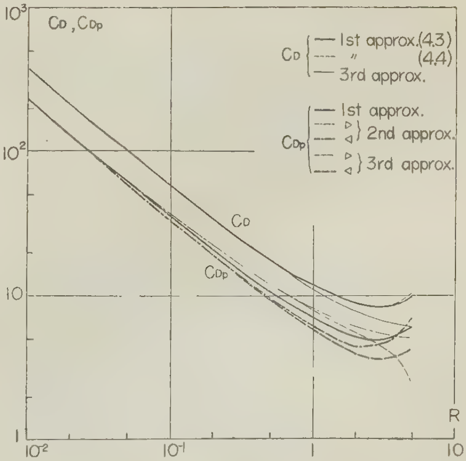

Fig. 3.

order of our approximation $O(R)$, although the pressure and frictional drags separately are not the same for the two cases to the order $O(1)$. This fact seems to be true also for cylinders of more general shape. Such a discussion will be given in an accompanying paper.[8)]

In view of the behaviour of the curves in Fig. 3, we may take

(i) $R \leq 5$ for C_D,

(ii) $R \leq 2$ for C_{Df},

as the Reynolds number ranges for which the formulae (6.5) and (6.9) are valid.

It is also to be noted that the ratio of the frictional drag to the total drag C_{Df}/C_D is not constant but a function of Reynolds number, although the ratios are known to be constant for the cases of circular and elliptic cylinders.[11),12)] (cf. Fig. 4).

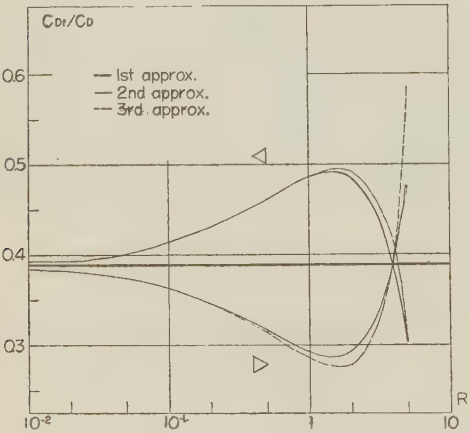

Fig. 4.

§ 7. Imai's New Theory of Drag

Recently I. Imai has proposed a new theory for the drag of a two-dimensional obstacle in a laminar flow,[6)] according to which the total drag coefficient at an arbitrary (but not so small) Reynolds number R is give by

$$C_D^{1/2} = C_{D\infty}^{1/2} + \beta R^{-1/2}, \tag{7.1}$$

where $C_{D\infty}$ is the limiting value of C_D for the same obstacle when $R \to \infty$, which may be calculated on the basis of Kirchhoff's free streamline theory, and β is a constant which depends on the shape of the obstacle.

In the case of a circular cylinder, Imai has shown that (7.1) is sufficiently accurate even for a rather low Reynolds number ($R=4$), using Brodetsky's results by the free streamline theory,[2)] the author's[7)] and A. Thom's[10)] numerical results, and Tomotika and Aoi's results[11)] by Oseen's approximation.

As for the case of a triangular cylinder, we know the results by the free streamline theory (case (a) corresponding to the flow past a flat plate, and case (b) to the flow past a bent lamina),[9)] although we have no numerical solution in an intermediate Reynolds number range. Thus, using our results by Oseen's approximation at Reynolds number of 3, we have the formulae:

$$\text{case (a)} \quad C_D^{1/2} = 0.699 + 3.279 R^{-1/2}, \tag{7.2}$$

$$\text{case (b)} \quad C_D^{1/2} = 0.938 + 2.865 R^{-1/2}. \tag{7.3}$$

Imai also proposed a formula[6)] for the drag of a two-dimensional obstacle in a turbulent flow, according to which the pressure drag coefficient is given by

$$C_{Dp}^{1/2} = C_{D\infty} + \beta^* R^{*-1/2}, \tag{7.4}$$

where R^* is the so-called effective Reynolds number for which Imai suggested the value of 30~50, and β^* is another constant.

If we determine the value of β^* from the value of the pressure drag coefficient at Reynolds numbr of 2, we have

$$\text{case (a):} \quad C_{Dp}^{1/2} = 0.699 + 1.998 R^{*-1/2}, \tag{7.5}$$

$$\text{case (b):} \quad C_{Dp}^{1/2} = 0.938 + 2.380 R^{*-1/2}, \tag{7.6}$$

for the pressure drag of the triangular cylinder.

On the other hand, Asaka and Ôshima[1)] studied experimentally the flow past a triangular cylinder at Reynolds number of $3\sim5\times10^4$, and obtained the values of the pressure drag coefficients: $C_{Dp}=1.34$ for case (a), and $C_{Dp}=1.773$ for case (b). Using these values, we can determine the effective Reynolds numbers R^* as: $R^*=16.4$ for case (a), and $R^*=26.3$ for case (b). The effective Reynolds number thus obtained are rather low compared with those for a circular cylinder. It seems that the discrepancy may be mainly due to the fact that we were compelled to use the results at very low Reynolds number ($R=2$), in order to determine the value of β^*.

§ 8. Conclusion

In this paper, the flow of a viscous fluid past an equilateral triangular cylinder has been studied using Imai's method of treating Oseen's approximation. The expression for the velocity in the flow field near the triangular cylinder was obtained correct to the order of R^2, and those for the frictional pressure and total drag to the order of R. The drag of the triangular cylinder at high Reynolds numbers was estimated by use of Imai's new theory of drag and was compared with Asaka and Ôshima's experimental, results. In the course of the study, it has been found that there exists a very simple relation between the flow past a triangular cylinder and that past the cylinder which can be obtained by rotating the original one by an angle π, such that total drag is not changed by the rotation within the order of our approximation.

Acknowledgements

In conclusion, I wish to express my hearty gratitude to Professor Isao Imai for his discussions and kind inspection of the manuscript, and to Professor Saburô Asaka who kindly showed me unpublished data.

Reversal Flow Theorem concerning Oseen's Approximation

By Mitutosi KAWAGUTI

Aeronautical Research Institute, University of Tokyo

(Received May 25, 1959)

We sought for the simple relations which exist between the two-dimensional flow of a viscous fluid past a cylindrical obstacle and the flow past the same obstacle rotated by an angle π about its axis, within the accuracy of Oseen's approximation. It is shown that the forces acting upon the cylinder do not change by the rotation of the cylinder, as far as the terms of order $O(R^{-1})$ are concerned. Further, for the special cases of symmetrical obstacles which experience no lift, it is shown that the total drags for the original and the rotated bodies coincide with each other within the accuracy of $O(R)$.

§ 1. Introduction

In a preceding paper, the author studied the flow past an equilateral triangular cylinder by Oseen's approximation.[1] In the course of the study, it was found that there exists a very simple relation between the flow past a triangular cylinder and that past a cylinder which can be obtained by rotating the original one by an angle π about its axis.

It occurred to the author that there may hold some simple relations between a flow past an obstacle and the flow past the same obstacle rotated by an angle π for the cases of cylinders of more general shape.

In this paper, we shall seek for such relations within the accuracy of Oseen's approximation.

§ 2. First Approximation

Since we shall use the same method and procedure as in the preceding paper,[1] we shall omit the detail of procedure and only show the results. We shall refer to the preceding paper as I.

We shall assume that the analytic function which transforms the profile of the cylindrical obstacle in the z-plane onto the unit circle in the Z-plane is given by

$$z=c_0Z+c_1Z^{-1}+\varepsilon c_2Z^{-2}+\cdots+\varepsilon^{n-1}c_nZ^{-n} \quad (2.1)$$

where ε is 1 for the original profile, and -1 for the rotated profile. In general, c_n may be complex numbers, but we may assume $|c_0|=1$ without loss of generality.

Proceeding as in I, we have a series of n equations for $a_{10}, a_{20}\cdots, a_{n0}$:

$$\left.\begin{array}{l} -U-\frac{i}{2}\bar{a}_{10}S+ia_{10}P+\cdots+i\varepsilon^{n-1}a_{n0}P=0 \\ \varepsilon a_{10}P+\cdots+\varepsilon^{n-1}a_{n-1,0}P+\bar{a}_{20}P=0 \\ \cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot \\ \varepsilon^{n-1}a_{10}P+\varepsilon^{n-1}a_{10}P+\cdots+a_{n0}=0 \end{array}\right\} \quad (2.2)$$

where U is the undisturbed velocity, a_{ij} is the coefficient of k^{i+j} in the expression of $\bar{A}_i$ (I. 5.3 a), and P stands for a certain function of c_i's independent of ε.

Eq. (2.2) can be regarded as a system of simultaneous equations for the unknown (a_{10}, $\varepsilon a_{20}, \cdots, \varepsilon^{n-1}a_{n0}$) whose coefficients are independent of ε. Therefore, $a_{10}, \varepsilon a_{20}, \cdots, \varepsilon^{n-1}a_{n0}$ are the same for the cases $\varepsilon=+1$ (original body) and $\varepsilon=-1$ (rotated body).

§ 3. The Second and Third Approximations

We shall now proceed to the higher approximations. In order to simplify the problem, let us assume that $c_0, \cdots, c_n$ in the transformation function (2.1) are real, so that the flow with which we are concerned is restricted to the flow past an obstacle that has symmetry about the x-axis. In this case, all the values of a_{ij} become purely imaginary.

Proceeding in the same way as in the first approximation, we can easily show that

(i) for the second approximation, εa_{11}, $\varepsilon^2 a_{21}, \cdots, \varepsilon^n a_{n1}$ have the same values for the original and the rotated cases.

(ii) for the third approximation, $a_{12}, \varepsilon a_{22}, \cdots, \varepsilon^{n-1}a_{n2}$, have the same values for the both cases.

Further we can guess from the process of our study that, in general, for the m-th approximation, the values of $\varepsilon^{m+1}a_{1\,m-1}, \cdots, \varepsilon^{m+n}a_{n,m-1}$ are the same for the both cases.

§ 4. The Drag and Lift

The drag and lift of a cylindrical obstacle submerged in a flow of a viscous fluid can be determined from the coefficient of $1/z$ in $f'(z)$ (cf. (I. 5.8), (I. 5.9)).

Now the first approximation of $f'(z)$ can be expressed as

$$f_0'(z)=\frac{i}{2}\frac{a_{10}}{z}+O\left(\frac{1}{z^2}\right) \quad (4.1)$$

Therefore, considering the results of § 2, we can say that, in the first approximation, the values of the drag and lift are the same for the original and the rotated bodies.

As a corollary of the theorem mentioned above, it can easily be shown that there acts no lift upon the cylinder whose cross-sectional shape has a symmetry about a line perpendicular to the direction of the undisturbed flow, as far as the first approximation in Oseen's approximate theory is concerned.

As for the higher approximations, we have restricted ourselves to the case of flow past an obstacle that has symmetry about the x-axis. Therefore, we are only concerned with the drag. Now we have

$$f_1'(z)=U+\frac{\varepsilon}{z}Q_1+\frac{i}{2}\frac{a_{11}}{z}+O(z^{-2}) \quad (4.2)$$

$$f_2'(z)=\frac{1}{z}Q_2+\frac{i}{2}\frac{a_{12}}{z}+O(z^{-2}) \quad (4.3)$$

where Q_1 and Q_2 are functions of c_i's and U independent of ε. Hence, we can conclude that if we expand the total drag as

$$C_D=C_{D1}+C_{D2}+C_{D3}+\cdots \quad (4.4)$$

where C_{D1}, C_{D2} and C_{D3} are the terms of order R^{-1}, R^0 and R^1 respectively, the values of C_{D1} and C_{D3} are the same for the original and the rotated bodies, while the values of C_{D2} are of the same magnitude but of opposite sign.

§ 5. The Value of C_{D2}

Further, if we can show that $C_{D2}=0$, the total drags for the original and the rotated bodies coincide with each other within the accuracy of $O(R)$. Although the author could not succeed in the general demonstration of the fact that $C_{D2}=0$, it can be shown that in a fairly general case where the transformation function is given by

$$z=Z+c_1Z^{-1}+c_2Z^{-2}+c_3Z^{-3}+c_4Z^{-4} \quad (c_i\text{: real}) \tag{5.1}$$

the value of C_{D2} is identically zero.

It seems to the author that the values of C_{D2} may be zero in more general cases. Even if it were not the case, the value of C_{D2} would be fairly small, since the terms in $Z^{-n}(n\geq 5)$ in the transformation function behave as $\cos n\theta$ and $\sin n\theta$ on the surface of the cylinder, and they could have little effect upon the symmetry of the profile about the line perpendicular to the direction of the undisturbed flow.

Further, it may be noted that even when $C_{D2}=0$, the second approximations of the pressure and the frictional drag do not vanish, as was shown for the triangular cylinder in the preceding paper.

§ 6. Conclusion.

In this paper, we sought for the simple relations which exist between a flow past an obstacle and the flow past the same obstacle rotated by an angle π. It was shown that the forces acting upon the cylinder do not change by the rotation of the cylinder, as far as the terms of order $O(R^{-1})$ are concerned. Further, for the special cases of symmetrical obstacles which experience no lift, it was shown that the total drags for the original and the rotated bodies coincide with each other within the accuracy of the third approximation to Oseen's approximate equation, i.e. $O(R)$.

In conclusion, I wish to express my hearty gratitude to Professor Isao Imai for his discussions and kind inspection of the manuscript.

Two-dimensional Stokes Flow of an Electrically Conducting Fluid in a Uniform Magnetic Field

By Hirowo YOSINOBU
Junior College of Engineering, University of Osaka Prefecture
and Tsunehiko KAKUTANI
Department of Physics, Faculty of Science, Kyoto University

(Received June 29, 1959)

This paper deals with the two-dimensional flow of a viscous, incompressible and electrically conducting fluid past a cylinder in a uniform magnetic field, using Stokes approximation. Detailed calculation is carried out for the flow past a circular cylinder in two cases: one in a parallel magnetic field and the other in a transverse magnetic field. The expansion formulae for the drag per unit span of the cylinder are obtained in terms of the Hartmann number in each case.

§ 1. Introduction

Magnetohydrodynamics is a new field in physics which has been developed in connexion with geo- and astrophysics and aero-space sciences. In particular, it seems to become more attractive to physicists lately in connexion with the problems of nuclear fusion. Many problems in magnetohydrodynamics have been so far investigated for their own importance and interest in each field. However, it may also be one of the effective ways of developing this new field to investigate how the well-established classical hydrodynamic problems may be modified under the new magneto-hydrodynamic circumstances. Indeed, since Hartmann's pioneering work, not a few works have been carried out along this line.

Recently, Chester[1] has investigated the effect of magnetic field upon the Stokes flow past a sphere. In the present paper, applying his ideas to the two-dimensional Stokes flow, we deal with the flow of a viscous and electrically conducting fluid past a circular cylinder in two cases: one in a uniform magnetic field parallel to the main stream and the other in a transverse uniform magnetic field. It is well known that the Stokes approximation cannot give an appropriate solution for the two-dimensional flow past a cylinder under the ordinary hydrodynamical circumstances, unless the flow field is bounded. In the present case where the fluid is electrically conducting and flows in the uniform magnetic field, however, appropriate solutions can be obtained. In the first case, where the uniform magnetic field is parallel to the main stream, the solution indicates that rotational flow field with appreciable vortices and induced electric currents is confined in two parabolic regions in front and in rear of the cylinder and that outside these regions the vorticity falls off exponentially and the flow is almost uniform. Similar parabolic regions are also formed on both sides of the cylinder in the second case, where the uniform magnetic field is transverse to the main stream. This fact enables us to obtain appropriate solutions in the present case, while in the classical Stokes flow no acceptable solution can be obtained except trivial one implying the fluid everywhere at rest, since the rotational field extends over the whole region.

The expansion formulae for the drag per unit span of the cylinder are also obtained in power series of Hartmann number. Numerical results show that the drag is always greater in the transverse magnetic field than in the parallel magnetic field, as is intuitively expected.

§ 2. Fundamental Equations and Stokes Approximation

We consider a steady flow of a viscous, incompressible and electrically conducting fluid past a circular cylinder with radius a in the presence of a uniform magnetic field. As the fluid is electrically conducting, electric current is induced, when the flow goes across the line of magnetic induction. This induced current, coupled with the magnetic field, yields a body force acting on the fluid, viz. Lorentz force. The interaction between the magnetic field and the motion of the fluid having to be taken into account, we must solve the hydrodynamic equations and the electromagnetic equations simultaneously.

The fundamental equations governing the motion of the fluid are the equation of continuity:

$$\operatorname{div} V=0\,, \tag{2.1}$$

and the modified Navier-Stokes equation:

$$\rho(V\cdot\operatorname{grad})V=-\operatorname{grad}P+\rho\nu\Delta V+q\boldsymbol{E}+\boldsymbol{J}\times\boldsymbol{B}. \tag{2.2}$$

Electromagnetic field is subject to the Maxwell equations:

$$\operatorname{curl}\boldsymbol{H}=\boldsymbol{J}\,, \tag{2.3}$$

$$\operatorname{div}\boldsymbol{B}=0\,, \tag{2.4}$$

$$\operatorname{curl}\boldsymbol{E}=0\,, \tag{2.5}$$

$$\operatorname{div}\boldsymbol{D}=q\,. \tag{2.6}$$

In the above six equations, we have used the usual notations for quantities of the field and adopted the rationalized M. K. S. system. The derivatives of the field quantities with respect to time do not appear, since we consider the steady state only. As a complementary relation to these equations, Ohm's law is assumed:

$$\boldsymbol{J}=\sigma(\boldsymbol{E}+V\times\boldsymbol{B})+qV\,, \tag{2.7}$$

where σ is the electric conductivity of the fluid. We also assume the fluid to be homogeneous and isotropic, so that the following two relations connect the magnetic induction $\boldsymbol{B}$ with the magnetic field $\boldsymbol{H}$ and the electric displacement $\boldsymbol{D}$ with the electric field $\boldsymbol{E}$ respectively:

$$\boldsymbol{B}=\mu\boldsymbol{H}\,, \tag{2.8}$$

$$\boldsymbol{D}=\varepsilon\boldsymbol{E}\,, \tag{2.9}$$

where the constants μ and ε are the magnetic permeability and the dielectric constant of the fluid respectively. Equations (2.1)∼(2.9) are the fundamental equations to be solved for the present problem.

We choose the origin of coordinates at the centre of a cross section of the cylinder and take the x_1-axis parallel to the direction of the undisturbed magnetic field, the x_3-axis along the axis of the cylinder and the x_2-axis perpendicular to both the x_1-and x_3-axes. The undisturbed flow is supposed to be parallel to the x_1-axis in the first case and to the x_2-axis in the second case.

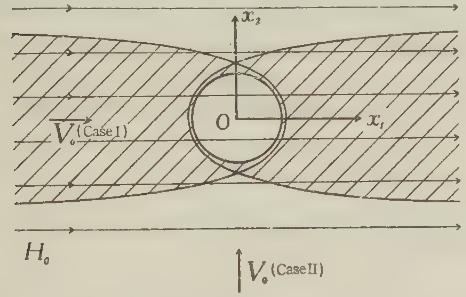

Fig. 1. Sketch of the field.

First, we neglect the terms involving excess charge q in (2.2) and (2.7) as in usual magnetohydrodynamic problems. We then assume two-dimensionality of the problem: namely 1) all the quantities in (2.1)~(2.9) are independent of x_3, so that all the derivatives of these quantities in x_3 disappear in the above equations, and 2) the fluid velocity V and the magnetic field $\boldsymbol{H}$ lie in the x_1 x_2-plane. In consequence of these assumptions, curl $\boldsymbol{H}$ in (2.3), and hence $\boldsymbol{J}$ too, becomes parallel to the x_3-axis. Also, owing to the assumption 2), $\boldsymbol{V}\times\boldsymbol{B}$ in (2.7) becomes parallel to the x_3-axis. Hence, we may conclude from (2.7) that $\boldsymbol{E}$ has only the x_3-component, E_3. Thus, solving Eq. (2.5), we obtain

$$E_3=E_0\,(\text{const})\,. \tag{2.10}$$

Since there is no electric current at infinity, the constant E_0 must be zero in the first case, because $\boldsymbol{V}$ and $\boldsymbol{B}$ at infinity are parallel to each other. Similarly, in the second case where $\boldsymbol{V}$ and $\boldsymbol{B}$ at infinity are perpendicular to each other, so that $\boldsymbol{V}\times\boldsymbol{B}$ is equal to $-V_0\mu H_0\boldsymbol{k}$, the constant E_0 must be equal to $V_0\mu H_0$, where V_0 and H_0 are the undisturbed velocity and magnetic field at infinity and $\boldsymbol{k}$ is one of the fundamental unit vectors $(\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k})$ referring to the coordinate system. Hence, we have, in the first case,

$$\boldsymbol{J}=\sigma\mu(\boldsymbol{V}\times\boldsymbol{H})\,, \tag{2.11}$$

and in the second case,

$$\boldsymbol{J}=\sigma\mu(V_0H_0\boldsymbol{k}+\boldsymbol{V}\times\boldsymbol{H})\,. \tag{2.12}$$

Substituting (2.11) and (2.12) into (2.2) and (2.3), and introducing non-dimensional variables $\boldsymbol{v}=\boldsymbol{V}/V_0$, $\boldsymbol{h}=\boldsymbol{H}/H_0$, $p=a/(\rho\nu V_0)\cdot P$ and $(x, y, z)=(x_1/a, x_2/a, x_3/a)$, we have, in the first case,

$$R(\boldsymbol{v}\cdot\nabla)\boldsymbol{v}=-\nabla p+\nabla^2\boldsymbol{v}+M^2(\boldsymbol{v}\times\boldsymbol{h})\times\boldsymbol{h}\,, \tag{2.13}$$

$$R_m(\boldsymbol{v}\times\boldsymbol{h})=\nabla\times\boldsymbol{h}\,, \tag{2.14}$$

and in the second case,

$$R(\boldsymbol{v}\cdot\nabla)\boldsymbol{v}=-\nabla p+\nabla^2\boldsymbol{v}+M^2(\boldsymbol{k}+\boldsymbol{v}\times\boldsymbol{h})\times\boldsymbol{h}\,, \tag{2.15}$$

$$R_m(\boldsymbol{k}+\boldsymbol{v}\times\boldsymbol{h})=\nabla\times\boldsymbol{h}\,, \tag{2.16}$$

where $R=aV_0/\nu$ is the Reynolds number, $R_m=aV_0\sigma\mu$ the magnetic Reynolds number, $M=(\sigma/\rho\nu)^{1/2}a\mu H_0=(SRR_m)^{1/2}$ the Hartmann number, ($S=\mu H_0^2/\rho V_0^2$ being the pressure number), and ∇ stands for $\boldsymbol{i}(\partial/\partial x)+\boldsymbol{j}(\partial/\partial y)$.

We now assume R_m to be small and apply the Stokes approximation to Eqs. (2.14) and (2.16). Then, neglecting the left-hand sides of (2.14) and (2.16), we have, in both cases,

$$\nabla\times\boldsymbol{h}=0\,. \tag{2.17}$$

Assuming that the permeabilities of the fluid and the cylinder are effectively equal, and bearing in mind that the magnetic field is uniform and parallel to the x_1-axis at infinity, we obtain as the solution of (2.4) and (2.17),

$$\boldsymbol{h}=\boldsymbol{i}\,, \tag{2.18}$$

so that to the Stokes approximation the magnetic field is everywhere uniform and parallel to the x_1-axis. Inserting (2.18) into (2.13) and (2.15), and assuming R to be small, we have, to the Stokes approximation,

$$-\nabla p+\nabla^2\boldsymbol{v}+M^2(\boldsymbol{v}\times\boldsymbol{i})\times\boldsymbol{i}=0\,, \tag{2.19}$$

and

$$-\nabla p+\nabla^2\boldsymbol{v}+M^2(\boldsymbol{k}+\boldsymbol{v}\times\boldsymbol{i})\times\boldsymbol{i}=0\,, \tag{2.20}$$

where the terms of Lorentz force have been retained, since M^2 is considered to be finite in spite of the vanishing R and R_m by taking S to be infinite.

We now introduce the non-dimensional perturbed velocities $\boldsymbol{v}'=\boldsymbol{v}-\boldsymbol{i}$ in the first case in (2.19) and $\boldsymbol{v}'=\boldsymbol{v}-\boldsymbol{j}$ in the second case in (2.20). Then these equations can be written down in a single identical form:

$$-\nabla p+\nabla^2\boldsymbol{v}'+M^2(\boldsymbol{v}'\times\boldsymbol{i})\times\boldsymbol{i}=0\,. \tag{2.21}$$

The triple vector product in this equation is expanded as

$$\begin{aligned}(\boldsymbol{v}'\times\boldsymbol{i})\times\boldsymbol{i}&=(\boldsymbol{i}\cdot\boldsymbol{v}')\boldsymbol{i}-(\boldsymbol{i}\cdot\boldsymbol{i})\boldsymbol{v}'\\&=u\boldsymbol{i}-\boldsymbol{v}'\\&=-v\boldsymbol{j}\,,\end{aligned} \tag{2.22}$$

where u and v are the x-and y-components of $\boldsymbol{v}'$, respectively. Thus, we have finally the following equation:

$$-\nabla p+\nabla^2\boldsymbol{v}'-M^2 v\boldsymbol{j}=0\,, \tag{2.23}$$

which should be solved in combination with the equation of continuity for $\boldsymbol{v}'$:

$$\nabla\cdot\boldsymbol{v}'=0\,. \tag{2.24}$$

§ 3. General Solutions and their Properties

We shall now proceed to solve the above simultaneous equations (2.23) and (2.24). Eliminating p from (2.23), we have

$$\nabla^2\omega-M^2\frac{\partial v}{\partial x}=0\,, \tag{3.1}$$

where $\omega=\partial v/\partial x-\partial u/\partial y$ is the vorticity. Eq. (2.24) shows that the perturbed velocity field has a stream function ψ such that

$$\left.\begin{aligned} u&=-\frac{\partial\psi}{\partial y}\,,\\ v&=\frac{\partial\psi}{\partial x}\,,\end{aligned}\right\} \tag{3.2}$$

and

$$\omega=\nabla^2\psi\,. \tag{3.3}$$

Substituting (3.2) and (3.3) into (3.1), we obtain the equation for ψ as

$$\left(\nabla^4-M^2\frac{\partial^2}{\partial x^2}\right)\psi=0\,. \tag{3.4}$$

In general, the solution of this equation can be expressed in the form:

$$\psi=\psi_1+\psi_2\,, \tag{3.5}$$

where ψ_1 and ψ_2 are solutions of equations

$$\left(\nabla^2-M\frac{\partial}{\partial x}\right)\psi_1=0\,, \tag{3.6}$$

and

$$\left(\nabla^2+M\frac{\partial}{\partial x}\right)\psi_2=0\,, \tag{3.7}$$

respectively. An equation similar to (3.6) and (3.7) is already familiar to us in the classical Oseen flow. Putting $\psi_1=e^{\frac{1}{2}Mx}f_1$ and $\psi_2=e^{-\frac{1}{2}Mx}f_2$ in (3.6) and (3.7) respectively, we have a single identical equation for f_1 and f_2 as:

$$\left\{\nabla^2-\left(\frac{M}{2}\right)^2\right\}(f_1,\,f_2)=0\,. \tag{3.8}$$

The fundamental solutions for (3.8) are expressed as

$$(f_1,\,f_2)=\left.\begin{matrix}I_n(kr)\\K_n(kr)\end{matrix}\right\}\times\left\{\begin{matrix}\sin n\theta\\ \cos n\theta\,,\end{matrix}\right. \tag{3.9}$$

where

$$k=\frac{1}{2}M,\ \ x=r\cos\theta,\ \ \ y=r\sin\theta, \tag{3.10}$$

and I_n, K_n denote the modified Bessel functions. The function $I_n(kr)$ is known to become infinite exponentially, when kr is large. On the other hand, the function $K_n(kr)$ becomes exponentially small when kr is large. Thus, bearing in mind that the perturbed velocity must vanish at infinity, the appropriate general solution for (3.4) is given by

$$\begin{aligned}\psi&=\psi_1+\psi_2\\ &=A_0e^{kx}K_0(kr)+B_0\int_0^\theta kr[K_1(kr)+K_0(kr)\cos\chi]e^{kr\cos\chi}d\chi\\ &\quad+2e^{kx}\sum_{n=1}^{\infty}K_n(kr)(A_n\cos n\theta+B_n\sin n\theta)\\ &\quad+C_0e^{-kx}K_0(kr)+D_0\int_0^\theta kr[K_1(kr)-K_0(kr)\cos\chi]e^{-kr\cos\chi}d\chi\\ &\quad+2e^{-kx}\sum_{n=1}^{\infty}K_n(kr)(C_n\cos n\theta+D_n\sin n\theta)\,,\end{aligned} \tag{3.11}$$

where A_n's, B_n's, C_n's and D_n's are arbitrary constants. As was shown by Filon[2)] in the classical Oseen flow, the term multiplied by B_0 in (3.11), which is a fundamental solution of (3.6), contains non-periodic term in θ and may be expanded as

$$\int_0^\theta kr[K_1(kr)+K_0(kr)\cos\chi]e^{kr\cos\chi}d\chi=\theta+\text{periodic terms in }\theta\,. \tag{3.12}$$

In the classical Oseen flow, this many-valuedness should be cancelled out by adding another many-valued fundamental solution θ, since the stream function must be one-valued. Similarly, in the present problem, we must add another many-valued function, the term multiplied by D_0 in (3.11), which is a fundamental solution of (3.7) and is expanded as

$$\int_0^\theta kr[K_1(kr)-K_0(kr)\cos\chi]e^{-kr\cos\chi}d\chi=\theta+\text{periodic terms in }\theta\,. \tag{3.13}$$

Necessity of one-valuedness of the stream function ψ imposes the following condition on the arbitrary constants B_0 and D_0:

$$B_0+D_0=0\ . \tag{3.14}$$

Thus, we have obtained the general solution for Eqs. (2.23) and (2.24).

The radial component u_r and the circumferential component u_θ of the perturbed velocity are derived from the stream function, as follows:

$$\begin{aligned} u_r &= -\frac{1}{r}\frac{\partial\psi}{\partial\theta} \\ &= ke^{kx}\Big[(B_1-B_0)K_1(kr)+\sum_{n=1}^{\infty}\cos n\theta\{(B_{n+1}-B_n)K_{n+1}(kr)+(B_n-B_{n-1})K_{n-1}(kr)\} \\ &\qquad -\sum_{n=1}^{\infty}\sin n\theta\{(A_{n+1}-A_n)K_{n+1}(kr)+(A_n-A_{n-1})K_{n-1}(kr)\}\Big] \\ &\qquad -ke^{-kx}\Big[(D_1+D_0)K_1(kr)+\sum_{n=1}^{\infty}\cos n\theta\{(D_{n+1}+D_n)K_{n+1}(kr)-(D_n+D_{n-1})K_{n-1}(kr)\} \\ &\qquad -\sum_{n=1}^{\infty}\sin n\theta\{(C_{n+1}+C_n)K_{n+1}(kr)-(C_n+C_{n-1})K_{n-1}(kr)\}\Big]\ , \end{aligned} \tag{3.15}$$

$$\begin{aligned} u_\theta &= \frac{\partial\psi}{\partial r} \\ &= ke^{kx}\Big[(A_1-A_0)K_1(kr)+\sum_{n=1}^{\infty}\cos n\theta\{(A_{n+1}-A_n)K_{n+1}(kr)-(A_n-A_{n-1})K_{n-1}(kr)\} \\ &\qquad +\sum_{n=1}^{\infty}\sin n\theta\{(B_{n+1}-B_n)K_{n+1}(kr)-(B_n-B_{n-1})K_{n-1}(kr)\}\Big] \\ &\qquad -ke^{-kx}\Big[(C_1+C_0)K_1(kr)+\sum_{n=1}^{\infty}\cos n\theta\{(C_{n+1}+C_n)K_{n+1}(kr)+(C_n+C_{n-1})K_{n-1}(kr)\} \\ &\qquad +\sum_{n=1}^{\infty}\sin n\theta\{(D_{n+1}+D_n)K_{n+1}(kr)+(D_n+D_{n-1})K_{n-1}(kr)\}\Big]\ . \end{aligned} \tag{3.16}$$

This solution has some remarkable properties. Since, for large values of kr, the modified Bessel function $K_n(kr)$ has the asymptotic expression:

$$K_n(kr)\sim\left(\frac{\pi}{2kr}\right)^{\frac{1}{2}}e^{-kr}\ , \tag{3.17}$$

all terms involving e^{kx} on the right-hand sides of Eqs. (3.15) and (3.16) are of the order of

$$(kr)^{-\frac{1}{2}}\,e^{-kr(1-\cos\theta)}\ . \tag{3.18}$$

Hence, they become exponentially small, as r tends to ∞, except in the region

$$kr(1-\cos\theta)=2kr\sin^2\frac{1}{2}\theta=O(1)\ , \tag{3.19}$$

so that

$$\theta=O((kr)^{-\frac{1}{2}})\ . \tag{3.20}$$

For large values of r they are sensible only in the vaguely parabolic region open in the direction of the positive x-axis. (cf. Fig. 1). Similarly, all terms involving e^{-kx} in (3.15) and (3.16) are of the order of

$$(kr)^{-\frac{1}{2}}e^{-kr(1+\cos\theta)}\ . \tag{3.21}$$

Hence, they are also sensible only in the vaguely parabolic region open in the direction of the negative x-axis (also cf. Fig. 1). In like manner, it is easily found that the vorticity is also sensible only in these parabolic regions, outside which the flow is nearly irrotational and uniform. The structures of these parabolic regions are similar to that of the wake formed behind a cylinder in the classical Oseen flow, but their mechanisms of formation are different from each other. Roughly speaking, in the classical Oseen flow, the vortices produced at the surface of the cylinder are diffused by viscosity of the fluid and swept away by the main stream. Thus, the vortices are mostly confined in the parabolic region behind the cylinder. As $R\to 0$, the fluid flows very slowly and can hardly sweep away the vortices. So, they are diffused equally in all directions and are distributed over the whole region. The vorticity falls off only as r^{-1}, as r becomes large. This is the reason why we cannot have an appropriate solution in the classical Stokes flow. In the present case where the magnetic field is present, however, the disturbances in velocity caused by the cylinder are transmitted as the so-called Alfvén wave along the lines of magnetic induction. The vortices are, therefore, not only diffused by viscosity but also transmitted along the lines of magnetic induction, though they are hardly swept away by the main stream since $R=0$. Hence, two parabolic rotational regions are formed along the lines of magnetic induction independently of the direction of the main stream, as shown above. This fact enables us to have appropriate solutions in the present case.

§ 4. Boundary Conditions

We shall now proceed to determine the arbitrary constants A_n's, B_n's, C_n's and D_n's in the general solution (3.11) by the boundary conditions.

Since the conditions at infinity have already been satisfied by the general solutions (3.15) and (3.16), we have only to consider the conditions at the surface of the cylinder. However, before applying the conditions to the general solutions, we consider some symmetrical properties of the flow in order to simplify the following calculations.

In the first case where the magnetic field is parallel to the undisturbed velocity, ψ must be an odd function of y, since the components of the perturbed velocity $u(=-\partial\psi/\partial y)$ and $v(=\partial\psi/\partial x)$ must be even and odd functions of y, respectively. This implies that

$$A_n=0 \quad \text{and} \quad C_n=0 \,. \tag{4.1}$$

Further considerations of symmetry with respect to the y-axis also imply that

$$D_n=(-1)^{n+1}B_n \,. \tag{4.2}$$

Then, the radial and the circumferential components of the perturbed velocity (3.15) and (3.16) are rewritten as

$$u_r=k\Big[(e^{kx}-e^{-kx})(B_1-B_0)K_1(kr)$$
$$+\sum_{n=1}^{\infty}\cos n\theta\{e^{kx}+(-1)^{n+1}e^{-kx}\}\{(B_{n+1}-B_n)K_{n+1}(kr)+(B_n-B_{n-1})K_{n-1}(kr)\}\Big] \,, \tag{4.3}$$

and

$$u_\theta=k\Big[\sum_{n=1}^{\infty}\sin n\theta\{e^{kx}+(-1)^{n+1}e^{-kx}\}\{(B_{n+1}-B_n)K_{n+1}(kr)-(B_n-B_{n-1})K_{n-1}(kr)\}\Big] \,, \tag{4.4}$$

respectively.

In the second case where the magnetic field is perpendicular to the undisturbed velocity, the similar considerations of symmetries with respect to the x- and the y-axes also imply that

$$B_n=0 \,, \qquad D_n=0 \,, \tag{4.5}$$

and

$$C_n=(-1)^{n+1}A_n \,, \tag{4.6}$$

respectively. Thus, the components of the perturbed velocity given in (3.15) and (3.16) are reduced to

$$u_r=-k\Big[\sum_{n=1}^{\infty}\sin n\theta\{e^{kx}+(-1)^{n+1}e^{-kx}\}\{(A_{n+1}-A_n)K_{n+1}(kr)+(A_n-A_{n-1})K_{n-1}(kr)\}\Big] \,, \tag{4.7}$$

and

$$u_\theta=k\Big[(e^{kx}-e^{-kx})(A_1-A_0)K_1(kr)$$
$$+\sum_{n=1}^{\infty}\cos n\theta\{e^{kx}+(-1)^{n+1}e^{-kx}\}\{(A_{n+1}-A_n)K_{n+1}(kr)-(A_n-A_{n-1})K_{n-1}(kr)\}\Big] \,, \tag{4.8}$$

respectively.

We now apply the boundary conditions at the surface of the cylinder to (4.3), (4.4) and (4.7), (4.8) in order to determine the constants B_n's and A_n's. The conditions to be satisfied by the perturbed velocity are, in the first case,

$$\boldsymbol{v}'=-\boldsymbol{i}\ , \quad \text{i. e.} \quad \left.\begin{aligned} u_r&=-\cos\theta \\ u_\theta&=\sin\theta \end{aligned}\right\} \text{ at } r=1\ , \tag{4.9}$$

and, in the second case,

$$\boldsymbol{v}'=-\boldsymbol{j}\ , \quad \text{i. e.} \quad \left.\begin{aligned} u_r&=-\sin\theta \\ u_\theta&=-\cos\theta \end{aligned}\right\} \text{ at } r=1\ . \tag{4.10}$$

We shall begin with the first case. Substituting (4.9) into (4.3) and (4.4), and making use of Fourier expansions:

$$\{e^{k\cos\theta}+(-1)^{n+1}e^{-k\cos\theta}\}\cos n\theta=\sum_{m=0}^{\infty}F_{n,m}(k)\cos m\theta\ , \tag{4.11}$$

$$\{e^{k\cos\theta}+(-1)^{n+1}e^{-k\cos\theta}\}\sin n\theta=\sum_{m=1}^{\infty}G_{n,m}(k)\sin m\theta\ , \tag{4.12}$$

we have

$$\begin{aligned} -\cos\theta=k\sum_{m=0}^{\infty}\cos m\theta\Big[&F_{0,m}(k)(B_1-B_0) \\ &+\sum_{n=1}^{\infty}F_{n,m}(k)\{K_{n+1}(k)(B_{n+1}-B_n)+K_{n-1}(k)(B_n-B_{n-1})\}\Big]\ , \end{aligned} \tag{4.13}$$

$$\sin\theta=k\sum_{m=1}^{\infty}\sin m\theta\left[\sum_{n=1}^{\infty}G_{n,m}(k)\{K_{n+1}(k)(B_{n+1}-B_n)-K_{n-1}(k)(B_n-B_{n-1})\}\right]. \tag{4.14}$$

Equating the coefficients of $\cos m\theta$ and $\sin m\theta$ on both sides of these equations, we obtain the following set of equations:

$$0=F_{0,0}(k)K_1(k)(B_1-B_0)+\sum_{n=1}^{\infty}F_{n,0}(k)\{K_{n+1}(k)(B_{n+1}-B_n)+K_{n-1}(k)(B_n-B_{n-1})\}\ , \tag{4.15}$$

$$-\frac{1}{k}=F_{0,1}(k)K_1(k)(B_1-B_0)+\sum_{n=1}^{\infty}F_{n,1}(k)\{K_{n+1}(k)(B_{n+1}-B_n)+K_{n-1}(k)(B_n-B_{n-1})\}\ , \tag{4.16}$$

$$0=F_{0,m}(k)K_1(k)(B_1-B_0)+\sum_{n=1}^{\infty}F_{n,m}(k)\{K_{n+1}(k)(B_{n+1}-B_n)+K_{n-1}(k)(B_n-B_{n-1})\}\ , \quad (m=2,\ 3,\ 4,\ \cdots) \tag{4.17}$$

$$\frac{1}{k}=\sum_{n=1}^{\infty}G_{n,1}(k)\{K_{n+1}(k)(B_{n+1}-B_n)-K_{n-1}(k)(B_n-B_{n-1})\}\ , \tag{4.18}$$

$$0=\sum_{n=1}^{\infty}G_{n,m}(k)\{K_{n+1}(k)(B_{n+1}-B_n)-K_{n-1}(k)(B_n-B_{n-1})\}\ . \quad (m=2,\ 3,\ 4,\ \cdots) \tag{4.19}$$

Since $F_{n,0}(k)$, $F_{n,m}(k)$ and $G_{n,m}(k)$ are expressed as*

$$F_{n,0}(k)=\frac{1}{2\pi}\int_{-\pi}^{\pi}\{e^{k\cos\theta}+(-1)^{n+1}e^{-k\cos\theta}\}\cos n\theta\,d\theta=0\ , \tag{4.20}$$

$$\begin{aligned} F_{n,m}(k)&=\frac{1}{\pi}\int_{-\pi}^{\pi}\{e^{k\cos\theta}+(-1)^{n+1}e^{-k\cos\theta}\}\cos n\theta\cos m\theta\,d\theta \\ &=\begin{cases} 0\ , & (m\text{: even}) \\ 2\{I_{n-m}(k)+I_{n+m}(k)\}\ , & (m\text{: odd}) \end{cases} \end{aligned} \tag{4.21}$$

$$\begin{aligned} G_{n,m}(k)&=\frac{1}{\pi}\int_{-\pi}^{\pi}\{e^{k\cos\theta}+(-1)^{n+1}e^{-k\cos\theta}\}\sin n\theta\sin m\theta\,d\theta \\ &=\begin{cases} 0\ , & (m\text{: even}) \\ 2\{I_{n-m}(k)-I_{n+m}(k)\}\ , & (m\text{: odd}) \end{cases} \end{aligned} \tag{4.22}$$

---

* Here we make use of the fact that when s is any positive integer, the modified Bessel function $I_s(x)$ can be expressed as:

$$I_s(x)=\frac{1}{2\pi}\int_{-\pi}^{\pi}e^{x\cos\theta}\cos s\theta\,d\theta\ ^{3)}\ .$$

it is easily found that all terms in Eqs. (4.15), (4.17) and (4.19) for even m should vanish. Then, Eqs. (4.16)∼(4.19) for odd m will serve as a system of linear algebraic equations for determining the B_n's. In order to facilitate later calculations, we shall now transform this system into more convenient form. Subtracting (4.16) from (4.18) and (4.17) from (4.19) for odd m, and making use of (4.21) and (4.22), we have, after some rearrangements,

$$\beta_{0,2s+1}B_0+\sum_{n=1}^{\infty}\beta_{n,2s+1}B_n=\begin{cases}\dfrac{1}{2k}, & (s=0)\\ 0, & (s=1,\ 2,\ 3,\ \cdots)\end{cases} \tag{4.23}$$

where

$$\beta_{0,2s+1}=I_{2s+1}(k)K_1(k)+I_{2s}(k)K_0(k)\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.24}$$

$$\beta_{n,2s+1}=I_{n+2s+1}(k)K_{n+1}(k)-I_{n+2s}(k)K_n(k)+I_{n-2s}(k)K_n(k)-I_{n-2s-1}(k)K_{n-1}(k)\ . \qquad \begin{pmatrix}s=0,\ 1,\ 2,\ \cdots\\ n=1,\ 2,\ 3,\ \cdots\end{pmatrix} \tag{4.25}$$

Similarly, adding (4.16) to (4.18) and (4.17) to (4.19) for odd m, we have

$$\beta'_{0,2s+1}B_0+\sum_{n=1}^{\infty}\beta'_{n,2s+1}B_n=0\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.26}$$

where

$$\beta'_{0,2s+1}=I_{2s+1}(k)K_1(k)+I_{2s+2}(k)K_0(k)\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.27}$$

$$\beta'_{n,2s+1}=I_{n+2s+2}(k)K_n(k)-I_{n+2s+1}(k)K_{n-1}(k)+I_{n-2s-1}(k)K_{n+1}(k)-I_{n-2s-2}(k)K_n(k)\ . \qquad \begin{pmatrix}s=0,\ 1,\ 2,\ \cdots\\ n=1,\ 2,\ 3,\ \cdots\end{pmatrix} \tag{4.28}$$

Thus, the B_n's can be determined by solving this system of simultaneous linear algebraic equations (4.23) and (4.26).

Next, we shall proceed to the second case. Substituting (4.10) into (4.7) and (4.8), and carrying out calculations similar to those in the first case, we get a system of simultaneous linear algebraic equations for determining the A_n's:

$$\alpha_{0,2s+1}A_0+\sum_{n=1}^{\infty}\alpha_{n,2s+1}A_n=\begin{cases}\dfrac{1}{2k}, & (s=0)\\ 0, & (s=1,\ 2,\ 3,\ \cdots)\end{cases} \tag{4.29}$$

$$\alpha'_{0,2s+1}A_0+\sum_{n=1}^{\infty}\alpha'_{n,2s+1}A_n=0\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.30}$$

where

$$\alpha_{0,2s+1}=I_{2s+1}(k)K_1(k)-I_{2s}(k)K_0(k)\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.31}$$

$$\alpha_{n,2s+1}=I_{n+2s+1}(k)K_{n+1}(k)-I_{n+2s}(k)K_n(k)-I_{n-2s}(k)K_n(k)+I_{n-2s-1}(k)K_{n-1}(k)\ , \qquad \begin{pmatrix}s=0,\ 1,\ 2,\ \cdots\\ n=1,\ 2,\ 3,\ \cdots\end{pmatrix} \tag{4.32}$$

$$\alpha'_{0,2s+1}=I_{2s+1}(k)K_1(k)-I_{2s+2}(k)K_0(k)\ , \qquad (s=0,\ 1,\ 2,\ \cdots) \tag{4.33}$$

$$\alpha'_{n,2s+1}=I_{n+2s+1}(k)K_{n-1}(k)-I_{n+2s+2}(k)K_n(k)-I_{n-2s-2}(k)K_n(k)+I_{n-2s-1}(k)K_{n+1}(k)\ . \qquad \begin{pmatrix}s=0,\ 1,\ 2,\ \cdots\\ n=1,\ 2,\ 3,\ \cdots\end{pmatrix} \tag{4.34}$$

§ 5. Forces on the Cylinder

Next, we shall calculate the force experienced by the cylinder. The first contribution to this force comes from the viscous stress exerted by the surrounding fluid on the surface of the cylinder, while the second comes from Maxwell's magnetic stress acting on the surface of the cylinder. Let X_1 and X_2 be the components of the force parallel to the x_1-

and x_2-axes acting on the unit axial length of the cylinder. Then we have

$$X_1=\int_C P_{n1}dC+\int_C T_{n1}dC\ , \tag{5.1}$$

and

$$X_2=\int_C P_{n2}dC+\int_C T_{n2}dC\ , \tag{5.2}$$

where dC is the line-element of the contour C of the cylinder and integrations are taken round the contour. P_{n1}, P_{n2} and T_{n1}, T_{n2} are the x_1, x_2-components of the viscous stress and Maxwell's stress acting on the surface of the cylinder, respectively and they are expressed as

$$P_{n1}=\left(-P+2\rho\nu\frac{\partial V_1}{\partial x_1}\right)l+\rho\nu\left(\frac{\partial V_2}{\partial x_1}+\frac{\partial V_1}{\partial x_2}\right)m\ , \tag{5.3}$$

$$P_{n2}=\rho\nu\left(\frac{\partial V_2}{\partial x_1}+\frac{\partial V_1}{\partial x_2}\right)l+\left(-P+2\rho\nu\frac{\partial V_2}{\partial x_2}\right)m\ , \tag{5.4}$$

$$T_{n1}=\mu\left(H_1^2-\frac{1}{2}H^2\right)l+\mu H_1H_2m\ , \tag{5.5}$$

$$T_{n2}=\mu H_1H_2l+\mu\left(H_2^2-\frac{1}{2}H^2\right)m\ , \tag{5.6}$$

where V_1, V_2 and H_1, H_2 are the x_1, x_2-components of the velocity $\boldsymbol{V}$ and the magnetic field $\boldsymbol{H}$ respectively, H the magnitude of $\boldsymbol{H}$ and l, m the direction-cosines of the outward normal to the contour of the cylinder.

Inserting (5.3) and (5.4) into the first integrals in (5.1) and (5.2), we have, after some calculations,

$$\int_C P_{n1}dC=\rho\nu V_0\int_s(-pl-\omega m)ds\ , \tag{5.7}$$

$$\int_C P_{n2}dC=\rho\nu V_0\int_s(\omega l-pm)ds\ , \tag{5.8}$$

where the non-dimensional variables introduced in § 2 have been used and the integrations $\int_s ds$ are now taken round the contour s in the non-dimensional xy-plane corresponding to the contour of the cylinder C in the x_1x_2-plane. Making use of (2.23), (3.2), (3.3), (3.6) and (3.7), we can express the pressure p and the vorticity ω in terms of ψ_1 and ψ_2 as

$$p=-M\frac{\partial}{\partial y}(\psi_1-\psi_2)\ , \tag{5.9}$$

and

$$\omega=M\frac{\partial}{\partial x}(\psi_1-\psi_2)\ , \tag{5.10}$$

respectively. Substitution of (5.9) and (5.10) into (5.7) and (5.8) yields

$$\int_C P_{n1}dC=\rho\nu V_0M\int_s\left\{-\frac{\partial}{\partial x}(\psi_1-\psi_2)m+\frac{\partial}{\partial y}(\psi_1-\psi_2)l\right\}ds=\rho\nu V_0M\int_s\frac{\partial}{\partial s}(\psi_1-\psi_2)ds\ , \tag{5.11}$$

$$\int_C P_{n2}dC=\rho\nu V_0M\int_s\left\{\frac{\partial}{\partial x}(\psi_1-\psi_2)l+\frac{\partial}{\partial y}(\psi_1-\psi_2)m\right\}ds=\rho\nu V_0M\int_s\frac{\partial}{\partial n}(\psi_1-\psi_2)ds\ , \tag{5.12}$$

where $\partial/\partial s$ and $\partial/\partial n$ denote the partial differentiations along the circumferential curve s and the outward normal n to s, respectively. The second integrals in (5.1) and (5.2) are both zero, since $H_1=H_0$ (const) and $H_2=0$, to the present approximation. In order to obtain finite values of the integrals, higher approximation for $\boldsymbol{H}$ should be considered. On the other hand, however, they can be calculated when the electric current and the magnetic field inside the cylinder are given, since they must be transformed into volume integrals of the corresponding components of Lorentz force acting on the cylinder, as

$$\int_C T_{n1} dC = \mu \iint_S (J_2 H_3 - J_3 H_2) dS \,, \tag{5.13}$$

$$\int_C T_{n2} dC = \mu \iint_S (J_3 H_1 - J_1 H_3) dS \,, \tag{5.14}$$

where J_1, J_2 and J_3 are the x_1, x_2 and x_3-components of the current density $\boldsymbol{J}$ and the integrations $\iint_S dS$ should be taken over the cross-sectional area of the cylinder. Since $H_1 = H_0$ and $H_2 = H_3 = 0$ to the present approximation, the integral on the right-hand side of (5.13) is zero and (5.14) is reduced to

$$\int_C T_{n2} dC = \mu \iint_S J_3 H_0 dS \,. \tag{5.15}$$

Consideration of the symmetry of the flow in the present problem yields $X_2 = 0$ in the first case and $X_1 = 0$ in the second case. Hence, no lift appears in both cases.

The drag D^{I} in the first case is then expressed as

$$D^{\mathrm{I}} = \rho \nu V_0 M \int_s \frac{\partial}{\partial s} (\psi_1 - \psi_2) ds \,. \tag{5.16}$$

The only contributions to the above integral will arise from multivalued solutions in ψ_1 and ψ_2. Considering (3.11), (3.12), (3.13) and (3.14), we can readily evaluate the integral, obtaining

$$D^{\mathrm{I}} = 4\pi \rho \nu V_0 M B_0 \,. \tag{5.17}$$

The drag D^{II} in the second case is expressed as

$$D^{\mathrm{II}} = \rho \nu V_0 M \int_s \frac{\partial}{\partial n} (\psi_1 - \psi_2) ds + \mu \iint_S J_3 H_0 dS \,. \tag{5.18}$$

Bearing the boundary condition (4.10) in mind, the above first integral is transformed into a simpler form as:

$$\begin{aligned} \int_s \frac{\partial}{\partial n} (\psi_1 - \psi_2) ds &= \int_s \left\{ -\frac{\partial}{\partial n} (\psi_1 + \psi_2) + 2 \frac{\partial \psi_1}{\partial n} \right\} ds = \int_0^{2\pi} (-u_\theta)_{r=1} d\theta + 2 \int_0^{2\pi} \left(\frac{\partial \psi_1}{\partial r} \right)_{r=1} d\theta \\ &= 2 \int_0^{2\pi} \left(\frac{\partial \psi_1}{\partial r} \right)_{r=1} d\theta \,. \end{aligned} \tag{5.19}$$

Making use of the relation given in the footnote in §4, this can be evaluated, giving

$$2 \int_0^{2\pi} \left(\frac{\partial \psi_1}{\partial r} \right)_{r=1} d\theta = 4\pi k \{ A_0 (I_1 K_0 - I_0 K_1) + \sum_{n=1}^{\infty} A_n (I_{n+1} K_n - I_n K_{n-1} - I_n K_{n+1} + I_{n-1} K_n) \,, \tag{5.20}$$

where the argument $k = M/2$ of the functions I_n and K_n is omitted for brevity.

Next, we shall calculate the second integral in (5.18). Since, as was shown in §2, there exists the constant electric field $E_3 = \mu V_0 H_0$ in the second case, constant current density $J_3 = \sigma^* \mu V_0 H_0$ must appear inside the cylinder, where σ^* is the electric conductivity of the cylinder. Then, we can easily evaluate the integral, obtaining

$$\mu \iint_S J_3 H_0 dS = \pi a^2 \sigma^* \mu^2 V_0 H_0^2 = \rho \nu V_0 \pi \left(\frac{\sigma^*}{\sigma} \right) M^2 \,. \tag{5.21}$$

Substituting (5.20) and (5.21) into (5.18), we have

$$\begin{aligned} D^{\mathrm{II}} = 4\pi \rho \nu V_0 \Big[& \frac{1}{2} M^2 \{ A_0 (I_1 K_0 - I_0 K_1) \} \\ & + \sum_{n=1}^{\infty} A_n (I_{n+1} K_n - I_n K_{n-1} - I_n K_{n+1} + I_{n-1} K_n) + \frac{1}{4} \left(\frac{\sigma^*}{\sigma} \right) M^2 \Big] \,. \end{aligned} \tag{5.22}$$

Thus, we have obtained the expressions for the drag (5.17) in the first case and (5.22) in the second case, respectively. We have now only to calculate B_0 by (4.23) and (4.26), and the A_n's by (4.29) and (4.30), respectively. For small values of M, B_0 and the A_n's are obtained to the order of M as follows:

$$B_0=\frac{2}{M(2\Omega+1)}\left\{1-\frac{4\Omega+1}{2\Omega+1}\left(\frac{M}{4}\right)^2+O(M^4)\right\}, \tag{5.23}$$

$$A_0=-\frac{2}{M(2\Omega-1)}\left\{1-\frac{8\Omega+1}{2\Omega-1}\left(\frac{M}{4}\right)^2+O(M^4)\right\}, \tag{5.24}$$

$$A_1=\frac{2}{M(2\Omega-1)}\left\{\left(\frac{M}{4}\right)^2+O(M^4)\right\}, \tag{5.25}$$

where $\Omega=-\{\gamma+\ln(M/4)\}$, $\gamma=0.57721\cdots$ being Euler's constant. The drag coefficients $C_{D^{\mathrm{I}}}=D^{\mathrm{I}}/\rho\nu V_0$ and $C_{D^{\mathrm{II}}}=D^{\mathrm{II}}/\rho\nu V_0$ are given to the order of M^2 by

$$C_{D^{\mathrm{I}}}=\frac{8\pi}{2\Omega+1}\left\{1-\frac{4\Omega+1}{2\Omega+1}\left(\frac{M}{4}\right)^2+O(M^4)\right\}, \tag{5.26}$$

and

$$C_{D^{\mathrm{II}}}=\frac{8\pi}{2\Omega-1}\left\{1-\frac{8\Omega^2+4\Omega+1-2(2\Omega-1)^2(\sigma^*/\sigma)}{2\Omega-1}\left(\frac{M}{4}\right)^2+O(M^4)\right\}, \tag{5.27}$$

respectively.

Table I. Drag coefficients *versus* Hartmann numbers

M	$C_{D^{\mathrm{I}}}$	$C_{D^{\mathrm{II}}}(\sigma^*/\sigma=0)$	$C_{D^{\mathrm{II}}}(\sigma^*/\sigma=1/2)$	$C_{D^{\mathrm{II}}}(\sigma^*/\sigma=1)$	$C_{D^{\mathrm{II}}}(\sigma^*/\sigma=2)$
0	0	0	0	0	0

1.0	8.63	—	—	—	—

Numerical values of $C_{D^{\mathrm{I}}}$ and $C_{D^{\mathrm{II}}}$ for various values of M and σ^*/σ have been computed by (5.26) and (5.27), respectively. They are tabulated in Table I and are shown graphically in Fig. 2. It will be seen that the drag is always greater in the second case than in the first case for the same values of M.

§ 6. Conclusion

We have considered the flow of a viscous and electrically conducting fluid past a circular cylinder in a uniform magnetic field. Analysis has been carried out in the limiting case where both the Reynolds number R and the magnetic Reynolds number R_m vanish, while the pressure number S is infinite so that the Hartmann number M is finite. It is worth noticing that appropriate solutions can be obtained for the two-dimensional flow past a circular cylinder in the present case in spite of $R=0$, for

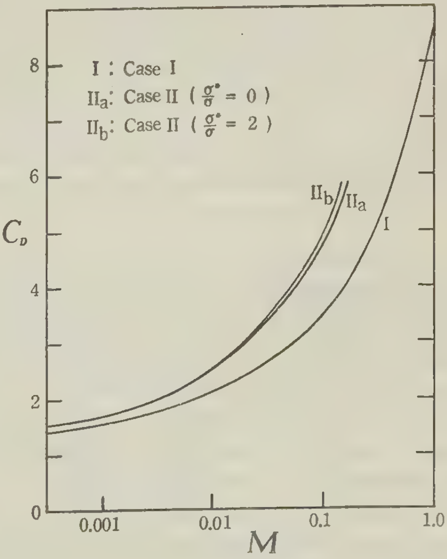

Fig. 2. Drag coefficients *versus* Hartmann number.

which no reasonable solution can be obtained in the classical case.

It will be expected that the present analysis can be generalized for the flow passing across a uniform magnetic field obliquely. Inspecting the linearized equations for the present problem, (2.23) and (2.24), and the boundary conditions at the surface of the cylinder, (4.9) and (4.10), an appropriate linear combination of the present solutions in the first and the second cases will yield the solution for such flow.

For a flow at finite Reynolds and magnetic Reynolds numbers, with finite pressure number, a new method of solution should be devised, which will be discussed in another paper to be published in a near future.

Acknowledgement

In conclusion, the writers wish to express their cordial thanks to Professor S. Tomotika for his continual guidance and encouragement, and especially for his kind inspection of the manuscript.

Statistical Aspects of Fracture in Concrete, I.

An Analysis of Flexural Failure of Portland Cement Mortar from the Standpoint of Stochastic Theory

By Motoo HORI

Central Research Laboratory, Onoda Cement Co., Ltd., Tokyo, Japan

(Received June 5, 1959)

An application of the theory of stochastic processes to the static fracture of non-homogeneous brittle materials such as portland cement concrete is presented. A large number of flexural failure tests on standard mortar specimens made in accordance with JIS have been performed under constant loads as well as under uniformly increasing loads, and the results are analyzed statistically from the standpoint of stochastic theory. It is concluded that the scatter observed in the breaking time or the static strength of concrete appears to be a result of inherent characteristics of the material itself associated with a Markoff process as a kind of rate process.

§ 1. Introduction

It is well known that the results of mechanical strength tests on solid materials generally show a remarkable scatter even under assumably identical conditions. Recent studies indicate that most of the observed scatter cannot necessarily be attributed to the impropriety of testing techniques or the inhomogeneity of test specimens, but must rather be considered as due to inherent characteristics of the material itself. In fact, it appears that the phenomenon of rupture in solids may be usually interpreted as a kind of Markoff process from the standpoint of stochastic theory. The theory of stochastic processes was first applied to the brittle fracture of glass by M. Hirata[1),2)], and then extended to various types of failure of polycrystalline metals and polymeric substances by T. Yokobori[3)] and B. D. Coleman[4)] respectively. This theory accounts not only for the structure sensitivity of mechanical breakdown, but also for its time dependence, in contrast to the classical extreme-value theories based on the weakest-link concept[5].

In non-homogeneous brittle materials, such as portland cement concrete, however, the stochastic-process model for fracture has not yet been applied, since the essential fluctuations associated with a Markoff process cannot easily be distinguished from the statistical variations caused by the macroscopic heterogeneity of test pieces. In order to verify the applicability of the stochastic theory to the static fracture of concrete, therefore, a large number of flexural failure tests on the standard mortar specimens as specified in JIS R 5201–1956 have been carried out under a series of sustained loads, as well as under loads increasing at a uniform rate used in the conventional strength test.

§ 2. Test Specimens

Test specimens were prepared in accordance with the Japanese Industrial Standard on "the Physical Testing Method of Cement" (JIS R 5201–1956) with some modifications as below. Extreme care was taken to reduce the apparent dispersion of test results due to non-uniformity of the specimens as much as possible.

(i) *Materials used.* Cement: Ordinary portland cement (Onoda Cement Co., Ltd.). Aggregate: Standard sand from Toyoura district.

(ii) *Mix proportion.* Water-cement ratio by weight 0.55. Cement-sand ratio by weight 1 : 2. Flow 195 mm.

(iii) *Type of specimens.* Prisms with the dimensions of 40×40×160 mm.

(iv) *Number of specimens.* At least about 100 specimens from three batches of mortar.

(v) *Mixing.* By means of a concrete mixer.

(vi) *Molding.* Two layers of mortar in molds, each layer compacted with 15 strokes by a tamping rod.

(vii) *Capping and demolding.* 8 and 24 hours after molding.

(viii) *Curing.* 24 hours in moist air, and subsequently, 27 days in lime-saturated water.

(ix) *Temperature and humidity.* Temperature: 20±1°C. Relative humidity: Not less than 80 and 90 per cent in the testing room and the moist air, respectively.

§ 3. Testing Procedure and Equipments

As preliminary experiments for checking the homogeneity of the specimens prepared, structure-insensitive mechanical properties, such as density and modulus of elasticity, were measured prior to rupture tests. Bulk density was determined within ±0.5 per cent by weighing. Dynamic modulus of elasticity was determined by using the so-called sonic resonance tests, namely, by measuring the fundumental flexural resonant frequency with a frequency monitor accurate to ±2 per cent, in accordance with "the Tentative Method of Test for Fundumental Transverse, Longitudinal, and Torsional Frequencies of Concrete Specimens" (ASTM C 215–58 T).

The flexural failure tests were carried out carefully by means of a bending strength tester of Michaelis double lever type as described in JIS R 5201–1956, which applied the load at the center point of a 10-cm span. In the conventional static strength measurements, the loading was adjusted strictly to the specified rate of 5 kg per second, corresponding to the increase in extreme-fiber stress of 1.17 kg/cm² per second. In the sustained loading experiments, the load was applied as quickly as possible without producing vibra-

Table I. Number of the specimens tested.

Loading condition	Bulk density	Dynamic modulus of elasticity	Static flexural strength	Breaking time under constant load
I (1.17 kg/cm²/sec)	116	116	116	0
II 60.0 kg/cm²	97	97	20	77
III 62.0 kg/cm²	116	116	18	98
IV 66.1 kg/cm²	116	116	16	100
V 67.5 kg/cm²	97	97	12	85
VI 71.5 kg/cm²	113	32	18	95
VII 75.7 kg/cm²	111	111	18	93
Total	766	685	218	548

tion, and then the time required for fracture under the constant load was measured with a stop-watch.

Seven series of flexure tests were conducted under different loading conditions, using more than some 100 specimens for each series. In the first series, the conventional flexural strength was measured at the specified rate of loading on a total of 116 test specimens. In each of other six series, however, most of the specimens were tested under the constant load, except about 10 to 20 specimens randomly selected for the conventional strength measurements. These series of sustained loading experiments were performed at the extreme-fiber stresses of 60.0, 62.0, 66.1, 67.5, 71.5 and 75.7 kg/cm² respectively. (See Table I.)

§ 4. Results of Preliminary Tests

The results of preliminary tests on the bulk density and the dynamic modulus of elasticity are presented in Table II, which gives the coefficient of variation within the limits of instrumental error. It is shown, therefore, that all the specimens tested may be regarded as practically uniform, so far as the structure-insensitive properties are concerned.

Table II. Results of preliminary tests.

	Bulk density	Dynamic modulus of elasticity
Number of specimens	766	685
Mean	2.16 g/cm³	2.79×10^5 kg/cm²
Standard deviation	6.8×10^{-3} g/cm³	5.3×10^3 kg/cm²
Coefficient of variation	0.32%	1.9%

The test results for the static flexural strength are summarized in Table III. The analysis of variance confirms that the variation in the average strengths for different series is not significant at the confidence level of 95 per cent, and consequently, that all the samples can be considered as having been drawn at random from a normal population. In fact, the frequency distribution of the flexural strength as a whole is approximately normal, as may be seen from the histogram in Fig. 1. The coefficient of variation is estimated at about 5.3 per cent, much greater than for the density or the modulus of elasticity, but rather small considering the structure sensitivity of the fracture process.

Table III. Test results for the static flexural strength.

Series	Number of test specimens	Average strength (kg/cm²)	Standard deviation (kg/cm²)	Coefficient of variation (%)
I	116	71.7	3.9	5.4
II	20	70.7	3.5	5.0
III	18	69.9	3.3	4.8
IV	16	69.6	4.5	6.5
V	12	71.2	2.7	3.8
VI	18	71.5	3.5	4.9
VII	18	72.1	3.6	5.0
Total	218	71.3	3.8	5.3

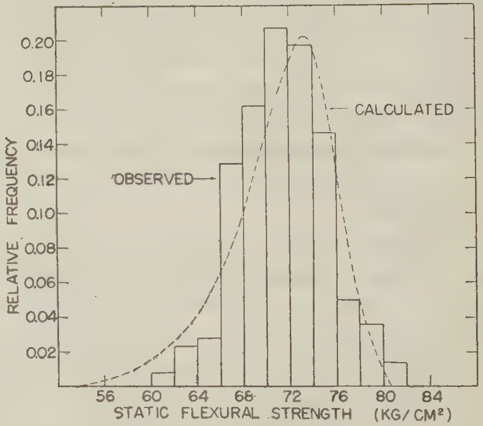

Fig. 1. Frequency histogram of the static flexural strength.

Table IV. Comparative data for the strongest and the weakest specimens.

	Specimen	Flexural strength (kg/cm²)	Bulk density (g/cm³)	Dynamic modulus of elasticity (10^5kg/cm²)
Strongest	S—I	80.9	2.16	2.81
	S—II	80.5	2.15	2.73
	S—III	80.3	2.15	2.79
	Mean	80.6	2.15	2.78
Weakest	W—III	62.1	2.17	2.84
	W—II	61.8	2.16	2.77
	W—I	60.5	2.15	2.79
	Mean	61.5	2.16	2.80

Furthermore, the regression analysis indicates that none of the correlations of the static strength with the density and the modulus of elasticity are significant at the confidence level of 95 per cent. As shown in Table IV, for example, no significant difference can be detected even between the structure-insensitive quantities measured on the strongest and the weakest specimens. This fact may also be taken as an indirect evidence that the homogeneity of the specimens used was quite satisfactory.

§ 5. Results of Sustained Loading Tests

It should be noticed that all the specimens tested under a constant load will not break at the same time, but there will be a characteristic distribution of breaking times. The results of sustained loading experiments actually show that the scatter of the delayed time for fracture under constant loads is much wider than that of the static strength, and that the frequency distribution is too positively skewed to be considered as normal.

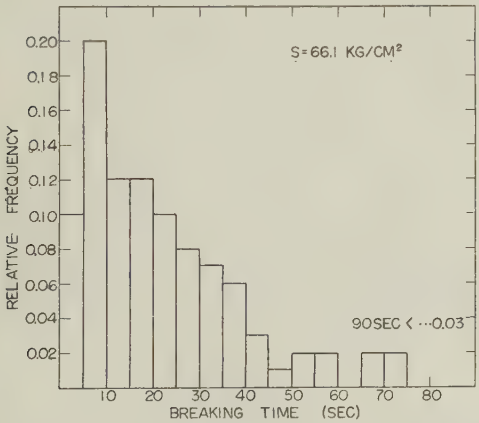

Fig. 2. Typical frequency histogram of the breaking time under a constant load.

As a typical example, the frequency histogram for the breaking times at the extreme-fiber stress of 66.1 kg/cm² is illustrated in Fig. 2. The distribution curves of breaking times under various constant loads are about the same in general trend, although the average time or the most probable time decreases rapidly with increasing load.

§ 6. Application of the Stochastic-Process Theory

The problems on the initiation of fracture appear to be explained in terms of a Markoff process. Let us take this approach in the present case, adopting the instant of load application as the origin of time t. If the transition probability of fracture, $\mu(t)dt$, is defined as the probability that a specimen known to be unbroken at a time t will break in the next time interval dt, then

$$\mu(t)dt = = -\frac{dP(t)}{P(t)} = -d\{\log P(t)\}\ , \qquad (1)$$

where $P(t)$ denotes the probability that the fracture has not yet occurred at time t, that is, the cumulative distribution function of survival. On integrating Eq. (1), we obtain

$$P(t) = \exp\left\{-\int_0^t \mu(t)dt\right\}\ . \qquad (2)$$

The probability density function of the breaking time can be written as

$$q(t) = -\frac{dP(t)}{dt} = \mu(t)\exp\left\{-\int_0^t \mu(t)dt\right\}\ . \qquad (3)$$

Hence, the mode t_m, the mean $\bar{t}$, and the variance σ_t^2 are given by

$$\left.\frac{d\mu(t)}{dt}\right|_{t=tm} = \mu^2(t_m)\ , \qquad (4)$$

$$\bar{t} = \int_0^\infty tq(t)dt = \int_0^\infty P(t)dt\ , \qquad (5)$$

$$\sigma_t^2 = \int_0^\infty t^2q(t)dt - \left\{\int_0^\infty tq(t)dt\right\}^2\ . \qquad (6)$$

In actual failure tests, the probability functions defined above may be directly determined from the observed histogram of breaking times. We shall now consider an ensemble of the specimens used in each experiment, and denote the number of specimens that survive without breaking to time t by $n(t)$. If the initial size of the ensemble N is very large, $n(t)$ will be related to $P(t)$ by

$$P(t) = \frac{1}{N}n(t)\ , \qquad (7)$$

with fluctuations that become negligible as N approaches infinity. On the other hand, if we consider a finite set of test specimens, the probability $P_n(t)$ that at a given time t there are n unbroken specimens left in our sample is obviously

$$P_n(t) = \frac{N!}{n!\,(N-n)!}P^n(t)\{1-P(t)\}^{N-n}\ . \qquad (8)$$

The average number of survivors at a given time is therefore

$$\bar{n}(t)=\sum_{n=N}^{0} nP_n(t)=NP(t) \,, \tag{9}$$

with a variance

$$\sigma_n{}^2(t)=\sum_{n=N}^{0}(n-\bar{n})^2P_n(t)=NP(t)\{1-P(t)\} \,. \tag{10}$$

These equations confirm that if one replace $n(t)$ by its average value $\bar{n}(t)$ Eq. (7) is vaild even for finite N, and that the coefficient of variation in $n(t)$ goes to zero with increasing N as $N^{-1/2}$.

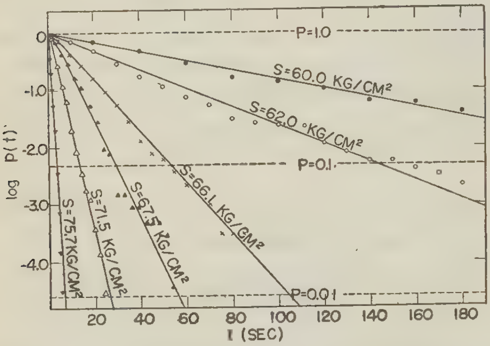

Fig. 3. Time dependence of the cumulative distribution function of survival.

When $P(t)$ is calculated in this way from the actual results of our sustained loading tests, the semi-logarithmic plot of $P(t)$ *versus* t for each stress may be represented fairly well by a straight line except some initial deviations, as shown in Fig. 3. The negative tangent of this line gives the transition probability density $\mu(t)$, which is thus found to be almost constant under a sustained load. Putting $\mu(t)=m$, Eqs. (2) and (3) reduce to

$$P(t)=\exp(-mt) \,, \tag{11}$$

$$q(t)=m\exp(-mt) \,, \tag{12}$$

which express a monotonously decreasing distribution with the mean of $1/m$. The initial discrepancy between the ideal distribution (12) and the observed histogram as in Fig. 2 indicates that the time lag required for $\mu(t)$ to reach its final value m is not strictly negligible. Supposing that $\mu(t)$ approaches m with a retardation time of τ, and putting $\mu(t)=m(1-e^{-t/\tau})$, one gets

$$P(t)=\exp[-m\{t-\tau(1-e^{-t/\tau})]\} \,, \tag{13}$$

$$q(t)=m(1-e^{-t/\tau})\exp[-m\{t-\tau(1-e^{-t/\tau})\}] \,. \tag{14}$$

From these considerations, it follows that the theory of stochastic processes can at least approximately be applied to the static failure of such heterogeneous materials as protland cement mortar. Since the static fracture of concrete accompanies necessarily somewhat plastic deformations in contrast with the purely brittle fracture of glass, however, the apparent time dependence of the transition probability density should be considered especially in the initial stage. It is accordingly suggested that the rupture phenomenon of inhomogeneous concrete may not be accurately described as a single process, but rather as two successive events of the formation and growth of critical cracks. If the transition probability densities of these two processes are assumed to be maintained constant in time and denoted by m_1 and m_2, the whole fracture process will be determined by

$$P(t)=\frac{1}{m_2-m_1}\{m_2\exp(-m_1t)-m_1\exp(-m_2t)\} \,, \tag{15}$$

$$q(t)=\frac{m_1m_2}{m_2-m_1}\{\exp(-m_1t)-\exp(-m_2t)\} \,, \tag{16}$$

which are in qualitative agreement with the observed distribution.

§ 7. Relationship of the Transition Probability to Loading Conditions

As illustrated in Fig. 3, it appears that the transition probability for fracture is in general closely related to the applied load. The final value of the transition probability density m is plotted against the applied extreme-fiber stress S in Fig. 4, which shows a roughly linear relationship of $\log m$ to S or $\log S$. Consequently, following two types of empirical formulae are obtained.

$$m=A\exp(\alpha S) \,, \tag{17a}$$

$$m=BS^{\beta} \,. \tag{17b}$$

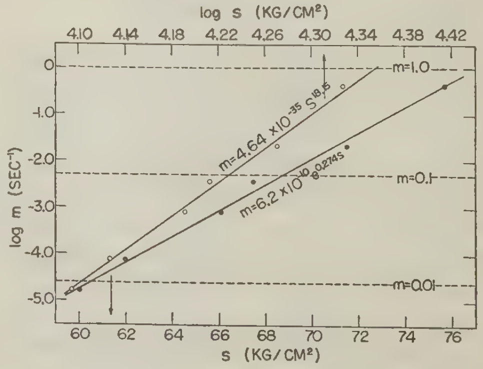

Fig. 4. Transition probability density for fracture plotted against applied extreme-fiber stress.

Here A, α, B, and β are parameters independent of S and in the present case $A=6.2\times10^{-10}$ (sec^{-1}), $\alpha=0.274$ (cm^2/kg), $B=4.64\times10^{-35}$[(cm^2/kg)$^\beta$/sec], and $\beta=18.15$. These two equations produce practically equivalent results over a considerable range of m. The first type can be directly predicted from a simplified theory of absolute reaction rates and has been approximately verified by recent experiments on various materials[1),3),6),7),8)]. The second type has the advantage that it leads to differential equations that are easier to handle than those derived from the first type.

Since the stress distribution within a real specimen is neither macroscopically nor microscopically uniform, the transition probability density of fracture must be defined in any volume element of the material. The weakest-link hypothesis permits us to derive a general superposition principle for calculating the transition probability for the whole volume of the specimen under consideration. This hypothesis states that the probability, $P(t)$, that a specimen composed of N elements has not yet broken at time t is equal to the probability that any element of the specimen has not yet broken at time t, that is to say,

$$P(t)=\prod_{n=1}^{N} P_n(t)\ , \tag{18}$$

where $P_n(t)$ is the probability that the n-th element has a lifetime greater than t. Insertion of Eq. (18) into Eq. (1) thus yields a superposition formula relating to transition probabilities as follows.

$$\mu(t)=\sum_{n=1}^{N} \mu_n(t)\ . \tag{18$'$}$$

Accordingly, the overall transition probability for the specimen under distributed stresses will be written in the integral form

$$\mu(t)\cong m=\iiint_V \rho(S)dV\ , \tag{19}$$

where V represents the loaded volume of the specimen. In analogy to Eq. (17b), for example,

$$m=\frac{B'}{V}\iiint_V S^\beta dV\ , \tag{19$'$}$$

where B' is a constant regardless of S. Equation (19) gives a mathematical expression of the so-called size effect of strength, implying that the breaking probability increases as the specimen volume increases.

As an example, we shall compare the breaking probabilities in tension and bending tests. While a macroscopically uniform distribution of uniaxial tensile stresses is realized in tension tests, a linear distribution of tensile and compressive stresses is induced by a bending moment in flexure tests. The transition probability for rupture under the uniform tensile stress $S=S_0$, m_t, is given by

$$m_t=\frac{B'}{V}\iiint_V S^\beta dV=B'S_0{}^\beta\ . \tag{20}$$

On the other hand, for a rectangular beam with a breadth of $2b$, a height of $2h$, and a span length of $2l$ subjected to pure bending, it is readily seen that the stress variation across a cross section becomes $S=S_0(x/h)$, where S_0 is the maximum tensile stress on the extreme fiber and x is the distance from the neutral axis. Substitution of this stress function into Eq. (19$'$) yields

$$\begin{aligned} m_b&=\frac{B'}{8bhl}\cdot 2b\cdot 2l\cdot S_0{}^\beta\int_0^h \frac{x^\beta}{h^\beta}dx\\ &=\frac{B'S_0{}^\beta}{2(\beta+1)}\ . \end{aligned} \tag{21}$$

Hence,

$$\frac{m_b}{m_t}=\frac{B_b}{B_t}=\frac{\bar{t}_t}{\bar{t}_b}=\frac{1}{2(\beta+1)}\ . \tag{22}$$

In the case of $\beta=18.15$, $\bar{t}_b/\bar{t}_t=38.3$. It has long been recognized that the breaking time or the fracture strength is much greater in bending than in tension.

In addition, Eqs. (17) suggest that the phenomenon of stress relaxation in viscoelastic substances also results in the time-dependent behavior of the transition probability discussed in the preceding section. Let us now for simplicity use a three-element Maxwell model, consisting of an elastic spring of modulus E_1 linked in parallel with a Maxwell unit, in which another spring of modulus E_2 is connected in series with a Newtonian dashpot of viscosity η. Then, the stress acting on the pure-spring element E_1 under a total load S_0 varies with time according to

$$S=S_0\left\{1-a\exp\left(-\frac{t}{\tau}\right)\right\}\ , \tag{23}$$

where $a=E_2/(E_1+E_2)$ and $\tau=\eta(E_1+E_2)/(E_1\cdot E_2)$. By substituting Eq. (23) into Eq. (17b) and taking $m_0=BS_0{}^\beta$, we get

$$m = BS^{\beta} = m_0\left\{1 - a\exp\left(-\frac{t}{\tau}\right)\right\}^{\beta}, \qquad (24)$$

which is found to give a frequency distribution of breaking times qualitatively similar to Eq. (14). It is natural to expect that the time constant of breaking probability is of the same order of magnitude as that of viscoelasticity.

§ 8. Considerations as a Rate Process

The rupture phenomenon usually seems to be understood as a kind of rate process associated with the nucleation or the propagation of critical cracks from a microscopic point of view[3),8),9),10),11)]. The theory of absolute reaction rates as developed originally by H. Eyring[12)] leads to

$$I = \frac{ZkT}{h}\exp\left\{-\frac{F(S)}{kT}\right\}, \qquad (25)$$

for the rate of a stress-dependent rate process, which corresponds to the transition probability density introduced above, $\mu(t)$, for the breaking process. Here Z is the number of atoms available for the reaction, $F(S)$ is the free energy of activation, T is the absolute temperature, k is Boltzmann's constant, and h is Planck's constant. Replacing $F(S)$ by a Taylor's expansion about $S=0$ and neglecting all terms after the second, or assuming $F(S) = F_0 - \alpha' S$, we can write

$$I = \frac{ZkT}{h}e^{-F_0/kT}\exp\left(\frac{\alpha'}{kT}S\right). \qquad (25')$$

It thus turns out that the theoretical rate equation gives as a first approximation an apparently identical expression with the empirical formula (17a). Without taking account of the effects of stress-concentrating flaws and stress relaxation, however, the experimental values of the activation free energy obtained from Eq. (17a) are not necessarily consistent with its molecular interpretation[8)].

The theory of rate processes provides a reasonable explanation for the marked dependence of the breaking time on temperature and humidity. The rate equation (25) points out that the rate of fracture should increase rapidly with increasing temperature, provided that the free energy of activation does not depend significantly upon temperature. On the contrary, the effects of moisture adsorption are generally thought to reduce the activation free energy for fracture[2),6)], so that the breaking probability would become small at high temperature because of the evaporation of adsorbed water. As a consequence, the fracture strength of glass reaches a minimum at a temperature of about 200°C[2),13),14)]. In the case of concrete containing a considerable amount of water, it might be expected that the breaking time would vary in a more complicated manner with the temperature and humidity of surrounding medium. In practice, experimental observations have shown that the flexural strength of concrete has a relatively high value in dry atmosphere or at low temperature.

§ 9. Statistical Interpretation of the Static Strength

In this section, the conventional static strength in a constant rate of loading experiment will be analyzed from the standpoint of the theory of stochastic processes. Denoting the rate of loading as v, we have

$$\mu[S(t), t] \cong m[S(t)] = m(vt), \qquad (26)$$

where the time dependence of the transition probability under a constant load is neglected. Therefore, Eqs. (2) and (3) reduce to

$$P'(S) = \exp\left\{-\frac{1}{v}\int_0^S m(S)dS\right\}, \qquad (27)$$

$$q'(S) = \frac{1}{v}m(S)\exp\left\{-\frac{1}{v}\int_0^S m(S)dS\right\}. \qquad (28)$$

The mode S_m, the mean $\bar{S}$, and the variance $\sigma_S{}^2$ are given by

$$v\frac{dm(S)}{dS}\bigg|_{S=S_m} = m^2(S_m), \qquad (29)$$

$$\bar{S} = \int_0^\infty Sq'(S)dS = \int_0^\infty P'(S)dS, \qquad (30)$$

$$\sigma_S{}^2 = \int_0^\infty S^2 q'(S)dS - \left\{\int_0^\infty Sq'(S)dS\right\}^2. \qquad (31)$$

These equations can be used to predict the results of a static strength measurement from a knowledge of the functional form of $m(S)$ obtained by the dead loading experiment. According to Eq. (17a),

$$P'(S) = \exp\left\{-\frac{A}{\alpha v}(e^{\alpha S} - 1)\right\}, \qquad (27a)$$

$$q'(S) = \frac{A}{v}\exp\left\{\alpha S - \frac{A}{\alpha v}(e^{\alpha S} - 1)\right\}, \qquad (28a)$$

$$S_m = \frac{1}{\alpha}\log\left(\frac{\alpha v}{A}\right), \qquad (29a)$$

$$\bar{S}=\frac{1}{\alpha}e^{A/\alpha v}\int_{A/\alpha v}^{\infty}e^{-x}\frac{dx}{x}=\frac{1}{\alpha}\left\{\log\left(\frac{\alpha v}{A}\right)+\int_{A/\alpha v}^{\infty}\log x\cdot e^{-x}dx\right\}, \tag{30a}$$

$$\sigma_S{}^2=\frac{1}{\alpha^2}e^{A/\alpha v}\left[\int_{A/\alpha v}^{\infty}(\log x)^2e^{-x}dx-e^{A/\alpha v}\left\{\int_{A/\alpha v}^{\infty}\log x\cdot e^{-x}dx\right\}^2\right]. \tag{31a}$$

For large values of $\alpha v/A$, Eqs. (30a) and (31a) become nearly

$$\bar{S}\cong\frac{1}{\alpha}\left\{\log\left(\frac{\alpha v}{A}\right)-\gamma\right\}, \tag{30a$'$}$$

$$\sigma_S{}^2\cong\frac{\pi^2}{6\alpha^2}. \tag{31a$'$}$$

Here γ is Euler's constant $(0.5772\cdots)$. According to Eq. (17b),

$$P'(S)=\exp\left\{-\frac{BS^{\beta+1}}{(\beta+1)v}\right\}, \tag{27b}$$

$$q'(S)=\frac{BS^{\beta}}{v}\exp\left\{-\frac{BS^{\beta+1}}{(\beta+1)v}\right\}, \tag{28b}$$

$$S_m=\left(\frac{\beta v}{B}\right)^{1/(\beta+1)}, \tag{29b}$$

$$\bar{S}=\Gamma\left(\frac{\beta+2}{\beta+1}\right)\left\{\frac{(\beta+1)v}{B}\right\}^{1/(\beta+1)}, \tag{30b}$$

$$\sigma_S{}^2=\left\{\Gamma\left(\frac{\beta+3}{\beta+1}\right)-\Gamma^2\left(\frac{\beta+2}{\beta+1}\right)\right\}\left\{\frac{(\beta+1)v}{B}\right\}^{2/(\beta+1)}, \tag{31b}$$

where Γ denotes the gamma function.

The numerical values of two parameters in Eq. (17a), $A=6.2\times10^{-10}$ (see^{-1}) and $\alpha=0.274$ (cm^2/kg), which were determined from the results of dead-loading flexure tests, were inserted into Eq. (28a) to obtain the theoretical distribution curve of the static flexural strength at the specified rate of loading $v=1.17$ (kg/cm^2/sec), shown in Fig. 1. Inspection of Fig. 1 indicates that the agreement between theory and experiment for the strength distribution is fairly good. As a matter of fact, the average value $\bar{S}=71.1$ (kg/cm^2) and the standard deviation $\sigma_S=4.7$ (kg/cm^2) for the predicted distribution are in satisfactory agreement with those for the observed histogram. (See Table III.). Although the negative skewness of the theoretical curve, $k=-1.14$, seems inconsistent with approximate normality of the experimental distribution, this discrepancy is probably due to the initial time dependence of the transition probability density $\mu(t)$. Consequently, it follows that most of the statistical variations in the results of static strength tests on concrete may be regarded as essential fluctuations associated with a stochastic process.

It is worth while to note that the dynamic theory of stochastic processes is equivalent to the static theory of extreme-value statistics based upon the weakest-link concept, as far as the static behavior of strength is concerned. It is evident that the distribution function of the static strength (27) is compatible with the weakest-link hypothesis (18) regardless of the functional form of $\mu(t)$ or $m(S)$. In addition, Eqs. (27a) and (27b) are identical in form to the first (exponential-type) and the third (Weibull-type) asymptotic distributions for the smallest values in extreme-value statistics respectively[15]. This implies that all the conclusions that J. Tucker[16] derived previously by applying W. Weibull's theory[17] to concrete must also be drawn from the standpoint of the present theory.

The stochastic-process theory permits a successful interpretation of the dependence of the observed strength on testing speed, sample size, stress distribution, temperature, humidity, and other influencing factors. For example, there exists considerable experimental evidence[18] to Eq. (29a) showing that the strength of concrete increases logarithmically with the rate of loading. Weibull's formula[17] in regard to the size effect of strength, $S_m\propto V^{-1/(\beta+1)}$, can be obtained immediately by noting that the parameter B in Eq. (29b) is proportional to the volume of the specimen V. For the ratio of the flexural strength S_{mb} to the tensile strength S_{mt}, Eqs. (29b) and (22) yield $S_{mb}/S_{mt}=(B_t/B_b)^{1/(\beta+1)}=(2\beta+2)^{1/(\beta+1)}$. The numerical value of $S_{mb}/S_{mt}=1.21$ for $\beta=18.15$ turns out to be somewhat too small compared with the experimental data[19], probably because this treatment ignores the presence of plastic deformations in concrete. The effects of temperature and humidity on the static strength of concrete will be discussed quantitatively in a future publication.

§ 10. Conclusions

The results of flexural failure tests on the standard mortar specimens prepared in accordance with JIS 5201-1956 have been analyzed statistically from the standpoint of the stochastic theory. It is concluded that the scatter observed in the delayed time for fracture or the static fracture strength of portland cement mortar appears to be a result of inherent characteristics of the material itself associated with a Markoff process as a kind of rate process. The theory of stochastic processes is therefore believed to be at least approximately applicable to the static failure of such inhomogeneous materials as concrete. More detailed investigations on the statistical aspects of rupture in concrete are now in progress and will be presented in the succeeding papers of this series.

In conclusion, the author expresses his sincere thanks to Prof. M. Hirata, University of Tokyo, for his suggestions and encouragement during the course of this work.

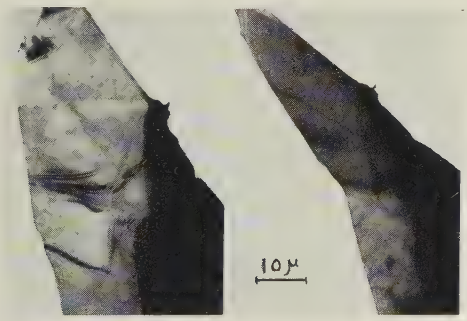
Energy Loss of Electrons passing through a Graphite Single Crystal at Different Incident Angles*

By Hiroshi WATANABE
Hitachi Central Research Laboratory
Kokubunji, Tokyo, Japan

(Received August 1, 1959)

When fast electrons pass through a thin solid foil, they excite plasma oscillation and lose the energy characteristic to the material of the foil. Ichikawa[1)] found theoretically that the characteristic energy loss value for graphite single crystal depends upon the incident angle of the fast electrons, and he pointed out that the experimental values at different incident angles give us information about the resonance energy parameters of graphite. Using the electron velocity analyzer of Möllenstedt type[2),3)], we measured the characteristic loss values for graphite at incident angles 0° and 45°.



(a) (b)

Fig. 1. Electron micrographs of a single crystal foil (a) the incident beam is parallel to c-axis, i.e. $\Theta=0°$, (b) $\Theta=45°$.

Fig. 1a and 1b give electron micrographs of a thin foil of graphite prepared by stripping. The angle Θ between the incident electron beam and c-axis of the crystal is 0° in Fig. 1a and 45° in Fig. 1b. The energy of electrons which have passed through the central portion (ca. $2\,\mu\times10\,\mu$) of the foil was analyzed. The result is given in Table I, which shows that the loss value *does not* depend upon the incident angle Θ.

Table I. The energy loss value of 25 kev electrons at incident angles of 0° and 45°.

Θ	energy loss value	number of measurement
0°	6.8±0.2 ev	9
45°	6.8±0.2 ev	13

The plasma frequency of π-electrons in graphite is given by Ichikawa[1)] as

$$\omega_p{}^2=\frac{4\pi ne^2}{m}[1-m/m(\Theta)^*] \qquad (1)$$

where

$$1/m(\Theta)=\frac{1}{2\hbar^2}\left[\sin^2\Theta+\frac{1}{2}\cdot\frac{\gamma_1}{\gamma_0}\cdot\left(\frac{c}{a}\right)^2\cdot\cos^2\Theta\right]a^2\gamma_0 \qquad (2)$$

and γ_0, γ_1 are the resonance energy between the nearest neighbors in a lattice layer and that between the nearest neighbors in the successive two layers, respectively. When $\Theta=0°$ in Eq. (2), ω_p depends only upon γ_1. Thus the γ_1 is estimated to be 0.33 ev from the energy loss value at $\Theta=0°$, being consistent with currently evaluated value of 0.2–0.5 ev[4),5)]. From the present result that the loss value does not depend upon the incident angle, γ_0 is estimated to be about 1.6 ev. Hove[4)] obtained 1.63 ev from a calculation of the magnetic susceptibility, and Noziére[6)] 2 ev from the cyclotron resonance and infra-red data. Our result 1.6 ev is in a good agreement with these values.

Nuclear Magnetic Resonance of Na^{23} in Sodium Chloride Crystals

By Eizo OTSUKA, Yudo OSHIO, Toyohide KOBAYASHI
and Hazimu KAWAMURA

Department of Applied Physics, Osaka City University, Osaka

(Received August 20, 1959)

The nuclear resonance line width of Na^{23} in a NaCl crystal usually observed is rather broader than the one calculated by the Van Vleck formula[1] for the dipolar broadening. The extra line width has been thought to arise from the satellites broadened an account of the internal strains through quadrupole interaction[2]. If this is true, the more perfect is the crystal, the narrower will be the line width. With this end in view, we have grown two single crystals of NaCl, which could seemingly avoid the fatal multiplication of dislocations. Moreover, the starting materials for the crystals were those obtained through careful precrystallization.

The observed second moments of the resonance lines of Na^{23} in these crystals are very small as expected. The data obtained from the measurements for the lower half of the crystal A in Fig. 1 are listed in Table I for two directions of the external magnetic field. For comparison we have also listed the calculated values for dipolar interaction, together with the observed ones for an ordinary NaCl crystal which was used in a former experiment[3] as a standard specimen as well as for a ten percent deformed crystal. The best crystal gives the values equal to the theoretical dipolar widths within the experimental errors. The deformed crystal also yields small values; however, this is caused by the run-away of the satellites as proved by the intensity measurement. The ordinary crystal lies in an intermediate situation and the rather large difference between the values of the second moments for the two directions would be attributed to the anisotropy due to crystal dislocations similar to that discussed in a previous paper[4]. From simple analyses[3)-6)] it is roughly estimated that the dislocation densities for the best, ordinary and deformed crystals are $c<10^7$, $c=3\sim4\times10^8$ and $10^9<c<10^{10}\,\mathrm{cm}^{-2}$, respectively.

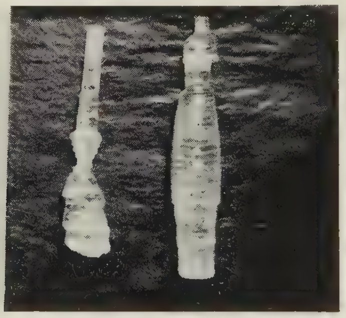

Fig. 1. The two single crystals of NaCl referred to from left to right as A and B in the text. The scale is shown for comparison.

Table I. Second moments in gauss^2.

Crystal	$H_0//[100]$	$H_0//[110]$
A	0.54 ± 0.04	0.54 ± 0.02
Ordinary crystal	1.24 ± 0.07	1.00 ± 0.04
Deformed crystal	0.53 ± 0.04	0.54 ± 0.03
Theoretical	0.555	0.550

Table II. T_1 by pulse-method at room temperature.

Crystal	T_1 in sec.
A	16.0
B	15.4
Ordinary crystal	12.5
Mixed crystal[3] (0.81 NaCl. 0.19 NaBr)	12.4

We have been interested also in the spin-lattice relaxation time of various kinds of NaCl crystals. Using a cross-coil system, we have measured T_1's for a couple of crystals by the consecutive 90° pulse method[7]. The results are shown in Table II. It should be understood that the experimental error is of the order of ten percent. The order of length of T_1, however, is consistent with a preliminary saturation experiment.

In conclusion, the extra-width of the nuclear resonance line of Na^{23} in NaCl is due to lattice imperfections as expected and the spin-lattice relaxation time is sample-dependent. It is not yet certain whether one should account for the difference of T_1 as arising from different purities or other types of imperfections such as dislocations.

Piezoelectric Effect in a Rectifying Contact of Semiconductor

By Tetsuro TANAKA and Hiroyoshi KAWAMURA
Institute for Chemical Research, Kyoto University, Kyoto

(Received August 1, 1959)

There is a space charge layer in a rectifying contact of metal rectifier or *p–n* junction, which brings the potential gradient in the layer. As the thickness of the space charge layer and accordingly the quantity of total space charge vary with the applied voltage, the barrier acts as a capacitor and the capacitance is the same as for a parallel plate capacitor. As the inter-electrode spacing of this capacitor is in equilibrium with the applied voltage, this construction is apparently similar to that of a condenser-microphone, and when mechanical force is applied to this capacitor, electromotive force appears between the two electrodes.

A barium titanate ceramic disc was attached on the non-rectifying side of selenium rectifier as shown in Fig. 1(a) for applying a vibrating force on the contact. The metal bodies on both sides serve to give a uniform vibrating force to the barrier. The output voltage at no biasing state may be related to the diffusion potential V_d, and the output voltage under the biasing voltage V may be related to (V_d+V). Curve (a) in Fig. 2 is a plot of $\log(V_d+V)$ *vs.* output voltage V_{op}.

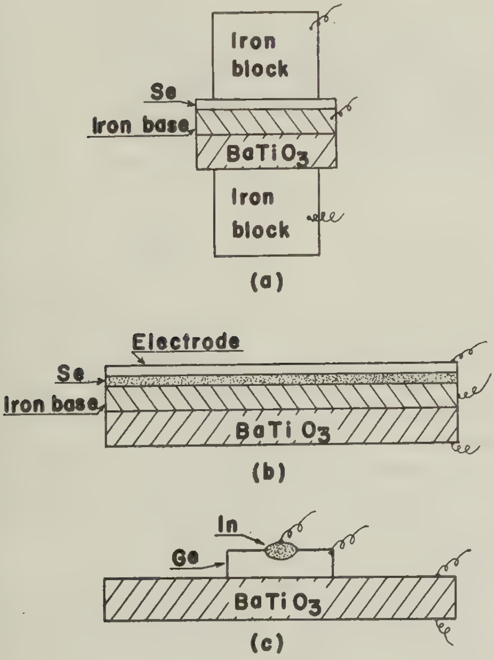

Fig. 1. Schematic diagram of specimens.

In this case, the vibrating force acts in the direction perpendicular to the barrier surface. It is seen that V_{op} is proportional to $(V_d+V)^{1/3}$. The value of V_d derived from the relation between V and barrier capacitance C was about 0.7 volts. In another experiment, specimen as shown in Fig. 1(b) was used. In this case the vibrating force was applied in the direction parallel to the barrier surface. From the results shown in Fig. 2 (b), V_{op} is approximately proportional to $(V_d+V)^{1/2}$ for this specimen. The value of V_d was also 0.7 volts.

A germanium *p–n* junction was attached on a barium titanate ceramic disc as shown in Fig. 1(c), and vibrating force was applied in the direction parallel to the barrier surface. The observed relation between V_{op} and (V_d+V) is shown in Fig. 2(c), where V_d is also 0.7 volts. In this case V_{op} is proportional to (V_d+V).

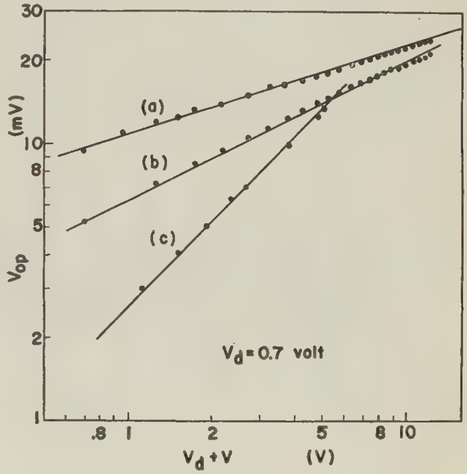

Fig. 2. Characteristic curves of V_{op} *vs.* (V_d+V).

By simple consideration, it may be derived that V_{op} should be proportional to (V_d+V) no matter if the barrier thickness is proportional to $(V_d+V)^{1/2}$ or $(V_d+V)^{1/3}$. The experimental results, however, are different from that are expected from the theory. It has not been clarified whether the discrepancy between theory and experiment came from the incompleteness in theory or from the imperfectness of measuring procedure. But the fact that there exists a remarkable piezoelectric effect in a rectifying contact, and that the output voltage increases with the biasing voltage is very interesting from the standpoint of practical use. More detailed studies will be reported in a near future.

On the Superstructure of the Ordered Alloy Au_3Zn[R]

By Hiroshi IWASAKI

The Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received July 15, 1959)

In the binary system Au–Zn, it is known that the solid solution with a stoichiometric composition Au_3Zn forms the superlattice with long period below 420°C. It is specified as Au_3Zn[H] and is thought to have a Ag_3Mg-type anti-phase domain structure[1]. However, the superlattice is stable only in temperature range 420°C∼270°C and transforms without atomic diffusion into the room-temperature phase Au_3Zn[R] with very complicated structure. Recently, Wilkens and Schubert[2] have studied the structure of this phase using the X-ray powder method and proposed a modified Au_3Zn[H] structure with an orthorhombic unit cell of lattice constants, $a=5.574$ kX, $b=5.583$ kX and $c=16.616$ kX.

The present author also studied the structures of Au_3Zn[R] and Au_3Zn[H] by the single crystal oscillation method, and came to conclude a different structure for Au_3Zn[R]. This structure, specified as $Au_3Zn[R_1]$, has a tetragonal symmetry with a unit cell of lattice constants, $a=5.575\pm0.004$ kX and $c=33.34\pm0.07$ kX*, in which 48 gold atoms and 16 zinc atoms are included. From the clear extinction rule of the observed diffraction spots, the space group was uniquely determined as $D_{4h}^{20}-I4_1/acd$. The atomic positions as shown in Table I were determined by comparing the calculated intensities with the observed ones.

Table I

Kind of atom	Position	x	y	z
Au	16(f)	0.194	0.194	0.250
Au	16(e)	0.250	0.250	0.125
Au	16(d)	0	0	0.059 ± 0.001
Zn	16(d)	0	0	0.181 ± 0.001

The arrangement of atoms is sketched in Fig. 1, in which for the sake of convenience each atom is placed on the lattice point of Au_3Zn[H]. The real structure of $Au_3Zn[R_1]$ is to be obtained by shifting many of the atoms along the direction of arrows.

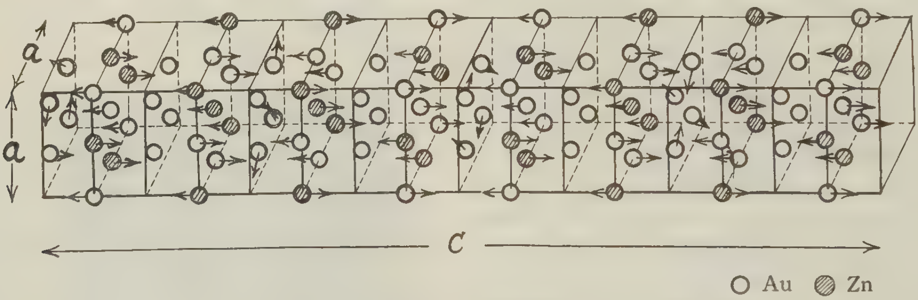

Fig. 1. The arrangement of atoms of $Au_3Zn[R_1]$.

It appears that $Au_3Zn[R_1]$ is a thermodynamically stable phase and is formed at a composition slightly poorer in zinc than stoichiometric Au_3Zn. At a composition richer in zinc than stoichiometric Au_3Zn the formation of the orthorhombic structure with a- and b-axis nearly equal to a-axis of and with c-axis half as long as c-axis of $Au_3Zn[R_1]$ has been found also by the present work, which corresponds to the structure proposed by German workers for Au_3Zn[R]. The present author specifies this structure as $Au_3Zn[R_2]$. There is a close relationship between the structures of $Au_3Zn[R_1]$ and $Au_3Zn[R_2]$. The former may correspond to an anti-phase domain structure of the latter with the period of out-of-step $M=1$, one unit cell of $Au_3Zn[R_2]$ and its shifted cell with a shifting vector, $(\boldsymbol{a}+\boldsymbol{b})/2$, being alternately stacked in the $\boldsymbol{c}$-direction, where $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ refer to the unit lattice vectors of $Au_3Zn[R_2]$. However, the stacking does not appear to be strictly regularly repeated, as it can be seen on oscillation photographs of $Au_3Zn[R_1]$ that diffraction spots with indexes $h+k=$odd are broadened in the stacking direction.

A full report will later be published.

The author wishes to express his sincere gratitude to Prof. S. Ogawa for his kind guidance. He is also indebted to Dr. M. Hirabayashi for his valuable suggestion.

Fine Structure in the $N^{14}(\gamma, n)N^{13}$ Activation Curve

By Naoshi MUTSURO, Yuji OHNUKI,
Kazuo SATO, Kosuke KAGEYAMA
and Motoharu KIMURA

Department of Physics, Tohoku
University Sendai, Japan

(Received August 1, 1959)

Photoneutron reactions of N^{14} have been measured by several authors for ten1)-3) years, and they observed some gross resonances besides the "giant resonance" in the energy region of 11~17 MeV.

Fujii4) tried to explain these gross resonances by extra-particle excitation mode. He assumed that N^{14} consists of C^{12}-core and two nucleus moving independently each other around it, and he obtained $E_r=13.5$ Mev, $\Gamma=0.9$ Mev as a gross resonance.

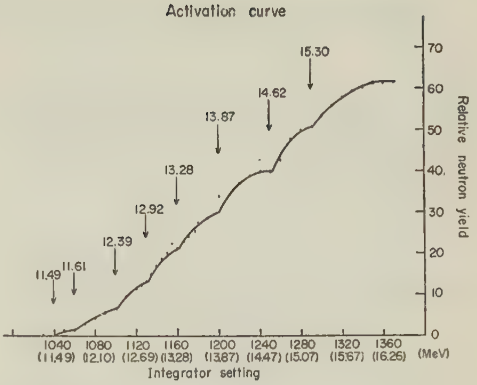
In order to check the existence of above gross resonance, $N^{14}(\gamma, n)N^{13}$ activation curve was measured in the energy region of 10~17 MeV.

The activation curve was taken by the Tohoku University 25 Mev betatron bremsstrahlung γ rays. Basic experiment consists of irradiation of a number of samples at various betatron energies every 70 Kev or 140 Kev step, and activation curve was taken by residual activity measurement. NaN_3 powder covered by aluminum thin foil (2.5 cmϕ $\times$0.5 cm in shape) were used as N^{14} samples, they were irradiated at 25 cm from the betatron target one after another.

In order to detect 10.1 min β^+ activity from N^{13}, NaN_3 sample was irradiated in the γ ray beam for 10 min and after waiting for 1 min to cool off the 6.6 sec aluminum activity to negligibly small compared to N^{13} activity, counts were taken for 9 min by scintillation counter set to annihilation peak. γ ray dose of each run was measured by Victoreen Radocon chamber, which is located at the centre of Lucite 11.7 cm cube, which was situated at 1.5 m from betatron target.

Number of counts for each run was normalized by unit dose. Activation curve is shown in the figure, in which the ordinate is in arbitrary scale, and the abscissa represents the integrator setting calibrated by threshold energy of the reaction $Cu^{63}(\gamma, n)Cu^{62}$ and $C^{12}(\gamma, n)C^{11}$ correct within ± 0.05 Mev.

The threshold energy of $N^{14}(\gamma, n)N^{13}$ reaction was obtained as 11.49 ± 0.05 Mev. A number of breaks are seen in the activation curve which are summarized also in the table. The 1-st column is the energies at each break, 2nd one is the corresponding energies of each levels of N^{14} as cited from Ajzenberg and Lauritzen table5). The breaks above 13.87 Mev are supposed as newly observed levels.



Above 15.3 Mev, perhaps a few breaks would exist, but we could not confirm yet, further investigation being aimed.

Because the energy interval of each activation point was such a broad one as 70 Kev or 150 Kev, other breaks may exist besides ones which were observed in this experiment. Even if other breaks existed, their intensity would be weak, perhaps less than 10% of the intensity of the detected breaks. From above results, we think that the resonance of single particle mode which Fujii3) predicted, may not exist, and that the gross resonance which has been seen in previous works may correspond the group of comparatively sharp resonances observed by us.

Table. Summary of observed "Breaks".

energy at each "breaks" in activation curve	corresponding level energy of N^{14}
11.49±0.05 Mev	11.49 Mev
11.61 〃	11.65
12.39 〃	12.42
12.92 〃	12.92
13.28 〃	13.24
13.87 〃	
14.62 〃	
15.80 〃	

As the spin of the ground state of N^{14} is 1^+, it is supposed that the levels corresponding to these breaks have odd parity, and possible spins for them are 2, 1 or 0. If the 12.42 Mev (4^-) level really corresponds to our 12.39 Mev break, there remains some questions to be studied.

We are now proceeding more precise experiment, and also planning the experiment to find out another breaks in the higher energy region.

Authors are indebted Mr. M. Mishina, Mr. A. Ono and Mr. T. Inoue for operating the betatron.

Rotational Transitions in Hydrogen and Deuterium

By Kazuo TAKAYANAGI

Department of Physics, Saitama University, Urawa

(Received July 30, 1959)

In a previous paper[1] the rotational excitation by collision in hydrogen gas was studied and the probability for the jump $l=0\to l=2$ was calculated, assuming an intermolecular potential of the Morse type. Using the same potential, calculation has been extended recently to the transitions 1→3, 2→4 in hydrogen and the corresponding transitions in deuterium[2]. The effective cross sections at T°K are of the form

$$Q(T)=\pi R_c^2F(T)=\pi R_c^2\beta^2(F(T)/\beta^2)\ .$$

R_c is a collision diameter introduced in the course of simplifying procedure. A reasonable choice of R_c is given by the closest distance of approach in the classical head-on collision with the mean velocity. β is a parameter indicating the relative importance of the non-spherical part of the potential. In the reference 1, $\beta=0.075$ was adopted. Results obtained in the reference 2 are summarized in Table I.

These values of F/β^2 make it possible to calculate the ultrasonic dispersion curves for these gases. The method of calculation is similar to the one used by Rhodes[3]. For hydrogen, the contribution from the fifth and the higher rotational levels were neglected. For deuterium, $F(3\to5)/\beta^2=3.75\times10^{-3}$ was assumed somewhat arbitrarily and the sixth and the higher levels were neglected. The ideal gas formula for the sound velocity was used without correction.

Table I. Values of F/β^2.

Rotational transition	H_2			D_2		
	100°K	200°K	300°K	100°K	200°K	300°K
0→2	2.7×10^{-3}	5.9×10^{-2}	2.0×10^{-1}	9.0×10^{-2}	5.4×10^{-1}	1.13
1→3	1.7×10^{-5}	2.6×10^{-3}	1.7×10^{-2}	4.0×10^{-3}	6.8×10^{-2}	2.1×10^{-1}
2→4	1.7×10^{-7}	1.6×10^{-4}	2.0×10^{-3}	2.5×10^{-4}	1.16×10^{-2}	5.4×10^{-2}

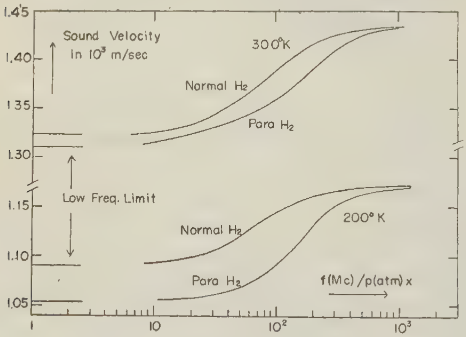

Fig. 1.

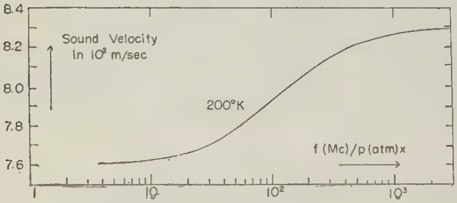

Fig. 2.

Fig. 1 shows the resulting curves for hydrogen at 200°K and 300°K. We have left the product $[R_c(\text{in Å})]^2\beta^2\equiv x$ undetermined. In the present cases, R_c is of the order of 4Å, so that it is expected that $x\simeq0.1$. Fig. 2 shows the dispersion curve for normal deuterium at 200°K. To calculate the corresponding curve at 300°K, we need the excitation probabilities among the higher levels. It is seen from the figures that the hydrogen and deuterium show the dispersion in almost the same frequency region. That this is actually the case

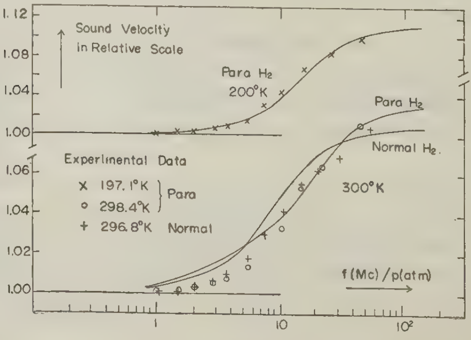

Fig. 3.

has been found experimentally[4]. In Fig. 3, comparisons are made between the experimental[3] and the theoretical curves for hydrogen. Following the reference 3, the relative velocities are plotted instead of their absolute values. $x=0.1$ was adopted since it gives a good fit at 200°K. The disagreement between the theory and the experiment at 300°K for the lower frequencies will probably be due to the presence of the other type of reactions such as

$$H_2(l=4)+H_2(l=0)\rightarrow H_2(l=2)+H_2(l=2)\ .$$

Magnetic Anisotropy of Evaporated Films Formed in Magnetic Field

By Minoru TAKAHASHI, Denjiro WATANABE,
Tetsuzo SASAGAWA, Hideo SAITO
and Shiro OGAWA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received July 31, 1959)

It has been reported[1] that thin films of some ferro-magnetic metals exhibit a distinct uniaxial anisotropy in the film plane when they are formed in magnetic field or are heat-treated in magnetic field after evaporation, but any quantitative observation of the anisotropy has never been done. The present authors succeeded in measuring quantitatively the anisotropy of evaporated films of Fe, Co, Ni and Ni–Fe, formed in magnetic field, by a highly sensitive torquemeter which was newly designed (sensitivity $\approx 5\times10^{-3}$ dyn-cm). As a substrate on which films were evaporated a quartz plate 13 mm in diameter was used. The plate surface was finely finished so as to be optically flat. Metals were evaporated from a small tungsten coil onto the substrate 5 cm distant from it. The substrate temperature was maintained at room temperature or at 300°C. The applied magnetic field ranged from 250 to 1500 Oe. The evaporation chamber was beforehand sufficiently degassed and the degree of vacuum was about 10^{-5} mm Hg when the evaporation was carried out. The specimen was horizontally held in vacuum in the torquemeter, in which a Helmholtz coil was used as a field source. The intensity of the magnetic field was

Table I. Values of anisotropy constant for evaporated films of Fe, Ni, Co and Fe–Ni.

Anisotropy const. / Temp. of substrate	K_u(Fe) (erg/cc)	K_u(Co) (erg/cc)	K_1(Ni) (erg/cc)	K_u(Ni_3Fe) (erg/cc)
Room temp.	2.2×10^3	13.8×10^3	$\sim1.0\times10^3$	3.2×10^3
300°C	0.8×10^3	4.4×10^3*	$\sim1.0\times10^3$	2.1×10^3 (2.5×10^3)**

* The substrate temperature was 430°C.

** After formed at 300°C and then successively annealed magnetically for 30 min.

414 Oe.

Some examples of torque curves are shown in Fig. 1. Here, H_a is the field strength applied during the film formation and the arrow shows the field direction. In all cases except Ni the curves can almost be approximated by $-K_u \sin 2\theta$. The uniaxial anisotropy constants calculated from these curves are given in Table I. It is remarkable that the less anisotropy is shown when the substrate has been held at the higher temperature and that in the case of Fe films the direction of H_a becomes nearly the direction of difficult magnetization rather than that of easy magnetisation. It is also worth while reporting that the torque value of nickel formed at room temperature is very changeable with lapse of time after the formation and that not uniaxial but unidirectional anisotropy is shown by the torque curve which has attained the stationary state.

The detailed report will be published in the near future.

A 4^+–0^+ Cross-Over Transition

By Haruhiko MORINAGA and Kasuke TAKAHASHI
Department of Physics, Tohoku University, Sendai

(Received August 24, 1959)

Low-lying 4^+ states in even-even nuclei decay to the ground states by cascade, in most cases, through underlying 2^+ states. So far, no direct transition to the ground state has been established[1]. Such transitions are of interest especially in connection with the collective behaviors of the nuclear matter, as in the cases of electric quadrupole and octupole transitions[2]. Unfortunately, such electric hexadecapole cross-over transitions are expected to occur with extremely small branchings (an order of 10^{-7} or so).

We have detected one of such transitions in the decay of Ni^{60} (Fig. 1). In order to detect the 4^+–0^+ cross-over transitions of the 2.505-Mev in the presence of the well-known 1.172-Mev and 1.333-Mev gamma-rays of intensities 10^7 stronger than the former, we looked for the photoneutrons released from heavy water by the 2.505-Mev gamma-rays, using a dysprosium neutron detector.

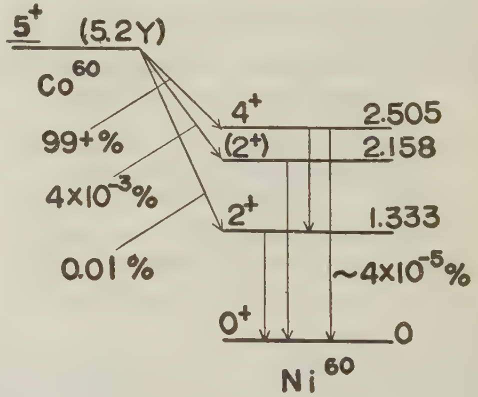

Fig. 1. Decay scheme of Co^{60}.

One gram sample of dysprosium oxide was taped on the surface of a cylindrical glass vessel containing 900 millilitre heavy water and irradiated in the 10,000 curie Co^{60} source at Japan Atomic Energy Research Institute. After 15 hour irradiation the characteristic 2.32-hour activity was produced in the dysprosium sample. In order to avoid a cumbersome calculation, the same detector assembly was irradiated with a Na^{24} source and the dysprosium activities produced were compared. After correcting for the difference in the geometries in two measurements and the energies of the released photoneutrons, we found that the branching ratio of the direct ground state transition from the 4^+ state to the cascade transition was 4×10^{-7}, if the former activation was assumed to be entirely due to the 2.505-Mev gamma-rays. Actually it is difficult to expect any high energy gamma-rays of other sources in the Co^{60} source with an intensity of an order of millicuries than this cross-over transition. So, we may conclude that the activity is produced by the 2.505-Mev cross-over transitions. The measured branching, however, may be subject to an error because of the rough estimate used in the correction, but the order will not be altered by more elaborate calculations.

Using the Weisskopf single particle estimate for both 4^+–2^+ and 4^+–0^+ transitions, one obtains a theoretical branching ratio of 1.3×10^{-7}. The measured value is very close to this value in the order of magnitude.

This work was done at Japan Atomic Energy Research Institute. We are grateful to Dr. A. Danno, Dr. E. Takekoshi, and Dr. K. Yoshihara for their help during the course of this experiment. The heavy water was loaned from Reactor Development Section of the Institute. This work was partly supported by the Ministry of Education.

The authors report a high energy gamma-ray in Sc^{46} which may be of this type, but the evidence that this corresponds to the 4^+–0^+ cross-over is scarce. Often in the type of even-even nucleus like Ti^{46}, to which Sc^{46} decays, the second 2^+ state appears below the 4^+ level which may give rise to such a gamma-ray.

Elastic Scattering of Protons by Helium between 9.2 MeV and 14.5 MeV

By Junpei SANADA

Institute for Nuclear Study, University of Tokyo,
Tanashi-Machi, Tokyo

(Received July 1, 1959)

The Scattering of protons by helium has been investigated from 9.2 MeV to 14.5 MeV with the INSJ variable-energy 160 cm cyclotron. The full angular distribution curves were taken at 12.04 MeV and 14.32 MeV. Both curves have a minimum at 115° and show the evidence of Coulomb-nuclear interference, though very small, at near 18° in the center-of-mass system. Tentative phase shift analysis has been made. It was found that the D-wave phase shifts are closely related with the shape of angular distribution at forward angles and they are small but cannot be neglected. Excitation curves between 9.2 MeV and 14.5 MeV were also taken at four angles of 25°31′, 49°21′, 90°0′ and 168°41′ in the center-of-mass system. $k^2\sigma(\theta)$ *versus* energy curves increase gradually with proton energy. They display no new state in Li^6 except the $\frac{1}{2}^-$ first excited state. The differential cross sections at energies near 9.5 MeV have served to resolve the confliction between the values hitherto obtained.

§1. Introduction

Helium plus one nucleon system is the first 1P shell nucleus. Its level structure is very interesting from viewpoints of the nature of nuclear forces and the excitation of alpha-particle core. Already many experiments¹⁾ on the elastic scattering of nucleons by helium have been performed and reveal through analyses²⁾ in terms of phase shifts that the virtual ground state and the first excited state of He^5 and Li^5 form the inverted doublet of $P_{3/2}$ and $P_{1/2}$. The $P_{3/2}$ state are confirmed also from another basis, *e.g.* from $He^4(d, p)He^5$ reaction³⁾. But the nature of $P_{1/2}$ state is more obscure than that of $P_{3/2}$ state. One of the purpose of the present work is to obtain further information about the behavior of $P_{1/2}$-wave phase shift.

On one hand, Brockman⁴⁾ observed the angular distribution at 17.45 MeV and showed the possibility of the existence of the $D_{5/2}$ state below this energy. He investigated successively the differential cross sections at 12 energies between 11.4 MeV and 18 MeV. He found that the contribution of the D-waves remains small. It is the worthwhile to check these apparently conflicting results by obtaining the fine excitation curves and full angular distributions with better angular resolution. If the existence of $D_{5/2}$ state be true, the differential cross sections should change more than ten percent as a peak or like the dispersion curve with bombarding energy.

We will now refer to the related theories. While the $P_{3/2}$ and $P_{1/2}$ phase shifts with large inverted splitting are accounted theoretically by using the spin-orbit force⁵⁾ which has been introduced rather phenomenologically, the attempts to find the splitting due to tensor force have also been made⁶⁾, especially due to the large tensor force⁷⁾ included in the two body potential which is lead by the meson theory of nuclear forces. If the spin-orbit force is valid, the D-wave phase shifts should be also inverted. However, if the tensor force is valid, the D-wave phase shifts should become normal⁷⁾. Then even if one cannot find the resonance concerning $D_{5/2}$ state, informations whether D-wave phase shifts are inverted or normal are very useful for the knowledge of the nature of nuclear forces.

The further interesting fact is the existence of $J=3^+/2$ state at an excitation energy of 16.80 MeV which is well known from the $He^3(d, p)He^4$ reaction⁹⁾. The deuteron reduced width of this state is very larger than that for proton and the state is a good single particle state of He^3+d, which arises presumably from a complex configuration such as excitation of alpha-particle core. It seems likely that a state with $J=1^+/2$ might lie near in energy to $J=3^+/2$ state[10]. The fine excitation curves will give informations about this problem.

§ 2. Experimental Method

A. General considerations

External proton beam from the INSJ 160 cm variable-energy cyclotron was lead through vacuum pipes to the 100 cm scattering chamber in the next room and focused by a combination of a pair of quadrupole magnets and a sector magnet. The details of apparatus above described will be soon given in a report[11] of this journal. The diagram of the experimental arrangement is shown in Fig. 1. Well colimated beam passed through a small gas target chamber, which was located at the center of the scattering chamber, and was collected by a Faraday cup. The beam current integrator was 100 percent feedback type deviced by Higinbotham and Rankowitz.[12] The gas target chamber was filled with thank helium, the purity of which was 99.6 mole percent. Protons scattered by helium entered the detecting system. Scintillation counters, consisting of cesium iodide crystal combined with a 6342 photo-multiplier tube, were set up on the turn table in the scattering chamber as shown in Fig. 1. Pulses from the counter were amplified with a Jordan and Bell type amplifier[13] and analysed with a Johnstone type twenty channel pulse height analyser.[14]

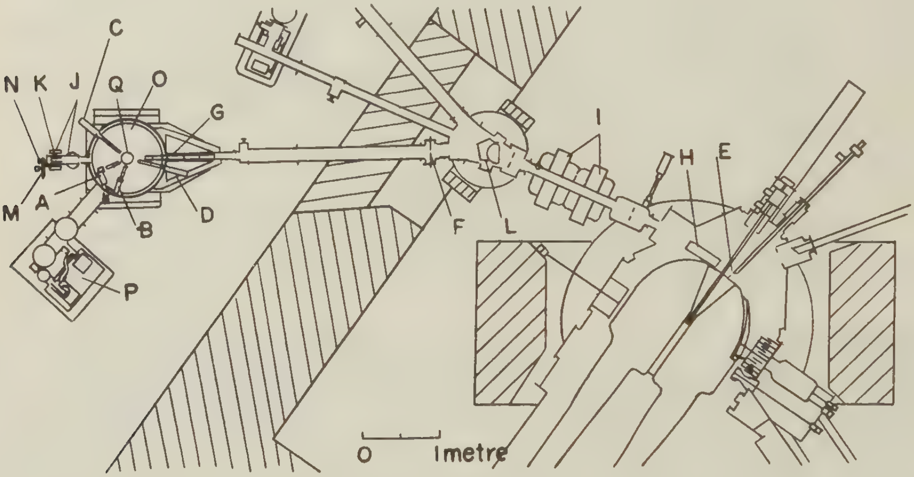

Fig. 1. The experimental arrangement. *A*: Detector I. *B*: Detector II. *C*: Detector III. *D*: Detector IV. *E*: Collimating slit. *F*: First defining slit. *G*: Second defining slit. *H*: Magnetic channel. *I*: Quadrupole magnets. *J*: Magnets for sweeping secondary electrons. *K*: Faraday cup. *L*: Sector magnet. *M*: Foil wheel. *N*: Ionization chamber. *O*: Scattering chamber. *Q*: Small gas target chamber.

Some details of the instrumentation which is characteristic of the present work are given in the paragraphs below.

B. Collimator

Most of unused part of external beam was stopped by a collimating slit, which was installed on the end of the current probe in the vacuum tank of cyclotron and was 2 mm in width. Two slits were inserted before and after a pair of quadrupole magnets to stop further diverging beam. The first defining slight was 7 mm in width and the second defining hole was 3.5 mm in diameter. Each was separated by 3.9 m. Thus the angular divergence of the beam was less than 0.1°. Three antiscattering baffles were inserted between the defining slits. Another two antiscattering baffles were added beyond the second defining hole to limit the spray of protons to a cone of half angle 0.6°. All these diaphragms were made of graphite to reduce the scattering and the neutron background.

C. Small gas target chamber

Because there were many sources of impurity vapor, such as concentric cables and other electronic components, in the scattering chamber, we decided to use a separated small gas target chamber. In earlier stage we attempted to use a chamber of 8 cm diameter with Mylar window developed by Corelli, Livingston and Seidlitz.[16] We found however two defects. Mylar became apt to break by a slight shock after traverse of protons of about 300 microcoulombs, because of high current density. The second was high background at the forward angles mainly due to the double scattering of incident protons by Mylar. The final form of the gas target chamber is shown in Fig. 2. A Mylar foil of 25 micron thick is cemented to a thin stainless steel plate and is made exchangeable easily. Moreover, the positions of beam entrance and exit on Mylar foil were changed by turning the target chamber step by step without breaking the vacuum of the scattering chamber. The diameter of the target chamber is increased to 15 cm. The background was reduced by a factor of four. The Mylar window is 1.6 cm high and extended to 290° of arc. The wall of the target chamber is made of brass of 1 cm thick. It bears one atmospheric pressure with slight deformation, though there is no intermediate supporting rod at the opening.

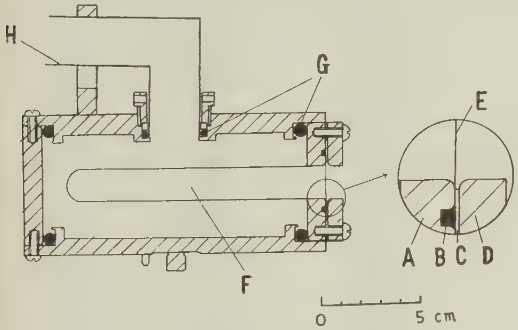

Fig. 2. Small gas target chamber. *A*: Side wall made of brass. *B*: Square gasket. *C*: Thin stainless steel plate. *D*: Semicircular ring. *E*: Mylar. *F*: Window. *G*: O-ring. *H*: Copper pipe to pumps, gas inlet and manometer.

D. Detector system

We used four detectors. When the measurements of angular distribution were made, the two detectors on the turn table were used as main detectors and the detector on the side wall of the scattering chamber set at an angle of 40° in the laboratory system was used as a monitor. When the excitation curves were taken, four detectors were used simultaneously. Dimensions of analysing slits are summarized in Table I. Good angular resolution was borne in mind particularly for the forward angles to obtain the fine structure of the angular distribution. The thicknesses of cesium iodide crystals were selected as thin as possible according to the range of protons to be detected. The gamma-ray and neutron background was negligible.

E. Procedure

After outgassing and flushing with helium, the target chamber was filled with the target gas to a pressure of 30 cm Hg. The pressure was measured with a mercury manometer which was read with a precision cathetometer. The temperature of target gas was measured with an alcohol thermometer, which was calibrated against the Dr. Siebert and Kühn's

Table I. Analysing slit dimensions. Values listed are in millimeters.

	For angular distribution		For excitation curve			
	Detector I.	Detector II.	Detector I.	Detector II.	Detector III.	Detector IV.

Distance between slits	200.1	143.1	201.1	143.1	340.6	343.3

standard thermometer. Relative value of the energy of protons was obtained from the frequency of proton resonance in the magnetic field of the sector magnet. At three values of energy, both ends and the middle of the energy range used, the energy of protons was measured by the combination of aluminium absorbers and a shallow ionization chamber. Using the range energy relation obtained by Bichsel, Mozley and Aron,[16] the relation between the frequency of proton resonance in the sector magnet and the absolute value of beam energy was decided.

In the measurement of differential cross sections, the sequence of angle in the angular distribution or of beam energy in the excitation curve was taken at random. At several angles or beam energies, the differential cross sections were measured twice or thrice at time appreciably separated each other.

§ 3. Results

Table II and Table III indicate the results of the angular distribution at 14.32 MeV and

and 12.04 MeV respectively. Table IV indicates the results of the excitation curves. The differential cross sections, which were measured twice or thrice, agreed within the experimental error. This served as the check of the stability of the instruments. The weighted means of these values are listed in the tables. The scattering angles and the differential cross sections in Tables II and III were transformed from the laboratory system into the center of mass system by means of a Lorentz transformation. The difference between this and the nonrelativistic transformation was at most 0.6 percent. In the case of the excitation curves the transformation was performed nonrelativistically, because the measurements were made without the monitor and the accuracy of differential cross sections is not so high. Their individual value suffered already the occrsional occurrence of a few percent fluctuation of the integrated current.

§ 4. Corrections and Errors

The errors in the third column in Tables II and III were estimated as follows. Errors due to counting statistics were ranging from 0.3 to 1.5 percent. Uncertainties in the geometry of analysing slits were less than 0.2 percent. Geometrical correction was applied using the relation developed by Critchfield.17) Error in measurement of gas density was 0.2 percent, including the uncertainty in the correction of the amount of impurity. Though

the amount of impurity was small, its contribution as background to the proton pulses at forward angles was not negligible. We observed well separated proton pulses due to heavier nuclei in the target gas at above 40° in the laboratory system. Assuming that they were nitrogen and oxygen, we estimated the amount of background pulses due to impurity at forward angles by making use of the results on the elastic scattering of protons from these nuclei.[18] This procedure was supported experimentally by the measurements of the proton-proton scattering,[19] which were made with the same instruments as those of the present work and showed separated proton pulses due to heavier nuclei until 15° in the laboratory system. At the extreme forward angles the Coulomb scattering was assumed. Thus estimated background amounted to 6 percent of whole proton pulses at 8° in the laboratory system and decreases with increasing angle. Uncertainty in this background subtraction was supposed to be a half of the estimated background, though it might be rather over estimation, because of safety.

At the forward angles some protons scattered from the structures in the scattering chamber entered the detector as mentioned in paragraph C of section 2. This background was measured by evacuating the gas target chamber.

Error in the alignment of instruments to the incident beam was 0.001 radian. This produced uncertainty of 2 percent in differential cross section at 8° in the laboratory system. The uncertainty decreased rapidly with increasing angle. The scattering angle was determined by reading the precise graduations on the periphery of the turn table. Its uncertainty is 0.01 degrees. Error in determination of the total number of incident protons was 0.8 percent.

Quadratic combination of the errors described above was in general less than 2 percent except at forward angles.

Counting statistics in the case of excitation curves was ranging from 0.4 to 1.7 percent.

The uncertainties of the mean energy of the proton beam in the scattering volume were less than 0,4 percent. The energy spread of the incident beam was 0.5 percent.

§ 5. Discussions

It is worthwhile to compare the results of the present work with the experimental and theoretical results so far obtained.

In proton-helium scattering, orbital angular momentum is no longer a constant of motion in virtue of spin-orbit interaction and waves of different total angular momentum are scattered differently. Thus, the cross section is expressed in terms of S phase shift δ_0, $P_{1/2}$ phase shift δ_1^-, $P_{3/2}$ phase shift δ_1^+, $D_{3/2}$ phase shift δ_2^-, $D_{5/2}$ phase shift δ_2^+, and so on. We attempted at first to fit the angular distribution at 14.32 MeV with S- and P-waves only. The present analysis is not thorough, but tentatively accomplished by trial and error, not by the iteration with regular step. We started with the values of phase shifts obtained by interpolation between the results at 9.48 MeV[20] and at 17.45 MeV.[21] A set of $\delta_0=-77°42'$, $\delta_1^-=50°0'$ and $\delta_1^+=92.36'$ gives the agreement with the experimental angular distribution, except the region of Coulomb-nuclear interference. The calculated values of differential cross section are listed in the fourth column of Table III. They are also shown in Fig. 3 together with experimental values. The values of phase shifts are compatible with those obtained by Brockman.[1] However, it was difficult to fit in the experimental results with S- and P-waves only.

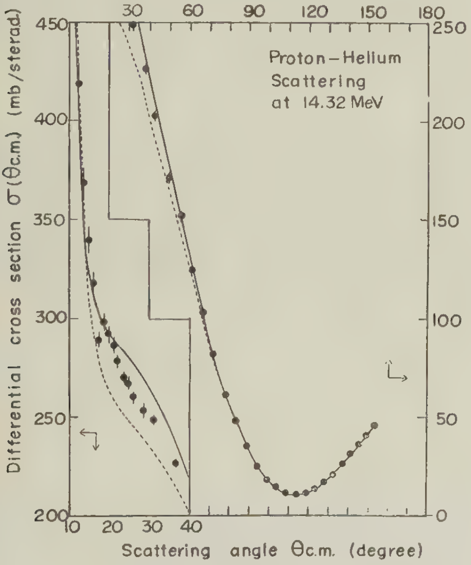

Fig. 3. Angular distribution at 14.32 MeV. The dashed curve indicates the calculated cross sections with *S*- and *P*-waves only (forth column of Table II). The solid curve indicates the calculated cross sections with phase shifts obtained by Gammel and Thaler[22] (fifth column of Table II).

Gammel and Thaler[22] have made an analysis in terms of an optical model potential interaction between the proton and alpha-particle. The purpose of their work was to predict the polarization of protons than the angular distribution. But it is interesting to use the phase shifts calculated by them in the angular distribution, as an example containing larger D phase shifts. The values of phase shifts were taken from Table III of reference 22. The results are listed in the fifth column of Table III and shown in Fig. 3. The fit is better than that with S- and P-waves only, but some over compensations are seen.

The calculations were made also to the angular distribution at 12.04 MeV. The results are shown in Table III and in Fig. 4. Almost the same discussions as above can be applied to this case. As to the case with S- and P-waves only, however, appreciably smaller values of phase shifts than those obtained by Brockman[1] were needed to fit particularly the forward angular distribution, and the agreement between the experimental and calculated values becomes very good. Consequently the decrease of $P_{1/2}$ and $P_{3/2}$ phase shifts might be more rapid from 9.5 MeV to 12 MeV than acceded so far.

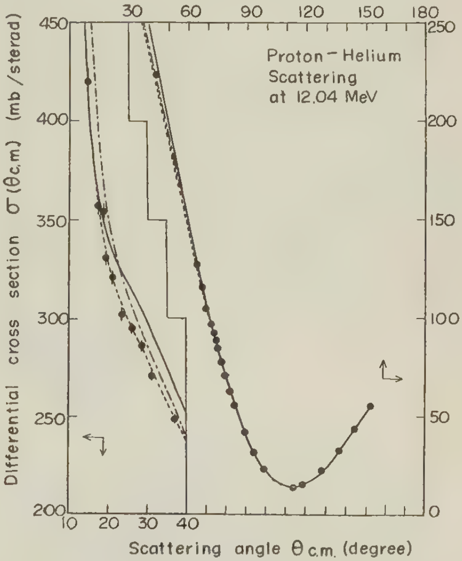

Fig. 4. Angular distribution at 12.04 MeV. The dashed curve indicates the calculated cross sections with *S*- and *P*-waves only (forth column of Table III). The solid curve indicates the calculated cross sections with phase shifts obtained by Gammel and Thaler[22] (fifth column of Table III). The dash-dotted curve indicates the calculated cross sections with $\delta_0=-66°54'$, $\delta_1^-=60°6'$ and $\delta_1^+=108°42'$, which were obtained by Brockman (see Table III of reference 1).

The excitation curves are shown in Fig. 5 in the form of $k^2\sigma(\theta\,\text{c.m.})$ versus proton energy together with other experimental results,(1, 20, 21, 24, 25, 26) k being the wave number of incident proton. The $k^2\sigma$ curves increase monotonously with increasing energy from 7.5 MeV to above 10 MeV and then decrease slightly to 17.45 MeV, except at 25°31′. The very broad resonance of $P_{1/2}$-wave is included in this energy range and recently Miller and

Phillips[23] have analysed the results hitherto obtained in terms of the dispersion theory of Wigner and Eisenbud. They have decided level parameters. $(E_{res})_{lab}$ for $P_{1/2}$ state has become 10.8 MeV.

We add a comparison between the values of differential cross section at energies near 9.5 MeV, because several results have been conflicting each other. The results by Cork and Hartsough at 9.73 MeV[25] and by Williams and Rasmussen at 9.76 MeV[26] agree well with the present work. The agreement of Putnam's results[20] at 9.48 MeV is also good except at 25°31′. Low values of the results at 9.55 MeV by Freemantle et al.[24] are seen in a forward hemisphere.

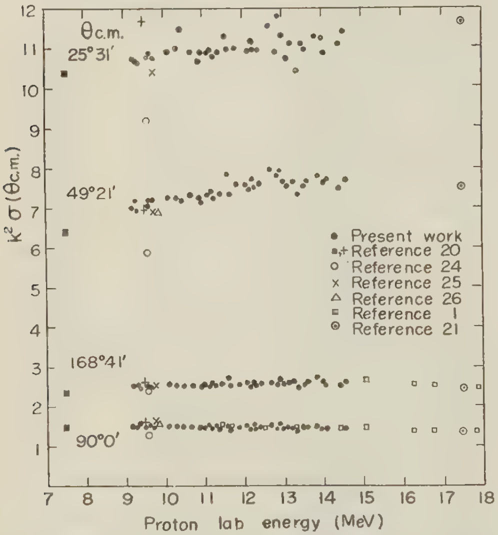

Fig. 5. Excitation curves. The results are shown together with cross sections obtained so far.

§ 6. Conclusions

D-wave phase shifts are closely related with the shape of angular distribution at forward angles and they are small but cannot be neglected in the present energy range. The experiments on the full angular distribution at higher energy such as 20 MeV are desirable for the behavior of D-wave phase shifts.

There is no resonance of $5^+/2$ or $1^+/2$ state between 9.2 MeV and 14.5 MeV. The excitation curves together with angular distributions will serve to a precise analysis for $P_{1/2}$ state.

Thorough phase shift analysis will be accomplished after obtaining the results of the polarization in proton-helium scattering in the present energy range, on which we are now making measurements.

Acknowledgement

A Large Multiplate Cloud Chamber for Cosmic Ray Observation

By Saburo MIYAKE, Kensaku HINOTANI, Itsuo KATSUMATA
and Tatsunosuke KANEKO

Osaka City University, Osaka, Japan

(Received July 27, 1959)

A large multiplate cloud chamber has been constructed for the observation of the extensive air showers by extremely high energy cosmic radiations. Its dimensions of sensitive volume are 200 cm wide, 130 cm high and 90 cm deep. It contains 21 sheets of lead plate of 1 cm thick, so that the total thickness of the absorber corresponds to about 48 radiation length or about three times of nuclear interaction mean free path. The design and operational character are reported in this paper.

§ 1. Introduction

The main purpose of the use of a large multiplate cloud chamber in the present case is to study high energy events by cosmic ray particles, especially, to observe directly the central region of extensive air showers. The frequency of such events is very small but each event has proper characteristic. The structure of events seems to be so complicated that other equipments, for example, G.M. counters or ionization chambers etc. except the cloud chamber are not useful to clarify the true structure. A multiplate cloud chamber is very useful in the stage of qualitative measurements but the dimensions of the chambers so far used are too small for this purpose. Since it is believed that the core region which supplies the energy to extensive shower region has the spread of about 1–2 m, and this region contains high energy nucleons, mesons and numerous electrons and γ rays; it is thought to be favourable that the dimension of the chamber is about 2 m to study the structure of the core region and the amount of the material in the chamber which acts as an absorber or target of high energy event is enough to observe various components separately.

The multiplate cloud chamber reported here has been constructed in 1958 and it is now being used at cosmic ray observatory of Tokyo University on Mt. Norikura.

§ 2. Design and Construction

Cloud chamber

Fig. 1 shows the crossectional sketch of the cloud chamber. It is made of steel and the inside surface of the chamber is plated with nickel. The total sensitive volume is about 3 m^3 although the dead space for photograph was decreased. The glass plates of front and both sides are tempered glass (" Temperite " Asahi Glass Co.) of 1.2 cm thickness. The chamber was over pressure type and glass plates were reinforced by out side steel frames as they do not obstruct the illumination and the photographing. The width was planned to enlarge as much as possible and the limit was at 200 cm due to restriction for manufacturing of the front glass. The height of the chamber was determined as 130 cm to be possible to contain about twenty sheets of lead absorber of about 1 or 2 cm thick. The depth was determined as 90 cm from restriction of the depth of a focus in photographic system and the illuminated depth of 65 cm was taken by photograph. The lead plates were enclosed by steel sheet of 0.25 cm thick and steel frame to strengthen for the bending and their surface was coated by nickel to prevent rust and was polished for good reflection of light. A cleaning electric field was given to the lead plates alternately.

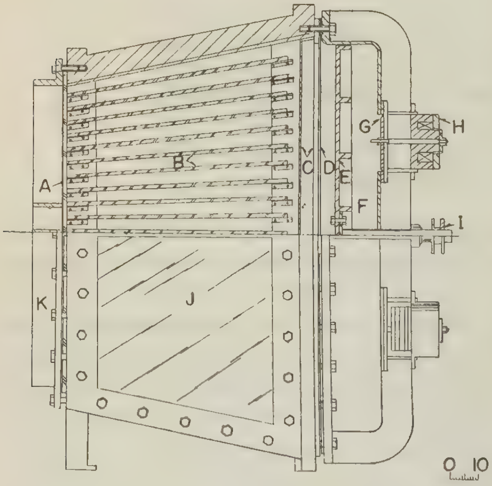

Fig. 1. Cross sectional sketch of the cloud chamber, showing *A*, the front glass; *B*, lead plates; *C*, velvet attached perforated plate; *D*, rubber diaphragm for expansion; *E*, stopper of rubber diaphragm controlling the expansion rate; *F*, back chamber space; *G*, exhaust valve for expansion; *H*, electromagnet for exhaust valve; *I*, rod with a toothed wheel of chain controlling the position of the stopper; *J*, the side glass; *K*, frame for front glass.

The chamber was tested at 1 atm. and used at 0.5 atm. over the atmospheric pressure. In operation, the bending by inner pressure is about 1 cm at the centre of the front glass plate.

Expansion mechanism

A rubber diaphragm which is pressed against a perforated plate with a large number of 6 mm holes is moved to its stopper by reducing the pressure of the back chamber. Six exhaust valves were installed in the back chamber as shown in Fig. 2 and they are operated by electromagnet. The expansion of the chamber is made by opening the exhaust valves simultaneously. When an expansion is made, the back chamber is compressed by opening a electromagnetic valve to an external tank containing compressed air of about 4 atm. The chamber is fully expanded after about 10 milliseconds, from the trigger pulse, and recompressed in about one min. After an ex-

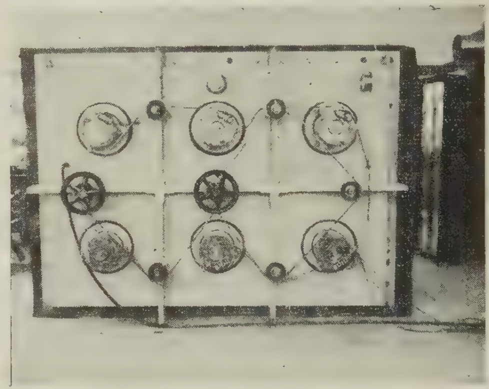

Fig. 2. Back view of the cloud chamber showing the six exhaust valves and seven rods for control of the stopper. Upper small valve is slow expansion valve.

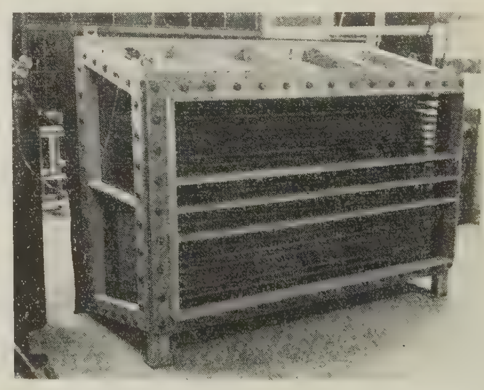

Fig. 3. Photograph of the cloud chamber.

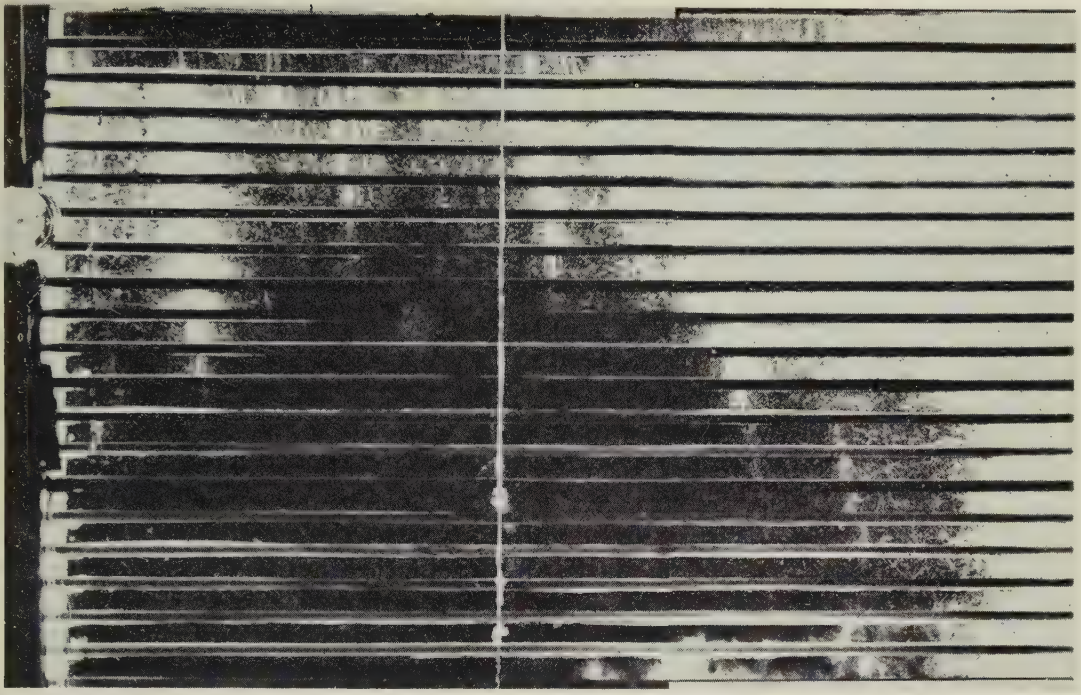

Fig. 4(a). Cinemascopic picture of an extensive air shower core. The shower size is estimated as 3×10^6 particles from the data of scintillation counters and the position of the shower core is 1 m on the right from the centre, namely, in this picture, the core falls on the right hand edge of this picture. From the number of tracks in the top space, the lateral distribution of charged particles in the vicinity of the shower core is obviously seen and energy flow distribution is also seen from the depth that the electron cascade has diminished.

pansion, slow expansions are repeated four times by using of slow expansion valve to clear out fog nuclei. The dead time of the chamber after an expansion is about 15 min.

Illumination

The chamber is illuminated from both sides by three flash tubes respectively. Light from the flash tube is reflected by parabolic mirror and illuminates the chamber through the solar slit. The flash tube is a xenon discharge tube which is made of fused quartz tube and hard glass sheath. The electric power source of flash tube is supplied from a condenser bank charged up to 10 kv for each tube.

Photography

Photographs were stereoscopically taken by three cameras. Two 35 mm cameras were mounted at a distance of 330 cm from the centre of the chamber as stereoangle was 17°. A 60×90 mm camera was mounted at front of the chamber at same distance. Photographs were taken at an aperture value of 8 to 11. The cameras are operated automatically by electromagnetic relay and motor.

Control circuits

The control circuit is composed of gate circuits, time sequence circuits, delayed pulse generators and operational circuits for expansion valve, cameras, sweeping electric field, flash tubes slow expansion valves and compression valves. And long delay circuit for the dead time interval of the chamber is composed of univibrator and scaler circuit and it makes also to operate a slow valve repeatedly.

Safety precausions

The cloud chamber is filled with 0.5 atmospheric over pressure argon gas. In a case of a diaphragm failure, the compressed air flows into the cloud chamber, and so the compressed air may results the destruction of the chamber. To avoid such accident, prevention has been made to get the compressed air out of the chamber instantaneouslly by opening the exhaust valves.

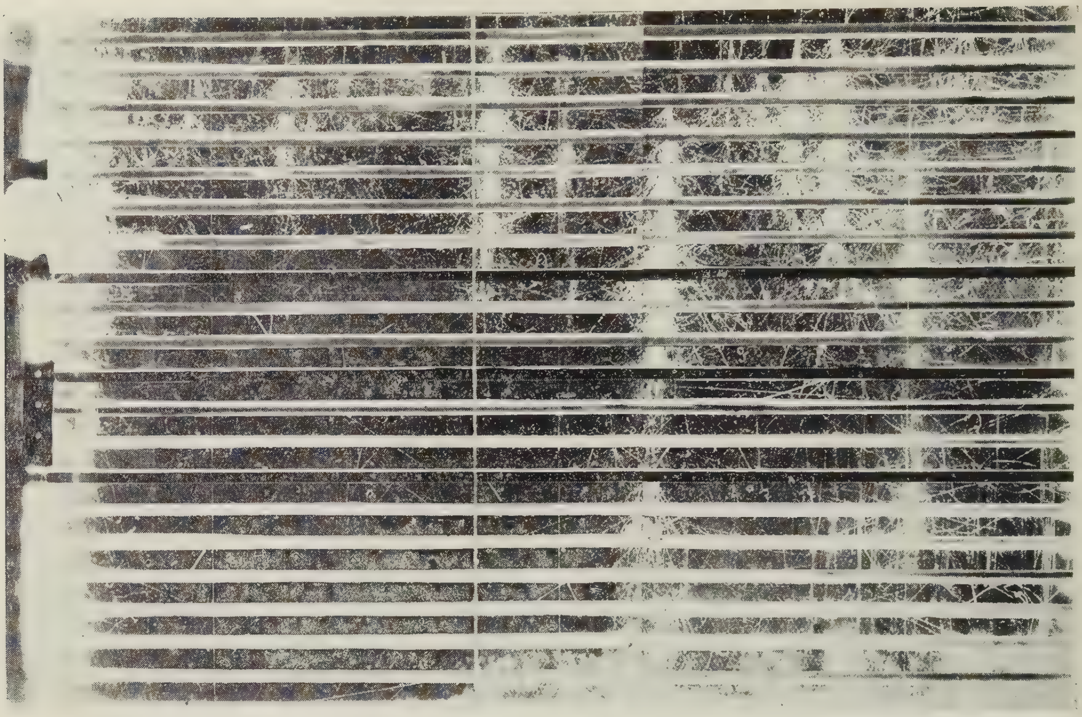

Fig. 4(b). This picture also shows the central region of extensive air shower. The shower size is estimated as 8×10^5 particles and the position of the shower core is about 1 m from the centre of the chamber. The age of the air shower seems to be young and hard showers by high energy nucleon components are seen in lower part of the chamber.

Chamber operations

The cloud chamber has been operated with ten plastic scintillators to study extensive air showers. Figures 4 a and b show typical photographs of the central region of the extensive air shower.

On the Theory of Brownian Motion and Spin Relaxation*

By Takeyasu KOTERA and Morikazu TODA

Department of Physics,
Faculty of Science, Tokyo University of Education,
Tokyo, Japan

(Received August 3, 1959)

The Brownian motion of a harmonic oscillator is treated quantum-mechanically and the same method is applied to the relaxation of a spin. The method is quite general and applicable to a system displaced from the equilibrium state by an arbitrary amount initially. The oscillator or the spin is interacting with a thermostat composed of a great number of harmonic oscillators. The equation of motion is solved in operator form taking average as to the thermostat to the second order of the interaction parameter. The Langevin equation, the Kramers-Chandrasekhar equation for a harmonic oscillator and the Bloch equation for a static field are derived.

§ 1. Introduction

The problem of Brownian motion has been investigated by many authors and formulated in many equivalent forms. It can be said, however, that the problem is recovering its fundamental importance since it is intimately connected to the fundamental theory of the statistical mechanics, that is, to the statistical mechanics of the irreversible processes. While the latter is concerned with large systems in which irreversible processes take place, the former focuses attention on small systems which behave purely mechanically under the influence of the environments.

The essential feature of the problem of the Brownian motion is to ask the motion of a small system under the influence of random, fluctuating disturbances. The motion of a colloidal particle in a gas or in a liquid is the best known example.

Since the classical works of Einstein and of Smoluchowsky the problem of Brownian motion is usually treated by the theory of stochastic processes. Useful concepts in this field, such as friction constant, fluctuating force, and relaxation time, common relations, e.g. Einstein relation, and important equations, Smoluchowski-Chapman equation and Langevin equation, are established in early days. Kramers[1)] generalized the idea of random flights and derived the so-called Kramers equation, which was extensively studied by Chandrasekhar.[2)] In the theory of stochastic processes, the equation which characterizes the dynamical system is the Langevin equation; by its aid estimation of the moments required in reducing the Smoluchowski-Chapman equation into Fokker-Planck type of differential equation is made possible.

From the microscopic point of view, however, the current way of analysis[2)] is not perfect in the sense that one has to introduce some hypothesis on macroscopic and unknown parameters such as the friction constant and the correlation constant of the fluctuating force. The relation between these two constants is usually determined by fitting the asymptotic behavior of the system under a certain condition to that of the equilibrium state. And the assumption of splitting the force into two parts is only justified by the results obtained afterwards. On the other hand, if one applies the general theory of the statistical mechanics of the irreversible processes from the beginning to the special system under consideration one will be led to a more consistent theory.

In previous papers[3),4)] one of the authors developed a method of treating Brownian motion which enables us to give the Kramers equation and the Langevin equation their dynamical ground: In a paper[3)] it was shown that the Liouville equation in quantum-mechanical form for the density matrix can be transformed into a operator equation which goes over to the classical Kramers-Chandrasekhar equation by the Wigner transformation, and that the Langevin equation can be derived therefrom. In the other paper it was shown, in classical mechanics, that the Langevin equation can be derived directly from the Newton's equation of motion and that the friction constant, random force and the relation between them are derived naturally in the course of calculation.

---

* Parts of the paper are based on a thesis submitted by Dr. Kotera in partial fulfillment of the requirements for a D. S. degree in Physics, Tokyo University of Education, 1959.

The purpose of this paper is to examine from purely microscopic point of view, starting from the Heisenberg's equation of motion, the validity of the current results, such as the Langevin equation for Brownian motion. To get through the analysis completely the interaction between the system and the thermostat is assumed. The problem is thus reduced to very special cases, without loosing, however, the essential point of the problem.

The point is that the irreversible behavior and the state of thermal equilibrium to approach are derived from the Heisenberg equation without any *ad hoc* assumption except that the thermostat is always in equilibrium.

The system, which we shall consider, consists of many oscillators interacting one another. We shall divide those into two parts: one oscillator whose motion we shall observe and the other oscillators which shall play as a whole the role of a thermostat. To treat this system we shall investigate the equation of motion of operators in Heisenberg representation.

We shall separate from each of these operators an operator with bar. Instead of considering the interaction within the thermostat explicitly we shall put some conditions (cf. Eq. (29)) on the barred operators of the thermostat assuming that the thermostat is always in the thermal equilibrium state.

The separation of an operator can be made in such a way that the time rate of change of the barred operator is of second order with respect to the interaction parameter. The rest of the operator is the part depending on other oscillators to the first order of the interaction parameter.

To get the relaxation equation for the density matrix in the $x-p$ representation we shall transfer from the Heisenberg representation to the Schroedinger representation. But we may treat the density matrix from the start (cf. Appendix B and the reference 3). When we make the classical distribution function from the density matrix using Wigner's method we get the Kramers-Chandrasekhar equation.

In the same manner we shall derive the Bloch equation[5] for a spin in a static magnetic field. The spin, whose magnitude is $\frac{1}{2}$, is then assumed to be coupled with a thermostat composed of a great number of harmonic oscillators.

§ 2. The Basic Equation for the System

We consider a system of many harmonic oscillators interacting one another. Then the hamiltonian is

$$\mathscr{H}=H_0+\lambda V\,, \tag{1a}$$

where

$$H_0=\sum_i H_i\,,\qquad H_i=\hbar\omega_i(a_i{}^*a_i+\tfrac{1}{2})\,. \tag{1b}$$

Suffix i labels the i-th oscillator. a_i and $a_i{}^*$ are related to the coordinate x_i and the momentum p_i of the i-th oscillator by the relations

$$\left.\begin{aligned} x_i&=\sqrt{\frac{\hbar}{2\omega_i m_i}}\,(a_i+a_i{}^*)\,,\\ p_i&=-i\sqrt{\frac{\hbar m_i\omega_i}{2}}\,(a_i-a_i{}^*)\,. \end{aligned}\right\} \tag{2}$$

We shall consider the Brownian motion of a specified oscillator, say, the i-th oscillator and take the other oscillators $j, k, \cdots (\neq i)$ as forming a thermostat. We shall use this specification throughout and call the i-th oscillator the central oscillator whose Brownian motion is to be noticed. Suffix i is used for the central oscillator only and suffixes j, k, are used always for oscillators in the thermostat.

Farther we assume that the leading terms of the interaction between the oscillators including the central one to be quadratic with respect to the displacements of the oscillators. Thus

$$\lambda V=\lambda\sum_j{}' c_{ij}x_ix_j+\lambda\sum_{j<k}{}' c_{jk}x_jx_k\,. \tag{3}$$

The first term on the right hand side of this equation represents the interaction of the central oscillator with the thermostat and the second term is responsible for the interaction within the thermostat. More generally we may add a term $V'(x_j, x_k, \cdots)$ to the right hand side of Eq. (3) assuming that V' depends on the coordinates of the thermostat only and that V' is of higher order in λ, the coupling constant: $V'=O(\lambda^2)$.[†] This term consists of unharmonic interaction within the thermostat and seems necessary to garantee the state of thermal equilibrium for the thermostat. However, as will be seen below, so long as we are concerned with the Brownian motion of the central oscillator, introduction of this extra-term gives no essential modification in the following calculation. We shall therefore omit this term for a while.

The equation of motion for the operator a_i runs

$$\dot{a}_i=-i\omega_i a_i+if_i/\sqrt{2\omega_i m_i}\,, \tag{4}$$

with

$$f_i=-\lambda\sum_j{}' c_{ij}/\sqrt{2\omega_j m_j}\cdot(a_j+a_j^*)\,. \tag{5}$$

A similar equation holds for a_i^*. Making use of the canonical transformation

$$\left.\begin{aligned} A_i&=e^{-(i/\hbar)H_0t}a_i\,e^{(i/\hbar)H_0t}=e^{i\omega_i t}a_i\,,\\ A_i^*&=e^{-(i/\hbar)H_0t}a_i^*\,e^{(i/\hbar)H_0t}=e^{-i\omega_i t}a_i^*\,, \end{aligned}\right\} \tag{6}$$

we rewrite Eq. (4) and its conjugate equation in the form

$$\left.\begin{aligned} \dot{A}_i&=if_i\,e^{i\omega_i t}/\sqrt{2\omega_i m_i}\,,\\ \dot{A}_i^*&=-if_i\,e^{-i\omega_i t}/\sqrt{2\omega_i m_i}\,. \end{aligned}\right\} \tag{7}$$

We shall introduce the interaction adiabatically from the infinite past ($t=-\infty$). This can be done by the replacement

$$\lambda\rightarrow\lambda\,e^{st}$$

and by taking the limit $s\rightarrow+0$.

Using Eqs. (5) and (6) we rewrite Eqs. (7) as

$$\left.\begin{aligned} \dot{A}_i&=\frac{-i\lambda}{\sqrt{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}(e^{-i\omega_j t}A_j+e^{i\omega_j t}A_j^*)e^{st+i\omega_i t}\,,\\ \dot{A}_i^*&=\frac{i\lambda}{\sqrt{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}(e^{-i\omega_j t}A_j+e^{i\omega_j t}A_j^*)e^{st-i\omega_i t}\,. \end{aligned}\right\} \tag{8}$$

These are the equations of motion for the central oscillator. We have analogous equations for the oscillator j of the thermostat. For instance for A_j,

$$\begin{aligned} \dot{A}_j=&\frac{-i\lambda}{\sqrt{2\omega_j m_j}}\frac{c_{ji}}{\sqrt{2\omega_i m_i}}(e^{-i\omega_i t}A_i+e^{i\omega_i t}A_i^*)e^{st+i\omega_j t}\\ &-\frac{i\lambda}{\sqrt{2\omega_j m_j}}\sum_k{}''\frac{c_{jk}}{\sqrt{2\omega_k m_k}}(e^{-i\omega_k t}A_k+e^{i\omega_k t}A_k^*)e^{st+i\omega_j t}\,, \end{aligned} \tag{9}$$

where the sum in the second term is taken over the thermostat oscillators k excluding j. If we add the extra-term V' mentioned before, we have an extra-term on the right hand side of Eq. (9). This is the only effect of V'.

If there were no interaction, $\lambda=0$, operators A_i, A_j, etc would be constant in time. We deal with the case where the coupling constant λ is sufficiently small, and want to solve the problem up to the second order in λ. As in the previous paper[3)] we divide the operators A and A^* into two parts. For instance

$$\begin{aligned} A_j=\overline{A}_j&-\frac{i\lambda}{\sqrt{2\omega_j m_j}}\frac{c_{ji}}{\sqrt{2\omega_i m_i}}\left(\overline{A}_i\int_{-\infty}^t e^{st+i(\omega_j-\omega_i)t}\,dt+\overline{A}_i^*\int_{-\infty}^t e^{st+i(\omega_j+\omega_i)t}\,dt\right)\\ &-\frac{i\lambda}{\sqrt{2\omega_j m_j}}\sum_k{}''\frac{c_{jk}}{\sqrt{2\omega_k m_k}}\left(\overline{A}_k\int_{-\infty}^t e^{st+i(\omega_j-\omega_k)t}\,dt+\overline{A}_k^*\int_{-\infty}^t e^{st+i(\omega_j+\omega_k)t}\,dt\right). \end{aligned} \tag{10}$$

Or

$$\begin{aligned} A_j=\overline{A}_j&-\frac{i\lambda}{\sqrt{2\omega_j m_j}}\frac{c_{ji}}{\sqrt{2\omega_i m_i}}\left(\overline{A}_i\frac{e^{st+i(\omega_j-\omega_i)t}}{s+i(\omega_j-\omega_i)}+\overline{A}_i^*\frac{e^{st+i(\omega_j+\omega_i)t}}{s+i(\omega_j+\omega_i)}\right)\\ &-\frac{i\lambda}{\sqrt{2\omega_j m_j}}\sum_k{}''\frac{c_{jk}}{\sqrt{2\omega_k m_k}}\left(\overline{A}_k\frac{e^{st+i(\omega_j-\omega_i)t}}{s+i(\omega_j-\omega_k)}+\overline{A}_k^*\frac{e^{st+i(\omega_j+\omega_k)t}}{s+i(\omega_j+\omega_k)}\right). \end{aligned} \tag{11}$$

We have the conjugate equation for A_j^*.

Similarly we have

[†] This restriction can be omitted (cf. § 6).

$$A_i=\overline{A}_i-\frac{i\lambda}{\sqrt{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}\left(\overline{A}_j\frac{e^{si+i(\omega_i-\omega_j)t}}{s+i(\omega_i-\omega_j)}+\overline{A}_j{}^*\frac{e^{st+i(\omega_i+\omega_j)t}}{s+i(\omega_i+\omega_j)}\right), \tag{12}$$

and the conjugate equation for $A_i{}^*$.

We note the fact that A_i, A_j, etc fluctuate: their time derivatives are first order in λ. The time rate of change of $\overline{A}_i$, $\overline{A}_j$, etc are much smaller because it is second order in λ. This can be shown easily from Eqs. (9), (10) and their conjugate equations.

Farther we can verify that

$$[\overline{A}_j, \overline{A}_i]=\mathrm{O}(\lambda^2)\,, \qquad [\overline{A}_j{}^*, \overline{A}_i{}^*]=\mathrm{O}(\lambda^2)\,, \qquad [\overline{A}_j, \overline{A}_i{}^*]=\delta_{ji}+\mathrm{O}(\lambda^2)\,. \tag{13}$$

These relations will be used later on. We have to note also that terms like $[\overline{A}_j, \overline{A}_i{}^*]$ or $[A_j{}^*, \overline{A}_i]$ for $j\neq i$ are of first order in λ.

In order to withdraw the interaction between the oscillators of the thermostat, in deriving the equation of motion of the central oscillator i, we shall take the average (of functions of the operators $\overline{A}_j$ and $\overline{A}_j{}^*$) as to the thermostat which is always in the state of thermal equilibrium. Especially we shall assume that the average $\langle\overline{A}_j\rangle$ of $\overline{A}_j$ $(j\neq i)$ or $\langle\overline{A}_j{}^*\rangle$ of $\overline{A}_j{}^*$ vanishes. So, in deriving the time derivative of the operators of the i-th oscillator we may put

$$c_{jk}=0 \qquad \text{for} \qquad j, k\neq i\,. \tag{14}$$

Using Eq. (11) and its conjugate equation we get from Eq. (8)

$$\begin{aligned}\dot{A}_i=&-\frac{i\lambda}{\sqrt{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}(\overline{A}_j e^{-i\omega_j t}+\overline{A}_j{}^* e^{i\omega_j t})\,e^{st+i\omega_i t}\\ &-\frac{\lambda^2e^{2st}}{2\omega_i m_i}\sum_j{}'\frac{c_{ij}{}^2}{2\omega_j m_j}\left(\overline{A}_i\left[\frac{1}{s+i(\omega_j-\omega_i)}-\frac{1}{s-i(\omega_j+\omega_i)}\right]\right.\\ &\left.\qquad+\overline{A}_i{}^* e^{2i\omega_i t}\left[\frac{1}{s+i(\omega_j+\omega_i)}-\frac{1}{s-i(\omega_j-\omega_i)}\right]\right),\end{aligned} \tag{15}$$

and its conjugate equation. Taking the limit $s\to+0$, we make use of the relation

$$\lim_{s\to+0}\left(\frac{1}{s+ix}\right)=\pi\delta(x)-i\,\mathrm{P}\left(\frac{1}{x}\right).$$

Then Eq. (15) may be rewritten as follows:

$$\begin{aligned}\dot{A}_i=&-\frac{i\lambda}{\sqrt{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}(\overline{A}_j e^{-i\omega_j t}+\overline{A}_j{}^* e^{i\omega_j t})\,e^{i\omega_i t}\\ &-\frac{\lambda^2}{2\omega_i m_i}\sum_j{}'\frac{c_{ij}{}^2}{2\omega_j m_j}\left(\overline{A}_j\left[\pi\delta(\omega_j-\omega_i)-i\,\mathrm{P}\left(\frac{2\omega_j}{\omega_j{}^2-\omega_i{}^2}\right)\right]\right.\\ &\left.\qquad+\overline{A}_i{}^* e^{2i\omega_i t}\left[-\pi\delta(\omega_j-\omega_i)-i\,\mathrm{P}\left(\frac{2\omega_j}{\omega_j{}^2-\omega_i{}^2}\right)\right]\right).\end{aligned} \tag{16}$$

Similarly the conjugate equation is obtained for $A_i{}^*$.

§ 3. Langevin Equation

Differentiating Eq. (6) with respect to time, we have

$$\left.\begin{aligned}\dot{a}_i&=-i\omega_i a_i+e^{-i\omega_i t}\dot{A}_i\,,\\ \dot{a}_i{}^*&=i\omega_i a_i{}^*+e^{i\omega_i t}\dot{A}_i{}^*\,.\end{aligned}\right\} \tag{17}$$

By the aid of Eq. (16), we may rewrite the above equations, to the second order in λ, as (in the second order terms of λ in Eq. (16), $\overline{A}_i$ or $\overline{A}_i{}^*$ may be replaced by A_i or $A_i{}^*$)

$$\dot{a}_i=-i\omega_i a_i-i\lambda\sqrt{\frac{1}{2\omega_i m_i}}\sum_j{}'\frac{c_{ij}}{\sqrt{2\omega_j m_j}}(\bar{A}_j e^{-i\omega_j t}+\bar{A}_j^* e^{i\omega_j t})$$
$$-\frac{\lambda^2}{2\omega_i m_i}\sum_j{}'\frac{c_{ij}^2}{2\omega_j m_j}\left(a_i\left[\pi\delta(\omega_j-\omega_i)-i\,\mathrm{P}\left(\frac{2\omega_j}{\omega_j^2-\omega_i^2}\right)\right]\right.$$
$$\left.+a_i^*\left[-\pi\delta(\omega_j-\omega_i)-i\,\mathrm{P}\left(\frac{2\omega_j}{\omega_j^2-\omega_i^2}\right)\right]\right)\,, \tag{18}$$

and the conjugate equation for a_i^*. Considering the relation (2) and disregarding the principal value terms (for these represent the reaction by the thermostat oscillators on the central oscillator resulting only a shift of frequency or a level-shift), we find

$$p_i=m_i\dot{x}_i\,, \tag{19a}$$

$$\dot{p}_i+\zeta p_i+\omega_i^2 m_i x_i=-\lambda\sum_j{}' c_{ij}\sqrt{\frac{\hbar}{2\omega_j m_j}}(\bar{A}_j e^{-i\omega_j t}+\bar{A}_j^* e^{i\omega_j t})\,, \tag{19b}$$

where

$$\zeta=\frac{\pi\lambda^2\bar{c}^2 g}{2\omega_i^2 m_i m_j} \tag{19c}$$

and g is the density of the thermostat oscillators at $\omega_j=\omega_i$ and $\bar{c}^2$ is the average of c_{ij}^2 over the thermostat oscillators at $\omega_j=\omega_i$.

From Eqs. (19a) and (19b) we have

$$\ddot{x}_i+\zeta\dot{x}_i+\omega_i^2 x_i=-\frac{\lambda}{m_i}\sum_j{}' c_{ij}\sqrt{\frac{\hbar}{2\omega_j m_j}}(\bar{A}_j e^{-i\omega_j t}+\bar{A}_j^* e^{i\omega_j t})\,. \tag{20}$$

This corresponds to the classical Langevin equation. The right hand side of Eq. (20) represents the fluctuating random force, which, as we shall see later, supplies thermal energy to the oscillator (fluctuation-dissipation theorem). We take the ensemble average as to the thermostat oscillators noticing that the average values of $\bar{A}_j$ and $\bar{A}_j^*$ on the right hand side of Eq. (20) vanish (cf. Eq. (29)). We get

$$\langle\ddot{x}_i\rangle+\zeta\langle\dot{x}_i\rangle+\omega_i^2\langle x_i\rangle=0\,. \tag{21}$$

This corresponds to the equation for a classical damped-oscillator.

§ 4. The Relaxation Equation

First, we observe the variation of an arbitrary operator F which we consider as a polynomial of a_i and a_i^*, where we can generally fix that operators a_i's appear always to the right of operators a_i^*'s, that is;

$$F=\sum_{\nu,\nu'}F_{\nu,\nu'}a_i^{*\nu}a_i^{\nu'}\,. \tag{22}$$

So, we have to consider the variation of the form $a_i^{*\nu}a_i^{\nu'}$. Because of Eq. (6), we have

$$\frac{d}{dt}(a_i^{*\nu}a_i^{\nu'})=i\omega_i(\nu-\nu')a_i^{*\nu}a_i^{\nu'}+e^{i\omega_i(\nu-\nu')t}\frac{d}{dt}(A_i^{*\nu}A_i^{\nu'})\,. \tag{23}$$

Here we calculate the time derivative of the operator which appears in the last term of the above equation. As

$$\frac{d}{dt}(A_i^{*\nu}A_i^{\nu'})=A_i^{*\nu}\left(\frac{d}{dt}A_i^{\nu'}\right)+\left(\frac{d}{dt}A_i^{*\nu}\right)A_i^{\nu'}\,, \tag{24}$$

we have then terms like $A_i^{*\nu}A_i\cdots\dot{A}_iA_i\cdots$. Using Eqs. (12), (16) and their conjugate equations, we take the limit $s\to+0$, and disregard the principal-value parts (as in § 3, they contribute to a level-shift only) as before. But we must be careful about the commutation relation (13) and non-commutativity of A_i and $\overline{A}_i$ etc. After some calculation, neglecting terms higher than the third, we get finally

$$\begin{aligned}\frac{d}{dt}(A_i^{*\nu}A_i^{\nu'})=&-\frac{\lambda^2}{2}\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(\overline{A}_j\overline{A}_j^*+\overline{A}_j^*\overline{A}_j)\\&\times\left(\nu'(\nu'-1)e^{2i\omega_i t}A_i^{*\nu}A_i^{\nu'-2}+\nu(\nu-1)e^{-2i\omega_i t}A_i^{*\nu-2}A_i^{\nu'}\right)\\&+2\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\overline{A}_j^*\overline{A}_j\nu\nu' A_i^{*\nu-1}A_i^{\nu'-1}\\&-\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(\nu'+\nu)A_i^{*\nu}A_i^{\nu'}\\&+\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\\&\times\left\{e^{2i\omega_i t}\left(\nu' A_i^{*\nu+1}A_i^{\nu'-1}+\frac{\nu'(\nu'-1)}{2}A_i^{*\nu}A_i^{\nu'-2}\right)\right.\\&\left.+e^{-2i\omega_i t}\left(\nu A_i^{*\nu-1}A_i^{\nu'+1}+\frac{\nu(\nu-1)}{2}A_i^{*\nu-2}A_i^{\nu'}\right)\right\}\\&+\lambda(\text{terms linear as to }\overline{A}_j\text{ and }\overline{A}_j^*)\,.\end{aligned}\tag{25}$$

We can omit the last terms first order in λ, as they are linear with respect to $\overline{A}_j$ and $\overline{A}_j^*$ of the thermostat and vanish after taking average as to the thermostat: we are not interested in these terms (cf. §2 and Eq. (29)). In virtue of Eqs. (25) and (6), Eq. (23) may be written as

$$\begin{aligned}\frac{d}{dt}(a_i^{*\nu}a_i^{\nu'})=&\,i\omega_i(\nu-\nu')a_i^{*\nu}a_i^{\nu'}\\&-\frac{\lambda^2}{2}\left(\frac{1}{2\omega_i m_i}\right)\sum{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(\overline{A}_j\overline{A}_j^*+\overline{A}_j^*\overline{A}_j)\\&\times(\nu'(\nu'-1)a_i^{*\nu}a_i^{\nu'-2}+\nu(\nu-1)a_i^{*\nu-2}a_0^{\nu'})\\&+2\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\overline{A}_j^*\overline{A}_j\nu\nu' a_i^{*\nu-1}a_i^{\nu'-1}\\&-\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(\nu'+\nu)a_i^{*\nu}a_i^{\nu'}\\&+\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\left(\nu' a_i^{*\nu+1}a_i^{\nu'-1}\right.\\&\left.+\nu a_i^{*\nu-1}a_i^{\nu+1}+\frac{\nu'(\nu'-1)}{2}a_i^{*\nu}a_i^{\nu'-2}+\frac{\nu(\nu-1)}{2}a_i^{*\nu-2}a_i^{\nu'}\right)\,.\end{aligned}\tag{26}$$

Considering the following commutation relations,

$$\left.\begin{aligned}&[a_i^*,\,a_i^{*\nu}a_i^{\nu'}]=-\nu' a_i^{*\nu}a_i^{\nu'-1}\,,\\&[a_i\,,\,a_i^{*\nu}a_i^{\nu'}]=\nu a_i^{*\nu-1}a_i^{\nu'}\,,\end{aligned}\right\}\tag{27}$$

we have from Eqs. (22) and (26)

$$\begin{aligned}\frac{d}{dt}F=&\,i\omega_i\{a_i^*[a_i,F]+[a_i^*,F]a_i\}\\&-\frac{\lambda^2}{2}\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(\overline{A}_j\overline{A}_j^*+\overline{A}_j^*\overline{A}_j)\\&\times([a_i^*,[a_i^*,F]]+[a_i,[a_i,F]])\end{aligned}$$

$$
\begin{aligned}
&-2\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\overline{A}_j{}^*\overline{A}_j[a_i{}^*,[a_i,F]]\\
&-\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)(-[a_i{}^*,F]a_i+a_i{}^*[a_i,F])\\
&+\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\pi\delta(\omega_i-\omega_j)\Big(-a_i{}^*[a_i{}^*,F]+[a_i,F]a_i\\
&+\frac{1}{2}[a_i{}^*[a_i{}^*,F]]+\frac{1}{2}[a_i[a_i,F]]\Big)\,.
\end{aligned}
\tag{28}
$$

As we have said in § 2, we take the average as to the thermostat;

$$
\left.
\begin{aligned}
&\langle(\overline{A}_j{}^*\overline{A}_j+\overline{A}_j\overline{A}_j{}^*)\rangle=2\langle N_j(\omega_j)\rangle+1\,,\\
&\langle\overline{A}_j{}^*\overline{A}_j\rangle=\langle N_j(\omega_j)\rangle\,,\\
&\langle\overline{A}_j\rangle=\langle\overline{A}_j{}^*\rangle=0\,,
\end{aligned}
\right\}
\tag{29}
$$

where N_j is the quantum number of the j-th oscillator of thermostat. The above two of Eqs. (29) are consistent because of Eqs. (13).

From Eq. (28), taking the average as to the thermostat oscillators and considering Eq. (29), we get the following equation written for the matrix elements:

$$
\begin{aligned}
\left(\frac{d}{dt}F\right)_{n,n'}=&\,i\omega_i(n-n')F_{n,n'}\\
&-\pi\lambda^2\left(\frac{1}{2\omega_i m_i}\right)\left(\frac{\bar{c}^2 g}{2\omega_i m_j}\right)\Big\{\left(\langle N_j(\omega_i)\rangle+\frac{1}{2}\right)\Big(\sqrt{n(n-1)}\,F_{n-2,n'}\\
&-2\sqrt{n(n'+1)}\,F_{n-1,n'+1}+\sqrt{(n'+1)(n'+2)}\,F_{n,n'+2}+\sqrt{n'(n'-1)}\,F_{n,n'-2}\\
&-2\sqrt{(n+1)n'}\,F_{n+1,n'-1}+\sqrt{(n+1)(n+2)}\,F_{n+2,n'}\Big)\\
&+2\langle N_j(\omega_i)\rangle\Big((n+n'+1)F_{n,n'}-\sqrt{nn'}\,F_{n-1,n'-1}\\
&-\sqrt{(n+1)(n'+1)}\,F_{n+1,n'+1}\Big)\\
&+(n+n')F_{n,n'}-2\sqrt{nn'}\,F_{n-1,n'-1}+\frac{1}{2}\sqrt{n(n-1)}\,F_{n-2,n'}\\
&+\frac{1}{2}\sqrt{n'(n'-1)}\,F_{n,n'-2}-\frac{1}{2}\sqrt{(n'+1)(n'+2)}\,F_{n,n'+2}\\
&-\frac{1}{2}\sqrt{(n+1)(n+2)}\,F_{n+2,n'}\Big\}\,,
\end{aligned}
\tag{30}
$$

where n means the n-th excitation of the i-th (central) oscillator and $F_{n,n'}$ means the n, n' element of the operator F.

Now, this Eq. (30) for the operator F in Heisenberg representation will be translated to the equation for the density matrix σ in Schroedinger representation. This can be done by noting that $\langle F\rangle=\mathrm{trace}\,(F\sigma)$, or by the following rules.

$$
\begin{aligned}
&F_{n',n}\rightarrow\sigma_{n,n'}\,,\\
&(n'-n)F_{n',n}\rightarrow(n'-n)\sigma_{n,n'}\,,\\
&\sqrt{n'(n'-1)}\,F_{n'-2,n}\rightarrow\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}\,,
\end{aligned}
$$

etc.

where $\sigma_{n,n'}$ means the n, n' element of the density matrix σ of the i-th (central) oscillator. Then we have the following equation;

$$
\begin{aligned}
\frac{d}{dt}\sigma_{n,n'}=&-i\omega_i(n-n')\sigma_{n,n'}\\
&-\pi\left(\frac{\lambda^2\bar{c}^2g}{4\omega_i^2m_im_j}\right)\Big\{\left(\langle N_j(\omega_i)\rangle+\frac{1}{2}\right)\Big(\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}\\
&-2\sqrt{n(n'+1)}\,\sigma_{n-1,n'+1}+\sqrt{n(n-1)}\,\sigma_{n-2,n'}+\sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'}\\
&-2\sqrt{(n+1)n'}\,\sigma_{n+1,n'-1}+\sqrt{n'(n'-1)}\,\sigma_{n,n'-2}\Big)\\
&+2\langle N_j(\omega_i)\rangle\Big((n+n'+1)\sigma_{n,n'}-\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1}-\sqrt{nn'}\,\sigma_{n-1,n'-1}\Big)\\
&+(n+n')\sigma_{n,n'}-2\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1}+\frac{1}{2}\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}\\
&+\frac{1}{2}\sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'}-\frac{1}{2}\sqrt{n(n-1)}\,\sigma_{n-2,n'}\\
&-\frac{1}{2}\sqrt{n'(n'-1)}\,\sigma_{n,n'-2}\Big\}\,. \qquad (31)
\end{aligned}
$$

The average of the quantum number $N_j(\omega_i)$ of the thermostat oscillator j whose frequency is equal to ω_i, is given by the well-known formula

$$\langle N_j(\omega_i)\rangle=\frac{1}{e^{\theta}-1}\,, \qquad (32)$$

when the temperature of the thermostat is T, where

$$\theta=\frac{\hbar\omega_i}{kT}\,, \qquad (33)$$

then, Eq. (31) may be written as follows;

$$
\begin{aligned}
\frac{d}{dt}\sigma_{n,n'}=&-i\omega_i(n-n')\sigma_{n,n'}\\
&-\frac{\kappa}{2}\{\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}+\sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'}\\
&+e^{-\theta}(\sqrt{n(n-1)}\,\sigma_{n-2,n'}+\sqrt{n'(n'-1)}\,\sigma_{n,n'-2})\\
&-(1+e^{-\theta})(\sqrt{n(n'+1)}\,\sigma_{n-1,n'+1}+\sqrt{(n+1)n'}\,\sigma_{n+1,n'-1})\\
&+[n+n'+e^{-\theta}(n+n'+2)]\sigma_{n,n'}-2\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1}\\
&-2e^{-\theta}\sqrt{nn'}\,\sigma_{n-1,n'-1}\} \qquad (34)
\end{aligned}
$$

where

$$
\begin{aligned}
\kappa&=\left(\frac{\lambda^2\bar{c}^2\pi g}{2\omega_i^2m_im_j}\right)(1-e^{-\theta})^{-1}\\
&=\zeta(1-e^{-\theta})^{-1}\,. \qquad (35)
\end{aligned}
$$

Here, ζ is the same as defined by Eq. (19c).

Eq. (34) is the generalization of the relaxation equation which Montroll and Shuler[6] derived. As they treated the diagonal terms only, the terms corresponding to $\sigma_{n,n'+2}$, $\sigma_{n+2,n'}$, $\sigma_{n-2,n'}$, $\sigma_{n,n'-2}$, $\sigma_{n-1,n'+1}$ and $\sigma_{n+1,n'-1}$ did not appear in their equation. From the equation of their type, the Kramers-Chandrasekhar equation can not be derived in its complete form.

§ 5. Kramers Chandrasekhar Equation

Using the density matrix element $\sigma_{n,n'}$, we can write the density matrix ρ in the q-representation as

$$\rho(q_1, q_2; t)=\sum_{n,n'} \sigma_{n,n'}(t)\rho_{n,n'}(q_1, q_2) , \tag{36}$$

where

$$\rho_{n,n'}(q_1, q_2)=\sqrt{\frac{\alpha}{2^n n! \sqrt{\pi}}}\sqrt{\frac{\alpha}{2^{n'} n'! \sqrt{\pi}}} H_n(\alpha q_1)H_{n'}(\alpha q_2) \exp\left(-\frac{\alpha^2}{2}(q_1^2+q_2^2)\right) . \tag{37}$$

Here $H_n(\alpha q_1)$ is the Hermite polynomial of order n and q_1 or q_2 is the coordinate of the i-th (central) oscillator, and

$$\alpha=\sqrt{\frac{m_i\omega_i}{\hbar}} . \tag{38}$$

If we use the n-representation, then

$$\rho_{n,n'}=|n\rangle\langle n'| ,$$

where $|n\rangle$ (or $\langle n|$) is the ket (or bra) vector of n-th excitation. Because

$$a_i|n\rangle\langle n'|=\sqrt{n}\, |n-1\rangle\langle n'| , \qquad a_i^*|n\rangle\langle n'|=\sqrt{n+1}\, |n+1\rangle\langle n'| ,$$

and

$$a_i=\frac{1}{\sqrt{2}}\left(\alpha q_1+\frac{1}{\alpha}\frac{\partial}{\partial q_1}\right), \qquad a_i^*=\left(\alpha q_1-\frac{1}{\alpha}\frac{\partial}{\partial q_1}\right) ,$$

we have the following relations;

$$\left.\begin{aligned}\sqrt{n}\, \rho_{n-1,n'} &=\frac{1}{\sqrt{2}}\left(\alpha q_1+\frac{1}{\alpha}\frac{\partial}{\partial q_1}\right)\rho_{n,n'} ,\\ \sqrt{n+1}\, \rho_{n+1,n'} &=\frac{1}{\sqrt{2}}\left(\alpha q_1-\frac{1}{\alpha}\frac{\partial}{\partial q_1}\right)\rho_{n,n'} .\end{aligned}\right\} \tag{39}$$

On the other hand, from Eqs. (36) and (34) we have

$$\begin{aligned}\frac{\partial}{\partial t}\rho(q_1, q_2; t)=&\sum_{n,n'}\left(\frac{d}{dt}\sigma_{n,n'}(t)\right)\rho_{n,n'}(q_1, q_2)\\ =&-i\omega_i\sum_{n\,n'}(n-n')\sigma_{n,n'}\rho_{n,n'}\\ &-\frac{\kappa}{2}\sum_{n\,n'}\{\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}+\sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'}\\ &+e^{-\theta}(\sqrt{n(n-1)}\,\sigma_{n-2,n'}+\sqrt{n'(n'-1)}\,\sigma_{n,n'-2})\\ &-(1+e^{-\theta})(\sqrt{n(n'+1)}\,\sigma_{n-1,n'+1}+\sqrt{(n+1)n'}\,\sigma_{n+1,n'-1})\\ &+[n+n'+e^{-\theta}(n+n'+2)]\sigma_{n,n'}\\ &-2\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1}-2e^{-\theta}\sqrt{nn'}\,\sigma_{n-1,n'-1}\}\rho_{n,n'}\\ =&-i\omega_i\sum_{n,n'}(n-n')\rho_{n,n'}\sigma_{n,n'}\\ &-\frac{\kappa}{2}\sum_{n\,n'}\{\sqrt{n'(n'-1)}\,\rho_{n,n'-2}+\sqrt{n(n-1)}\,\rho_{n-2,n'}\\ &+e^{-\theta}(\sqrt{(n+1)(n+2)}\,\rho_{n+2,n'}+\sqrt{(n'+1)(n'+2)}\,\rho_{n,n'+2})\\ &-(1+e^{-\theta})(\sqrt{(n+1)n'}\,\rho_{n+1,n'-1}+\sqrt{n(n'+1)}\,\rho_{n-1,n'+1})\\ &+[n+n'+e^{-\theta}(n+n'+2)]\rho_{n,n'}-2\sqrt{nn'}\,\rho_{n-1,n'-1}\\ &-2e^{-\theta}\sqrt{(n+1)(n'+1)}\,\rho_{n+1,n'+1}\}\sigma_{n,n'} .\end{aligned} \tag{40}$$

Making use of the relation (39) and noting Eq. (38) we have from Eqs. (40) and (36)

$$\frac{\partial}{\partial t}\rho(q_1, q_2; t)=-\frac{i}{\hbar}\left[-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial q_1^2}-\frac{\partial^2}{\partial q_2^2}\right)+\frac{m\omega^2}{2}(q_1^2-q_2^2)\right]\rho(q_1, q_2; t)$$

$$-\frac{\kappa}{2}(1+e^{-\theta})\left[\frac{m\omega}{\hbar}(q_1-q_2)^2\right]\rho(q_1,q_2;t)$$
$$+\frac{\kappa}{2}(1-e^{-\theta})\left[(q_1-q_2)\left(\frac{\partial}{\partial q_2}-\frac{\partial}{\partial q_1}\right)\right]\rho(q_1,q_2;t)\,. \tag{41}$$

This is to be compared to the equation which Zwazig[7)] derived from the relaxation equation of Montroll and Shuler.[6)]

To make the classical distribution function expressed in terms of position r and momentum p from the density matrix, we make use of the Wigner's distribution function; that is

$$f(r,p;t)=\frac{1}{\pi\hbar}\int_{-\infty}^{\infty} e^{i2py/\hbar}\,dy\rho(r,y;t)\,, \tag{42}$$

where

$$q_1=r-y\,,\qquad q_2=r+y\,. \tag{43}$$

From the transformation (43), the following relations are derived easily;

$$\left.\begin{aligned}&-\left(\frac{\partial^2}{\partial q_1^2}-\frac{\partial^2}{\partial q_2^2}\right)=\frac{\partial^2}{\partial r\partial y}\,,\qquad q_1^2-q_2^2=-4ry\,,\\&(q_1-q_2)^2=4y^2\,,\qquad (q_1-q_2)\left(\frac{\partial}{\partial q_2}-\frac{\partial}{\partial q_1}\right)=-2y\frac{\partial}{\partial y}\,,\end{aligned}\right\} \tag{44}$$

Integrating partially, and bearing Eq. (42) in mind, from (44) we have

$$\left.\begin{aligned}i\frac{p}{\hbar}\frac{\partial f}{\partial r}&=\frac{1}{\pi\hbar}\int_{-\infty}^{\infty} e^{i2py/\hbar}\,dy\left\{\frac{1}{2}\left(\frac{\partial^2}{\partial q_1^2}-\frac{\partial^2}{\partial q_2^2}\right)\right\}\rho\,,\\ i\hbar r\frac{\partial f}{\partial p}&=\frac{1}{\pi\hbar}\int_{-\infty}^{\infty} e^{i2py/\hbar}\,dy\left\{\frac{1}{2}(q_1^2-q_2^2)\right\}\rho\,,\\ -\hbar^2\frac{\partial^2}{\partial p^2}f&=\frac{1}{\pi\hbar}\int_{-\infty}^{\infty} e^{i2py/\hbar}\,dy(q_1-q_2)^2\rho\,,\\ 2\frac{\partial}{\partial p}(pf)&=\frac{1}{\pi\hbar}\int_{-\infty}^{\infty} e^{i2py/\hbar}\,dy(q_1-q_2)\left(\frac{\partial}{\partial q_2}-\frac{\partial}{\partial q_1}\right)\rho\,.\end{aligned}\right\} \tag{45}$$

By multiplying $e^{i2py/\hbar}/\pi\hbar$ to Eq. (41) and integrating over y, and using Eq. (45) we have the following equation;

$$\frac{\partial}{\partial t}f+\frac{p}{m}\frac{\partial}{\partial r}-m\omega^2 r\frac{\partial}{\partial p}f=\frac{\kappa}{2}(1+e^{-\theta})m\omega\hbar\frac{\partial^2}{\partial p^2}f+\kappa(1-e^{-\theta})\frac{\partial}{\partial p}(pf)\,, \tag{46}$$

Here, we write

$$\hbar\omega\theta^*=2\tanh(\theta/2)\,. \tag{47}$$

As easily seen, at high temperatures

$$\theta^*\approx\frac{1}{kT}\,. \tag{48}$$

Bearing in mind that $\kappa(1-e^{-\theta})=\zeta$ (cf. Eqs. (19c) and (35)), we obtain finally

$$\frac{\partial}{\partial t}f+\frac{p}{m}\frac{\partial}{\partial r}f-m\omega^2 r\frac{\partial}{\partial p}f=\zeta\frac{\partial}{\partial p}\left\{(pf)+\frac{m}{\theta^*}\frac{\partial}{\partial p}f\right\}\,. \tag{49}$$

This is Kramers-Chandrasekhar equation. Here we notice that our ζ is twice the Zwanzig's[7)]. As there were extra or rather missing terms in his calculation, his ζ had to be a half of ours.

§ 6. Spin Relaxation

In this section we shall be concerned with the relaxation phenomena of a spin $\frac{1}{2}$ under a constant magnetic field. As before, we consider the thermostat composed of a infinite number of harmonic oscillators. The interaction between the spin and the thermostat oscillators will be assumed simply to be

$$\lambda V = \sum \lambda_j (Q_{jx} s_x + Q_{jy} s_y + \varepsilon_j Q_{jz} s_z) \tag{50}$$

where $\vec{Q}_j = (Q_{jx}, Q_{jy}, Q_{jz})$ stands for the coordinate of the j-th oscillator in the thermostat, $\boldsymbol{s} = (s_x, s_y, s_z)$ the spin coordinate and ε_j is a numerical constant introduced in order to ascertain slight generality.

Such a problem is included in the general treatment by F. Bloch[5]. According to his result the relaxation equation is

$$d\boldsymbol{M}/dt = \gamma \boldsymbol{M} \times \boldsymbol{H} - \boldsymbol{i} M_x / T_2 - \boldsymbol{j} M_y / T_2 - \boldsymbol{k}(M_z - M_0)/T_1 \,, \tag{51}$$

where M_x, M_y and M_z are the components of magnetization $\boldsymbol{M}$, $\boldsymbol{i}$, $\boldsymbol{j}$ and $\boldsymbol{k}$ the unit vectors along x, y and z axises. $\gamma = 2\mu / s\hbar$ as usual. The external field is along the z-axis and M_0 is the equilibrium magnetization. If the interaction is the form given by Eq. (50), the theory of Bloch indicates that

$$\left.\begin{aligned} \frac{1}{T_1} &= 2\Phi'_{11}(1+e^{-\kappa}) \,, \\ \frac{1}{T_2} &= \frac{1}{2T_1} + \Phi^0_{11} \,, \end{aligned}\right\} \tag{52}$$

with $\kappa = \hbar\omega_0 / kT = \gamma \mathrm{H}_0 / kT$. We have $(Q^{\pm} = Q_x \pm iQ_y)$

$$\left.\begin{aligned} \Phi'_{11} &= \frac{\pi}{4\hbar^2} \sum_{E'} P(E')(E'|\lambda_j Q_j^{\pm}|E'+\hbar\omega_0)(E'+\hbar\omega_0|\lambda_j Q_j^{\pm}|E') \,, \\ \Phi^0_{11} &= \frac{\pi}{4\hbar^2} \sum_{E'} P(E')(E'|\lambda_j \varepsilon_j Q_{jz}|E')(E'|\lambda_j \varepsilon_j Q_{jz}|E') = 0 \,, \end{aligned}\right\} \tag{53}$$

where $P(E')$ is the probability that the thermostat has the energy $E' = \sum (n_j + \frac{1}{2})\hbar\omega_j$. As only the oscillator with frequency $\omega_j = \omega_0$ has the matrix elements

$$(n|Q_j^{\pm}|n+1) = (n+1|Q_j^{\pm}|n) = \sqrt{n+1}\sqrt{\frac{\hbar}{2m_j\omega_j}} \,, \tag{54}$$

we are lead to

$$\frac{1}{2T_1} = \frac{1}{T_2} = \pi \frac{1+e^{-\kappa}}{1-e^{-\kappa}} \sum_j \frac{\lambda_j^2}{4m_j\omega_j\hbar} \delta(\omega_j - \omega_0) \,. \tag{55}$$

This is the consequence of Bloch applied to the present case.

Now we shall use the method of the foregoing sections to this problem. The total hamiltonian is

$$\mathscr{H} = 2\mu\, \mathrm{H}_0 \cdot s_z + \sum_j \left(\frac{\vec{P}_j^2}{2m_j} + \frac{1}{2} m_j \omega_j^2 \vec{Q}_j^2 \right) + \lambda V + V' \tag{56}$$

where V' stands for the interaction within the thermostat. If we write

$$\left.\begin{aligned} s^{\pm} &= s_x \pm i s_y \,, \\ Q_j^{\pm} &= Q_{jx} \pm i Q_{jy} \,, \end{aligned}\right\} \tag{57}$$

the equations of motion for the spin become

$$\left.\begin{aligned}
\dot{s}^{+}&=i\omega_0 s^{+}+\frac{i}{\hbar}\sum\lambda_j(-Q_j{}^{+}s_z+\varepsilon_j Q_{jz}s^{+})\,,\\
\dot{s}^{-}&=-i\omega_0 s^{-}+\frac{i}{\hbar}\sum\lambda_j(Q_j{}^{-}s_z-\varepsilon_j Q_{jz}s^{-})\,,\\
\dot{s}_z&=\frac{i}{\hbar}\sum\lambda_j\frac{1}{2}(-Q_j{}^{-}s^{+}+Q_j{}^{+}s^{-})\,.
\end{aligned}\right\}\tag{58}$$

Next, we define

$$\left.\begin{aligned}
&S^{\pm}=e^{\pm i\omega_0 t}s^{\pm}\,, && S_z=s_z\,,\\
&A_j{}^{\pm}=e^{i\omega_j t}(a_{jx}\pm ia_{jy})\,, && A_{jz}=a_{jz}e^{i\omega_j t}\,,\\
&A_j{}^{*\pm}=e^{-i\omega_j t}(a_{jx}{}^{*}\pm ia_{jy}{}^{*})\,, && A_{jz}{}^{*}=a_{jz}{}^{*}e^{-i\omega_j t}\,,
\end{aligned}\right\}\tag{59}$$

where

$$\left.\begin{aligned}
\vec{a}_j&=\sqrt{\frac{m_j\omega_j}{2\hbar}}(\vec{Q}_j+i\vec{P}_j/m_j\omega_j)\,,\\
\vec{a}_j{}^{*}&=\sqrt{\frac{m_j\omega_j}{2\hbar}}(\vec{Q}_j-i\vec{P}_j/m_j\omega_j)\,.
\end{aligned}\right\}\tag{60}$$

Commutation relations are

$$\left.\begin{aligned}
&[A_j{}^{+},A_k{}^{-}]=[A_j{}^{*+},A_k{}^{*-}]=[A_j{}^{+},A_k{}^{*+}]=[A_j{}^{-},A_k{}^{*-}]=0\,,\\
&[A_j{}^{+},A_k{}^{*-}]=[A_j{}^{-},A_k{}^{*+}]=2\delta_{jk}\,,\\
&[A_{jz},A_{kz}{}^{*}]=\delta_{jk}\,.
\end{aligned}\right\}\tag{61}$$

With these transformations we get the following set of equations for the spin

$$\left.\begin{aligned}
\dot{S}^{+}&=\frac{i}{\hbar}\sum\lambda_j\sqrt{\frac{\hbar}{2m_j\omega_j}}\{-(e^{-i\omega_j t}A_j{}^{+}+e^{i\omega_j t}A_j{}^{*+})S_z e^{-i\omega_0 t}\\
&\qquad\qquad+\varepsilon_j(e^{-i\omega_j t}A_{jz}+e^{i\omega_j t}A_{jz}{}^{*})S^{+}\}\,,\\
\dot{S}^{-}&=\frac{i}{\hbar}\sum\lambda_j\sqrt{\frac{\hbar}{2m_j\omega_j}}\{(e^{-i\omega_j t}A_j{}^{-}+e^{i\omega_j t}A_j{}^{*-})S_z e^{i\omega_0 t}\\
&\qquad\qquad-\varepsilon_j(e^{-i\omega_j t}A_{jz}+e^{i\omega_j t}A_{jz}{}^{*})S^{-}\}\,,\\
\dot{S}_z&=\frac{i}{\hbar}\sum\lambda_j\sqrt{\frac{\hbar}{2m_j\omega_j}}\{-\tfrac{1}{2}(e^{-i\omega_j t}A_j{}^{-}+e^{i\omega_j t}A_j{}^{*-})S^{+}e^{i\omega_0 t}\\
&\qquad\qquad+\tfrac{1}{2}(e^{-i\omega_j t}A_j{}^{+}+e^{i\omega_j t}A_j{}^{*+})S^{-}e^{-i\omega_0 t}\}\,.
\end{aligned}\right\}\tag{62}$$

An analogous set of equations holds for the thermostat oscillators. That is

$$\left.\begin{aligned}
\dot{A}_j{}^{+}&=-\frac{i\lambda_j}{\sqrt{2m_j\omega_j\hbar}}S^{+}e^{i(\omega_0+\omega_j)t}+\dot{A}_j{}^{+\prime}\,,\\
\dot{A}_j{}^{-}&=-\frac{i\lambda_j}{\sqrt{2m_j\omega_j\hbar}}S^{-}e^{i(-\omega_0+\omega_j)t}+\dot{A}_j{}^{-\prime}\,,\\
\dot{A}_{jz}&=-\frac{i\lambda_j}{\sqrt{2m_j\omega_j\hbar}}S_z e^{i\omega_j t}+\dot{A}_{jz}{}'\,,\\
&\text{etc.}
\end{aligned}\right\}\tag{63}$$

The terms $\dot{A}_j{}'$ etc. are those due to the interaction within the thermostat. The operators with bar are to be introduced by, for instance,

$$\left.\begin{aligned}
S^+ &= \bar{S}^+ + \frac{i}{\hbar}\sum \lambda_j \sqrt{\frac{\hbar}{2m_j\omega_j}}\Big\{ -\Big(\bar{A}_j^+\int^t e^{-i(\omega_j+\omega_0)t}\,dt + \bar{A}_j^{*+}\int^t e^{i(\omega_j-\omega_0)t}\,dt\Big)\bar{S}_z \\
&\quad + \varepsilon_j\Big(\bar{A}_{jz}\int^t e^{-i\omega_j t}\,dt + \bar{A}_{jz}^*\int^t e^{i\omega_j t}\,dt\Big)\bar{S}^+\Big\}, \\
S_z &= \bar{S}_z + \frac{i}{\hbar}\sum \lambda_j \sqrt{\frac{\hbar}{2m_j\omega_j}}\Big\{ -\frac{1}{2}\Big(\bar{A}_j^-\int^t e^{-i(\omega_j-\omega_0)t}\,dt + \bar{A}_j^{*-}\int^t e^{i(\omega_j+\omega_0)t}\,dt\Big)\bar{S}^+ \\
&\quad + \frac{1}{2}\Big(\bar{A}_j^+\int^t e^{-i(\omega_j+\omega_0)t}\,dt + \bar{A}_j^{*+}\int^t e^{i(\omega_j-\omega_0)t}\,dt\Big)\bar{S}^-\Big\}, \\
A_j^+ &= \bar{A}_j^+ - \frac{i\lambda_j}{\sqrt{2m_j\omega_j\hbar}}\bar{S}^+\int^t e^{i(\omega_0+\omega_j)t}\,dt + A_j^{+\prime}, \\
&\text{etc.}
\end{aligned}\right\} \tag{64}$$

where, as before, A_j' etc. are the terms due to the interaction within the thermostat. These terms may be omitted for the equation of motion of the spin. Instead, we put the equilibrium properties on the barred operators of the thermostat oscillators: For example, the averaged quantities like $\langle\bar{A}_j\rangle$ are to vanish. We insert the above expressions in the right hand side of Eqs. (62) and take the average. After rather lengthy calculation we get finally

$$\left.\begin{aligned}
\frac{d}{dt}\langle S^+\rangle &= -\sum\frac{\pi\lambda_j^2}{4m_j\omega_j\hbar}\{\langle\bar{A}_j^{*+}\bar{A}_j^-\rangle\delta(\omega_j-\omega_0)\langle S^+\rangle + \delta(\omega_j-\omega_0)\langle S^+\rangle\}, \\
\frac{d}{dt}\langle S^-\rangle &= -\sum\frac{\pi\lambda_j^2}{4m_j\omega_j\hbar}\{\langle\bar{A}_j^-\bar{A}_j^{*+}\rangle\delta(\omega_j-\omega_0)\langle S^-\rangle - \delta(\omega_j-\omega_0)\langle S^-\rangle\}, \\
\frac{d}{dt}\langle S_z\rangle &= -\sum\frac{\pi\lambda_j^2}{4m_j\omega_j\hbar}\{\langle\bar{A}_j^-\bar{A}_j^{*+} + \bar{A}_j^{*+}\bar{A}_j^-\rangle\delta(\omega_j-\omega_0)\langle S_z\rangle + \delta(\omega_j-\omega_0)\}.
\end{aligned}\right\} \tag{65}$$

The average is, however, as is seen easily,

$$\begin{aligned}
&\frac{1}{2}\langle\bar{A}_j^{*+}\bar{A}_j^- + \bar{A}_j^-\bar{A}_j^{*+}\rangle = \langle\bar{A}_j^{*+}\bar{A}_j^-\rangle + 1 = \langle\bar{A}_j^-\bar{A}_j^{*+}\rangle - 1 \\
&= \frac{1}{\hbar\omega_j}\left\{\left\langle\frac{P_{jx}^2}{2m_j} + m_j\omega_j^2Q_{jx}^2\right\rangle + \left\langle\frac{P_{jy}^2}{2m_j} + m_j\omega_j^2Q_{jy}^2\right\rangle\right\} = \frac{2\langle E_j\rangle}{\hbar\omega_j} = \frac{1+e^{-\hbar\omega_j/kT}}{1-e^{-\hbar\omega_j/kT}}.
\end{aligned} \tag{66}$$

Therefore the relaxation equation takes the form

$$\frac{d}{dt}\langle \boldsymbol{S}\rangle = -\frac{1+e^{-\kappa}}{1-e^{-\kappa}}\sum\frac{\lambda_j^2\pi\delta(\omega_j-\omega_0)}{4\omega_j m_j\hbar}(\boldsymbol{i}\langle S_x\rangle + \boldsymbol{j}\langle S_y\rangle + 2\boldsymbol{k}(\langle S_z\rangle - \langle S_z\rangle_0)) \tag{67}$$

where

$$S^{\pm} = S_x \pm iS_y\,, \qquad \langle S_z\rangle_0 = \frac{1}{2}\left(\frac{e^{-\kappa/2}-e^{\kappa/2}}{e^{-\kappa/2}+e^{\kappa/2}}\right). \tag{68}$$

Thus the Bloch equation is justified.

Before closing this section it seems worth noting the following: We may place the $\bar{S}$-operators to the left of $\bar{A}$-operators in Eqs. (64). If we do so, Eqs. (65) are to be changed accordingly. But the relaxation equation is not changed as can be seen easily.

Appendix A.

As a special case of Eq. (26) in § 4, we can derive the equation governing the change of energy of the i-th (central) oscillator[8]. In Eq. (26) we put $\nu=\nu'=1$. Then we have the following equation;

$$\begin{aligned}
\frac{d}{dt}(a_i^*a_i) &= \lambda^2 2\pi\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\delta(\omega_i-\omega_j)\bar{A}_j^*\bar{A}_j \\
&\quad - \lambda^2\pi\left(\frac{1}{2\omega_i m_i}\right)\sum_j{}'\left(\frac{c_{ij}^2}{2\omega_j m_j}\right)\delta(\omega_i-\omega_j)[2a_i^*a_i - a_i^{*2} - a_i^2].
\end{aligned} \tag{A.1}$$

Here we take the average with respect to the thermostat oscillators, on which we put the same properties as before (cf. Eqs. (29)). Then we have

$$\frac{d}{dt}(a_i^* a_i) = \frac{\lambda^2 \bar{c}^2 \pi g}{2\omega_i^2 m_i m_j} \left\{ \langle N_j(\omega_i) \rangle - \frac{1}{2}(2a_i^* a_i - a_i^{*2} - a_i^2) \right.$$

$$= \zeta \left\{ \langle N_j(\omega_i) \rangle + \frac{1}{2} - \frac{1}{2}(a_i^* a_i + a_i a_i^* - a_i^{*2} - a_i^2) \right\}, \tag{A.2}$$

(cf. Eq. (19c)). Because the energy of the i-th (central) oscillator E_i can be expressed as

$$E_i = \hbar\omega_i \left(a_i^* a_i + \frac{1}{2} \right), \tag{A.3}$$

and its time derivative is

$$\frac{d}{dt} E_i = \hbar\omega_i \frac{d}{dt}(a_i^* a_i), \tag{A.4}$$

we have, from Eq. (A.2), the following equation;

$$\frac{d}{dt} E_i = \zeta \left\{ \hbar\omega_i \left(\langle N_j(\omega_i) \rangle + \frac{1}{2} \right) - \frac{\hbar\omega_i}{2}(a_i^* a_i + a_i a_i^* - a_i^{*2} - a_i^2) \right\}. \tag{A.5}$$

According to the relation (2), we can write

$$\frac{\hbar\omega_i}{2}(a_i^* a_i + a_i a_i^* - a_i^{*2} - a_i^2) = \frac{p_i^2}{m}. \tag{A.6}$$

So, Eq. (A.5) may be written as

$$\frac{d}{dt} E_i = \zeta \left\{ \hbar\omega_i \left(\langle N_j(\omega_i) \rangle + \frac{1}{2} \right) - \frac{p_i^2}{m} \right\}. \tag{A.7}$$

This must be compared with the equation

$$\frac{d}{dt} E_i = \zeta \left\{ \hbar\omega_i \left(\langle N_j(\omega_i) \rangle + \frac{1}{2} \right) - E_i \right\}, \tag{A.8}$$

which can be derived from the Montroll-Shuler's relaxation equation[6].

We rather think that Eq. (A.7), which can be derived also from the Kramers-Chandrasekhar equation, is more reasonable one than Eq. (A.8). The Eq. (A.8) is too sooth to describe the process in which the system approaches to equilibrium.

Appendix B.

We can show that Eq. (34) is equivalent to the following operator equation derived previously by one of the authors[3] for the density matrix σ:

$$\frac{\partial \sigma}{\partial t} = \frac{1}{i\hbar}(H_0 \sigma - \sigma H_0) + \zeta \left\{ \left(\langle N_j(\omega_i) \rangle + \frac{1}{2} \right) \hbar\omega_i m_i \frac{\partial^2 \sigma}{\partial p^2} + \frac{\partial}{\partial p} \left(\frac{p\sigma + \sigma p}{2} \right) \right\}. \tag{B.1}$$

To verify this equivalence, we have only to note the following;

$$\{x(x\sigma - \sigma x) - (x\sigma - \sigma x)x\}_{n,n'} = \{x^2\sigma - 2x\sigma x + \sigma x^2\}_{n,n'}$$

$$= \frac{\hbar}{2m_i\omega_i} \{(n+1)\sigma_{n,n'} + \sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'} + n\sigma_{n,n'} + \sqrt{n(n-1)}\,\sigma_{n-2,n'}$$

$$-2\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1} - 2\sqrt{(n+1)n'}\,\sigma_{n+1,n'-1} - 2\sqrt{n(n'+1)}\,\sigma_{n-1,n'+1}$$

$$-2\sqrt{nn'}\,\sigma_{n-1,n'-1} + \sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2} + (n'+1)\sigma_{n,n'}$$

$$+\sqrt{(n'-1)n'}\,\sigma_{n,n'-2} + n'\sigma_{n,n'}\},$$

and

$$
\begin{aligned}
\{x(p\sigma+\sigma p)-(p\sigma+\sigma p)x\}_{n,n'} &= \{xp\sigma+x\sigma p-p\sigma x-\sigma p x\}_{n,n'}\\
&= \frac{i\hbar}{2}\{(n+1)\sigma_{n,n'}-\sqrt{(n+1)(n+2)}\,\sigma_{n+2,n'}-n\sigma_{n,n'}+\sqrt{n(n-1)}\,\sigma_{n-2,n'}\\
&\quad +2\sqrt{(n+1)(n'+1)}\,\sigma_{n+1,n'+1}-2\sqrt{nn'}\,\sigma_{n-1,n'-1}\\
&\quad -\sqrt{(n'+1)(n'+2)}\,\sigma_{n,n'+2}+(n'+1)\sigma_{n,n'}+\sqrt{(n'-1)n'}\,\sigma_{n,n'-2}-n'\sigma_{n,n'}\}\,. \qquad \text{(B.3)}
\end{aligned}
$$

Further we have (cf. Eqs. (32) and (33))

$$\frac{1+e^{-\theta}}{2(1-e^{-\theta})}=\frac{1}{e^{\theta}-1}+\frac{1}{2}=\left(\langle N_j(\omega_i)\rangle+\frac{1}{2}\right), \qquad \text{(B.4)}$$

and in general

$$\frac{\partial}{\partial p}G=\frac{1}{i\hbar}(xG-Gx)\,. \qquad \text{(B.5)}$$

By repeated use of the last equation, we get from Eq. (34) the operator equation (B.1).

Appendix C.

If we regard p, x as classical variables instead of operators, we can derive the Kramers-Chandrasekhar equation by the method as follows.

Let

$$\left.\begin{aligned}\bar{a}_j&=\bar{A}_j\,e^{-i\omega_j t}\,,\\ \bar{a}_j{}^*&=\bar{A}_j{}^*\,e^{i\omega_j t}\,,\end{aligned}\right\} \qquad \text{(C.1)}$$

and

$$\left.\begin{aligned}\bar{p}_j&=-i\sqrt{\omega_j m_j\hbar/2}\,(\bar{a}_j-\bar{a}_j{}^*)\,,\\ \bar{x}_j&=\sqrt{\hbar/2\omega_j m_j}\,(\bar{a}_j+\bar{a}_j{}^*)\,,\end{aligned}\right\} \qquad \text{(C.2)}$$

then, Eq. (19) may be written as

$$\left.\begin{aligned}\dot{x}_i&=p_i/m_i\,,\\ \dot{p}_i&=-\omega_i^2 m_i x-\zeta p_i-\lambda\sum_j c_{ij}\bar{x}_j\,.\end{aligned}\right\} \qquad \text{(C.3)}$$

Further from Eqs. (6), (12) and its conjugate equation we have

$$\left.\begin{aligned}p_i&=\bar{p}_i-\frac{\pi\lambda}{2}\sum_j{}'\,c_{ij}\,\delta(\omega_i-\omega_j)\bar{x}_j\,,\\ x_i&=\bar{x}_i-\frac{\pi\lambda}{2\omega_i m_j}\sum_j{}'\,c_{ij}\,\delta(\omega_i-\omega_j)\,\bar{p}_j\,,\end{aligned}\right\} \qquad \text{(C.4)}$$

where $\bar{p}_i$ and $\bar{x}_i$ have analogous meaning as $\bar{p}_j$ and $\bar{x}_j$ defined by the relations (C.1) and (C.2). And we must notice that $\bar{p}_j$ and $\bar{x}_j$ in Eqs. (C.4) are those of the thermostat oscillators whose angular frequency are equal to ω_i.

Here we regard Eqs. (C.3) and (C.4) as the equations for the classical variables. This is reasonable, for we may consider a, a^*, A and A^* as the classical variables transformed from the classical variables p and x. In this interpretation, the following translations are needed

$$\left.\begin{aligned}[a,G]&\to\frac{\partial}{\partial a^*}G\,,\\ [a^*,G]&\to-\frac{\partial}{\partial a}G\,,\end{aligned}\right\} \qquad \text{(C.5)}$$

where G is an arbitrary function of a and a^*.

Now, we introduce an arbitrary function $F(p_i, x_i)$ of classical variables p_i and x_i. Using the classical Eq. (C.3) we get

$$\begin{aligned}\frac{d}{dt}F&=\dot{p}_i\frac{\partial}{\partial p_i}F+\dot{x}_i\frac{\partial}{\partial x_i}F\\&=-\omega_i^2m_ix_i\frac{\partial}{\partial p_i}F+\frac{p_i}{m_i}\frac{\partial}{\partial x_i}F\\&\quad-\zeta p_i\frac{\partial}{\partial p_i}F-\lambda\sum_j{}'c_{ij}\bar{x}_j\frac{\partial}{\partial p_i}F\,.\end{aligned}\tag{C.6}$$

Here we assume that

$$\left.\begin{aligned}\langle\bar{x}_j^2\rangle&=\frac{kT}{m_j\omega_j^2}\,,\\\langle\bar{x}_j\bar{p}_j\rangle&=0\,,\end{aligned}\right\}\tag{C.7}$$

where $\langle\ \rangle$ means the average taken over the thermostat oscillators. These assumptions correspond to those of (29). Then using Eq. (C.4) and considering that the difference between p_i and $\bar{p}_i$ is the order of λ, we have to the second order in λ

$$\left\langle-\lambda\sum_j{}'c_{ij}x_j\frac{\partial}{\partial p_i}F\right\rangle=\zeta m_ikT\frac{\partial^2}{\partial p_i^2}F\,.\tag{C.8}$$

Taking the average of Eq. (C.6) over the thermostat oscillators, from Eq. (C.8) we have

$$\frac{d}{dt}F=-\omega_i^2m_ix_i\frac{\partial}{\partial p_i}F+\frac{p_i}{m_i}\frac{\partial}{\partial x_i}F-\zeta p_i\frac{\partial}{\partial p_i}F-\zeta m_ikT\frac{\partial^2}{\partial p_i^2}F\,.\tag{C.9}$$

Let $f(p_i, x_i; t)$ be the distribution function of i-th (central) oscillator, then the following relation must be satisfied;

$$\int\left(\frac{d}{dt}F\right)f\,dp_i\,dx_i=\int F\frac{\partial}{\partial t}f\,dp_i\,dx_i\,.\tag{C.10}$$

Using Eqs. (C.9) and (C.10), we get

$$\begin{aligned}\int F\frac{\partial}{\partial t}f\,dp_i\,dx_i&=\int\left(-\omega_i^2m_ix_i\frac{\partial}{\partial p_i}F+\frac{p_i}{m_i}\frac{\partial}{\partial x_i}F-\zeta p_i\frac{\partial}{\partial p_i}F+\zeta m_ikT\frac{\partial^2}{\partial p_i^2}F\right)f\,dp_i\,dx_i\\&=\int F\left(\omega_i^2m_ix_i\frac{\partial}{\partial p_i}f-\frac{p_i}{m_i}\frac{\partial}{\partial x_i}f+\zeta\frac{\partial}{\partial p_i}(p_if)+\zeta m_ikT\frac{\partial^2}{\partial p_i^2}f\right)dp_i\,dx_i\,,\end{aligned}\tag{C.11}$$

where to get the last line we have used the partial integration.

To satisfy Eq. (C.11) for an arbitrary function F, the distribution function f must satisfy the following equation

$$\frac{\partial}{\partial t}f-\omega_i^2m_ix_i\frac{\partial}{\partial p_i}f+\frac{p_i}{m_i}\frac{\partial}{\partial x_i}f=\zeta\frac{\partial}{\partial x_i}\left(p_if+m_ikT\frac{\partial}{\partial p_i}f\right)\,.\tag{C.12}$$

This is the classical Kramers-Chandrasekhar equation which we have wanted to derive.

Electrical Properties of Alkali Antimonides

By Shunji IMAMURA

Technical Research Laboratories, Japan Broadcasting Corporation,
361, Kinuta-machi, Setagaya-ku, Tokyo, Japan

(Received June 5, 1959)

Systematic studies of the preparation procedures and the electrical characteristics of the alkali antimonides, such as sodium, potassium, rubidium and cesium antimonides, were carried out. It has been found that these antimonides can be classified into two groups, i.e., a group which transits from p-type to n-type with successive activation, e.g. sodium and potassium antimonides, and a group which keeps constantly p-type, e.g. cesium antimonide. Rubidium antimonide was recognized to be an intermediate compound lying between these two groups. Supply of excess alkali metal, deposition of additional antimony and superficial oxidation gave remarkable effects on the dark and photoconductivity and the photoemission, but these effects proceeded in opposite derections in these two groups. With decreasing temperature, the mobility of n-type compound decreased, whereas that of p-type one increased. A picture of impurity states in these compounds was proposed in order to interprete the above mentioned phenomena, taking the ionic radius of alkali atom and the crystal structure into consideration.

§ 1. Introduction

Alkali antimonides are intermetallic compound composed of alkali metal and antimony as represented by M_3Sb. Among them, cesium antimonide (Cs–Sb) is a well known photocathode material with high efficiency in visible spectral region. Many investigations on the mechanism of photoemission have been concentrated on this material.[1] Cs–Sb has usually not stoichiometic composition and is a p-type semiconductor confirmed by the measurements of Hall effect[2] and thermoelectromotive force.[3] Other alkali antimonides, such as Rb–Sb, K–Sb and Na–Sb, have been scarcely studied so far because of their low efficiency of the emission for visible light. However, it is worthwhile to investigate systematically these all alkali antimonides, not only Cs–Sb, in order to obtain more information about their emission mechanism.

In 1953, Suhrmann and Kangro[4] reported that K_3Sb was an n-type semiconductor. This fact seems to be strange compared with the p-type conduction in Cs–Sb. In 1958, we showed[5] that Rb–Sb, K–Sb and Na–Sb were n-type semiconductors and that the dark and photoconductivity and the photoemission behaved in opposite manner to Cs–Sb when a small amount of antimony or oxygen was introduced on these materials. Recently, Sommer[6] independently reported almost similar results. The main purpose of the present paper is to elucidate these remarkable phenomena in alkali antimonides.

§ 2. Preparation of Samples and Experimental Method

As is usual for the experimental study of photo-cathode, great care must be taken to avoid impurities and contaminations. We used Sb of the purity of 99.999% containing As as main impurity and alkali chromate of the highest purity commercially available as alkali metal source.

Fig. 1(a) shows the experimental tube for the measurements of conductivity, photoconductivity, photoemission and optical transmission. For the measurement of Hall effect the another tube shown in Fig. 1(b) was employed, whose electrodes were made of nonmagnetic materials.

After evacuation and degassing, Sb was deposited onto the aquadag electrode provided on the inner wall of the glass tube. In order to obtain the electric characteristics in bulk and to separate the internal from the external photoelectric effect, much thicker layer than that in usual photo-tubes was adopted. The thickness of Sb layer, ranged from 1000 Å to 2000 Å, was monitored by the optical transmission which was previously calibrated by multiple interference method. The alkali metal was distilled by heating the mixture of the alkali chromate and the reducing agents such as powdered Al, Si and W. At temperatures between 150° and 180°C, the alkali antimonides were prepared by the reaction of the alkali metal vapor with Sb layer.

In Cs–Sb, the thickness of the final layer is about 8.1 times larger than that of the initially deposited Sb layer.[7] In other alkali antimonides, an expansion of the same order may be expected.

During the formation processes, the resistance, the photoemission current, the photoconduction current and the sign of thermo-electromotive force were measured.

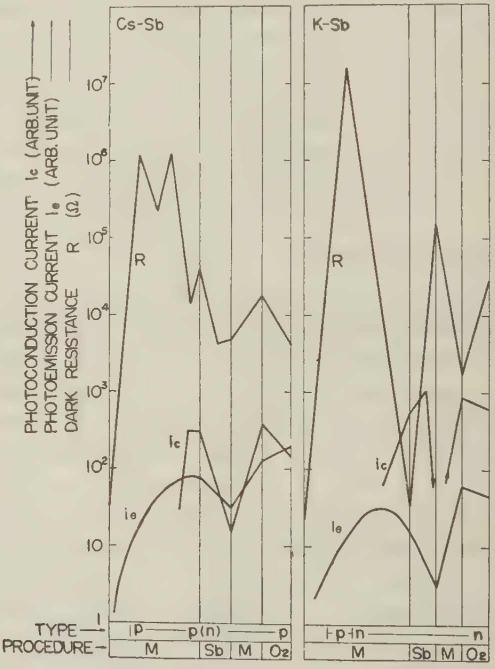
§ 3. Experimental Results

3.1. Behaviors in the course of preparation

Fig. 2 shows schematically the behaviors of the dark resistance at 170°C, the photoemission current at 20°C and the photoconduction current at 20°C in the course of preparation. In abscissa, " M ", " Sb " and " O_2 " denote an alkali metal reaction with Sb layer, an additional small amount deposition of Sb and a superficial oxidation at oxygen pressure about 10^{-4} mm Hg respectively. The abscissa shows also the sign of majority carrier determined by thermo-electromotive force.

Dark resistance:

In Cs–Sb (Fig. 2a), if Cs supply proceeded, the resistance increases rapidly and then reaches a maximum value, at this stage the color of the layer is transparent yellow. If Cs is supplied furthermore, the resistance decreases and then slowly increases, the color becoming deep red. The resistance decreases considerably by the process " Sb " or " O_2 ". Fig. 2b shows the behaviors of K–Sb as a representative of Rb–Sb, K–Sb and Na–Sb. After the maximum resistance is established, the resistance decreases relatively rapidly and the color changes abruptly from red to violet, though this color change is insufficient in some samples of Rb–Sb and is not apparent in Na–Sb. This state corresponds to the nearly degenerated one, which will be described later. In contrast with Cs–Sb, the resistance increases by " Sb " or ', O_2 ".



(a) (b)

Fig. 2. Schematic representation of the behaviors in the course of preparation. (a) Cesium antimonide. (b) Potassium antimonide.

Photoconduction:

Photoconduction current could not be measured until the resistance bigins to decrease through the maximum value and becomes appreciable with over alkali supply. In the K–Sb group, enhancement of the photoconductivity is brought by additional deposition of Sb after the resistance decreased fairly, in contrast with the case of Cs–Sb. "O_2" suppresses the photoconductivity and increases noise current in all antimonides.

Photoemission:

The photoemission increases with increasing resistance during alkali metal supply. If alkali metal supply is continued further, after the resistance peak is established the emission decreases slowly in Cs–Sb and rapidly in other antimonides. "Sb" causes also the emission decrease in all antimonides. "O_2" causes the emission increase in Cs–Sb, i.e., the so-called "oxygen sensitization" occurs, whereas in other antimonides this treatment causes the emission decrease, though some samples, especially Rb–Sb, show the opposite behavior. The absolute luminous sensitivity was 40–60 μA/lm for Cs–Sb, 10–20 μA/lm for Rb–Sb, 5–10 μA/lm for K–Sb and <1 μA/lm for Na–Sb.

Thermo-electromotive force:

The sign of the thermo-electromotive force was observed during the preparation. In Cs–Sb, the sign is always negative, indicating that positive charge carriers are predominant. If plenty of Cs is occasionally introduced, some samples change to n-type. However, this state is not stable, but returns to p-type with subsequent heat treatment. This phenomenon is considered to be surface conduction and seems to be the same as observed by several investigators.[8] In K–Sb and Na–Sb the transition from p-type to n-type takes place just after, or in some cases even before, the peak resistance is attained. In Rb–Sb, this transition occurs rather later than former two, and some samples keep p-type conduction and do not degenerate.

3.2 Electrical properties

Temperature dependence of conductivity:

Temperature dependence of the conductivity was measured over the range from 500° to 77°K, at several stages during preparation. In Cs–Sb, the slope in log conductivity versus $1/T$ plot decreases with Cs supply from ca. 0.4 eV at initial stage to ca. 0.15 eV at final stage. Wallis[9] has collected in his paper many different values of activation energy of Cs–Sb ranged from 0.4 to 0.025 eV, which were reported by many investigators. Such dispersion seems to be proper characteristics expectable from inhomogeneity of this compound. The curve of largest slope serves the value of the zero interception of the intrinsic order ($10^3-10^4\ \Omega^{-1}\,\mathrm{cm}^{-1}$), and so it is considered ideally to give the minimum energy difference between the conduction band and the filled band.

Fig. 3 shows a typical one in K–Sb as a representative of all n-type compounds. The slope decreases with alkali metal supply. The largest slope is considered similarly to give the intrinsic gap, and the mean value for many samples is listed in Table I with the values for other compounds. A remarkable

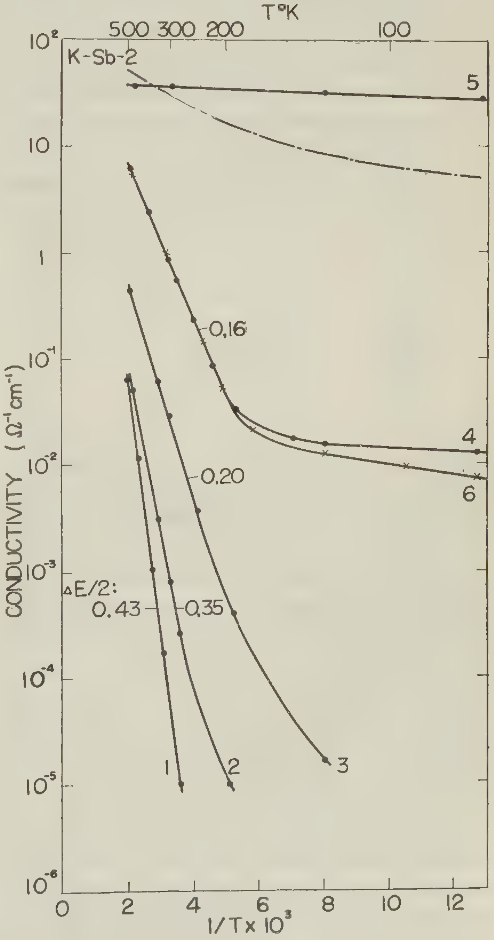


Fig. 3. Conductivity vs. $1/T$ for K–Sb. Numbers denote the preparation stages. Chain curve shows a degeneration limit.

Table I. Maximum value of electric activation energy.

	Cs–Sb	Rb–Sb	K–Sb	Na–Sb
Max. activation energy $\varDelta E/2$ (eV)	0.4	0.5	0.5	0.6

difference from Cs–Sb is the flat part at low temperatures (curve 4). At the final stage of activation, temperature dependence almost disappears (curve 5). This state gives the large value of carrier concentration of the order of $10^{18}\,\mathrm{cm}^{-3}$ by using the value of mobility $\mu=10\,\mathrm{cm}^2\,\mathrm{v}^{-1}\,\mathrm{sec}^{-1}$ as given later, and satisfies a condition for degeneration (chain curve) calculated from the equation:

$$T=\left(\frac{h^2}{2mk}\right)\left(\frac{3n}{8\pi}\right)^{2/3}.$$

Hence, supply of excess alkali atom to Rb–Sb, K–Sb and Na–Sb makes finally a degenerated state. The color of the layer is red in the state 4 and is violet in the state 5. According to the detailed measurement of optical transmission spectra, however, actual layer is not so homogeneous that even at earlier stage of activation (e.g. curve 4) the degenerated state is partially produced. The flat part of curve 4 is presumably due to this partial semi-metallic conduction. Curve 6 is obtained by "Sb" and shows that the degeneration has been removed.

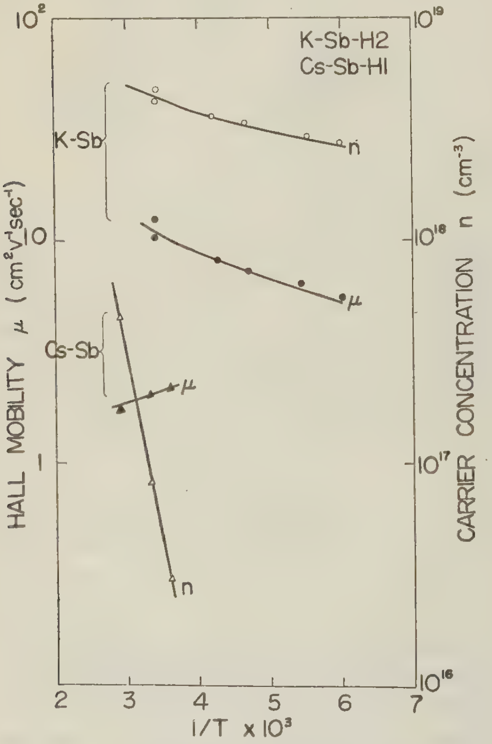

Fig. 4. Hall mobility and carrier concentration vs. $1/T$.

Hall effect:

The sign of the majority carriers observed in this measurement coincided with that in the thermo-electromotive force measurement. As is shown in Fig. 4, Hall mobility of Cs–Sb increases with decreasing temperature, in agreement with Sakata's observation.[2] As a contrast, the mobility of the nearly degenerated K–Sb, as a representative of all n-type compounds, decreases with decreasing temperature. This may be taken as an indication of the presence of impurity scattering due to large impurity concentration in n-type compound. The mobility of Cs–Sb is, in general, smaller than that of other n-type antimonides by about one order of magnitude, though the values are dispersing.

§ 4. Impurity Model for Alkali Antimonides and Discussion

Before discussing the impurity state in these antimonides, we must consider chemical impurities in host material. Since Sb is the common component in these compounds, impurities contained in Sb will not be a cause for the opposite behaviors in two groups. Alkali metal vaporization is performed by a fractional distillation process, and so the alkali metal vapor is considered to be fairly pure. However, in the procedure of reaction of Sb with the alkali metal vapor of lower vapor pressure, such as Na, impurities of higher vapor pressure, such as Cs, should be avoided, because it forms quickly undesired compound. Existence of such alkali metal as Cs gives definite effect on the photoemission because of its high efficiency. But this effect was not observed in the present experiment. Consequently, chemical impurities may be left out of consideration. In practice, deposited Sb layer does not form regular lattice, and the reaction with alkali metal is essentially a solid phase reaction. Then, many imperfections must exist in these compounds. Microscopic density of Cs_3Sb calculated from X-ray's data is $4.42\,\mathrm{g\,cm}^{-3}$, while macroscopic density calculated from optically determined thickness is $1.54\,\mathrm{g\,cm}^{-3}$. This discrepancy may be taken as a support of above suggestion. Lattice defect, stacking fault, dislocation and grain boundary must effect on the electrical properties. On the other hand, there are such definite experimental results as Cs–Sb is a *p*-type semiconductor and contains excess Cs atoms.[10,11] Although it is difficult to determine the origin of the acceptors, it is one reasonable way to identify the Cs atom, which occupied Sb site substitutionally, as acceptors, as was pointed out by Jack and Wachtel.[10] In other alkali antimonides, the same interpretation may be adopted on the *p*-type conduction at initial stage in activation process. When alkali atoms are introduced in large quantity, these excess atoms, this time, occupy the interstitial positions in the lattice if possible and act as donors. Ionic radii of K and Na are so small that it is possible to enter the interstitial position, and, therefore, if donor concentration N_D becomes larger than acceptor concentration N_A, a transition from *p*- to *n*-type may be observed. In Cs–Sb, however, it is difficult to occupy the interstitial position because of the large ionic radius of Cs, so that *n*-type conduction does not appear, except surface conduction of *n*-type. Rb is considered to have the limit radius for this possibility. It has been reported so far that Cs_3Sb has a cubic lattice[10] and K_3Sb and Na_3Sb have a hexagonal structure,[12] provided that the preparation methods have been different from those used in photo-cathodes. Table II shows microscopic densities calculated from X-ray's data assuming that each compound is able to crystalize in two different structures, because the transition between these may be possible. Parentheses denote the interpolated values. Remarkable result is that the density of *n*-type sample is smaller in hexagonal form than that in cubic one and that of *p*-type sample is small in cubic form. Crystal form of small density is able to involve larger amount of interstitial atoms than that of larger density. In K–Sb, for instance, interstitial K atom is more stable in hexagonal crystal than in cubic one.

Table II. Densities of alkali antimonides calculated from X-ray's data,[10),12)] assuming that crystal structure of each compound is either cubic or hexagonal. Parentheses denote interpolated values.

Compound	ionic radius of alkali ion (Å)	lattice const.		density (g cm^{-3})
		a(Å)	c(Å)

Rb_3Sb : hex.	1.48	(6.1)	(11.0)	(3.54)
Cs_3Sb : cub.	1.70	9.18		4.42
Cs_3Sb : hex.	1.70	(6.2)	(11.2)	(4.63)

The interpretation of decrease of activation energy with alkali metal supply and the estimation of the donor concentration at degenerated state are made as follows: If N_D increases successively, the distance between donor impurities decreases and the wave functions of the impurities overlap. Though the levels will distribute at random in the forbidden band, the model proposed by Conwell[13] may be applied in this problem. That is to say, the vanishing of the activation energy should occure at $r_s=2\kappa a_H^*$, where r_s is given by $4/3\times\pi r_s^3=1/N_D$, κ is a suitable dielectric constant and a_H^* is the radius of the first Bohr orbit for a carrier of effective mass m^*. The value of κ of Cs–Sb may be estimated to be slightly larger than the optical dielectric constant $\kappa_0=4$, obtained from the refractive index,[9] as $\kappa=6$, by taking some ionic natures of this compound into consideration. Nearly equal value of κ is expected for the other compounds, too. Assuming $m^*=0.3\,\mathrm{m}$, r_s

$=2\kappa a_H{}^*=2.1\times10^{-7}$ cm, hence $N_D=2.7\times10^{19}$ cm^{-3}. This value is fairly in agreement with the free carrier concentration at the degenerated state, though somewhat larger. This large value of N_D must give some effects on the crystal lattice more or less. A variation of crystal structure, presumably from cubic to hexagonal or from amorphous to hexagonal one, accompanying the color change and abrupt increase of N_D may possibly occur in this condition.

In n-type sample, "Sb" and "O_2" decrease the interstitial and substitutional atoms composing some compounds with these elements, and consequently the conductivity decreases, though still $N_D>N_A$ holds. In n-type sample, N_D decreases in the similar way, and thereupon the conductivity increases.

The detailed discussions of the photoemission and the photoconduction will be presented in the subsequent paper.

At last, we must state a remark on the intrinsic electrical nature of the alkali antimonides. The Brillouin zone of Cs–Sb of cubic structure is just filled with electrons at the stoichiometric composition Cs_3Sb[10] so that the property of intrinsic semiconductor will be expected. But, it is somewhat questionable to assume that the hexagonal alkali antimonide with stoichiometric composition is an intrinsic semiconductor as it is the case for cubic structure, because the zone of such structure may be not completely filled with electrons.

§ 5. Conclusions

From the systematic studis of the preparation procedures and the electrical properties, a picture of donor and acceptor states in each alkali antimonide consistent with the experimental results has been presented taking the ionic radius of alkali atom and the crystal structure into consideration. The present viewpoint should be further correlated to the explanation of photoelectric phenomena, as will be described in the subsequent paper. Photoelectrical study will infer whether the present model has a more general validity or not.

Photoelectrical Properties of Alkali Antimonides

By Shunji IMAMURA

Technical Research Laboratories, Japan Broadcasting Corporation, 361, Kinuta-machi, Setagaya-ku, Tokyo, Japan

(Received June 5, 1959)

Photoemission, photoconduction and optical absorption of sodium, potassium, rubidium and cesium antimonides were studied at several stages in the course of preparation. In the former three, supply of excess alkali atoms caused the decrease in optical absorption and photoemission at the photon energies higher than the absorption edge, whereas in the last one these phenomena were not remarkable. Photoconduction characteristics were interpreted by assuming two impurity states (donor and acceptor) in each antimonide. At last, two kinds of energy band structures in k-space were proposed on the basis of the crystal structures (cubic and hexagonal), using the energy values obtained from measurements.

§ 1. Introduction

Many studies have been concentrated on the photoemission[1] and the optical absorption[2] of Cs-Sb. Photoemission of this compound is usually attributed to a volume effect, because of the large optical absorption coefficient and the high quantum efficiency in the spectral region within which the photo-electrons are available. But only a few measurements were carried out on photoconductivity[2], despite of great importance for the understanding of the optical excitation process in this compound.

In addition, very few studies on the photoemission were made on the other antimonides of alkali metals[4], such as Rb-Sb, K-Sb and Na-Sb. Recently, the photoelectric characteristics of these compounds were reported by Spicer[5] in cooperation with Sommer. Entirely independently of these investigators, we made detailed studies on photoelectrical properties, including the spectral distribution of the photoemission and photoconduction[6].

In the preceding paper[7], we have discussed the physical nature of the impurity states in these alkali antimonides. Present paper has two purpose. The first is to examine the correlation of the impurity with the optical properties, such as photoconduction, photoemission and optical absorption, and the second is to give a suitable energy band model for these alkali antimonides.

§ 2. Experimental Method

In the preparation of samples, special care was taken on the layer thickness. Since these materials are photo-emitter, the measurement of the photoconduction is disturbed by the emitted photo-electrons which skim toward the positive electrode. For this reason, so far the photoconduction measurement has not been carried out in the spectral region within which the photoemission is available. To avoid this difficulty, the comparatively thick layers, from 1.0μ to 2.0μ, were employed. When incident light falls on glass side surface as illustrated in Fig. 1, almost light is absorbed in the layer, because of the large optical absorption coefficient, and the transmitted light is very weak at the vicinity of vacuum side surface. Thus, the photoconductivity can be measured over extended spectral range without interference due to externally emitted photo-electrons. For the measurement of the photoemission the light was projected from vacuum side. We have shown in the preceding paper that activation and additional treatment give considerable change on the electrical characteristics. Therefore, the optical and photoelectrical measurements were made at several stages in these processes. The light from tungsten lamp was chopped at the frequency of 180 cp and the photo-current was measured using a high sensitivity tuned amplifier. Such method was especially required

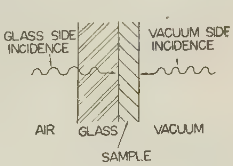

Fig. 1. Direction of light incidence.

for the measurement of photoconductivity, because the photo-current was quite only a fraction of the dark current. The glass prism double monochromator was employed for the spectral measurement. In order to measure the photoconductivity decay, sample was illuminated with pulsed light from argon discharge tube, whose pulse width is shorter than 1μ sec, and the photo-current was observed with a cathode-ray oscilloscope.

§ 3. Experimental Results and Discussion

3.1 Optical absorption

Samples with different thickness were prepared for the measurement of transmittance. The difference of the logarithms of transmission for different thickness is proportional to the absorption coefficient. Although satisfactory method to determine the absorption edge has not been developed yet so far, the edge can be approximately given by extrapolation of the above mentioned transmission difference curve, even if exact value of layer thickness is unknown. Fig. 2 shows the transmission spectra and the transmission difference curves for typical samples. The magnitude of absorption coefficient in higher photon energy region is estimated to be of the order of 10^5 cm^{-1}. The absorption in lower photon energy

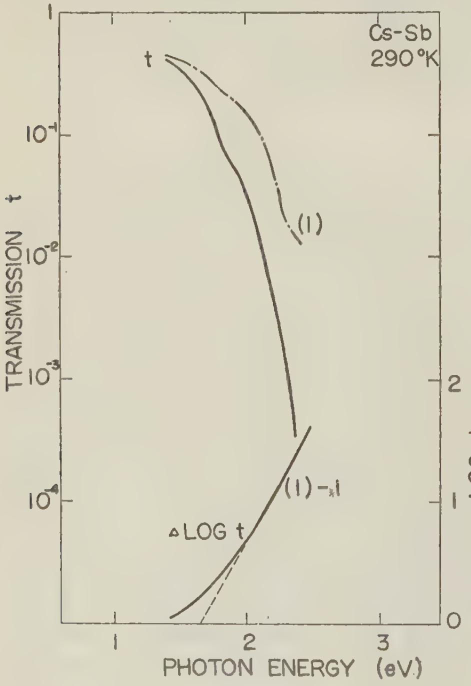

Fig. 2(a).

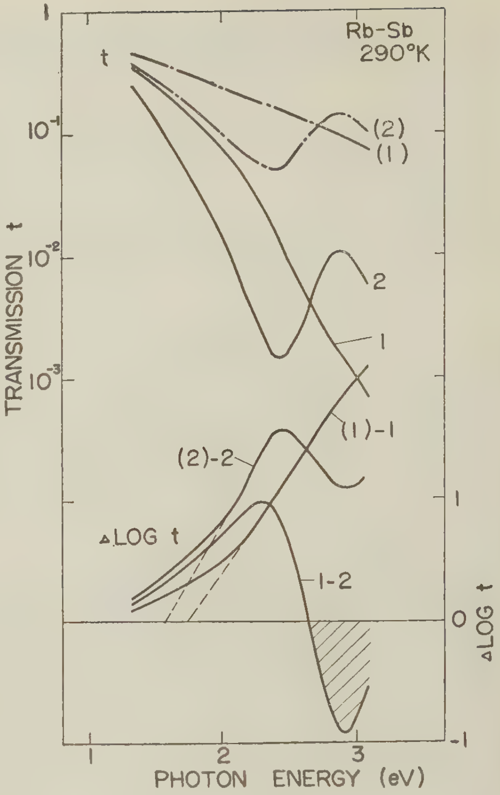

Fig. 2(b).

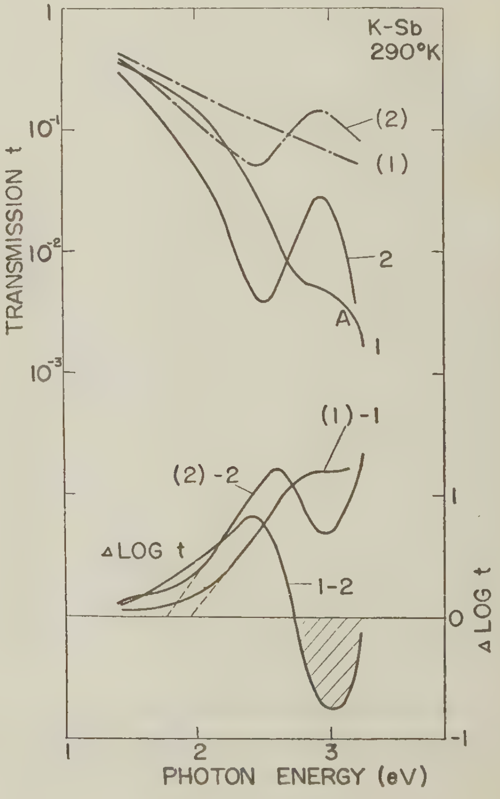

Fig. 2(c).

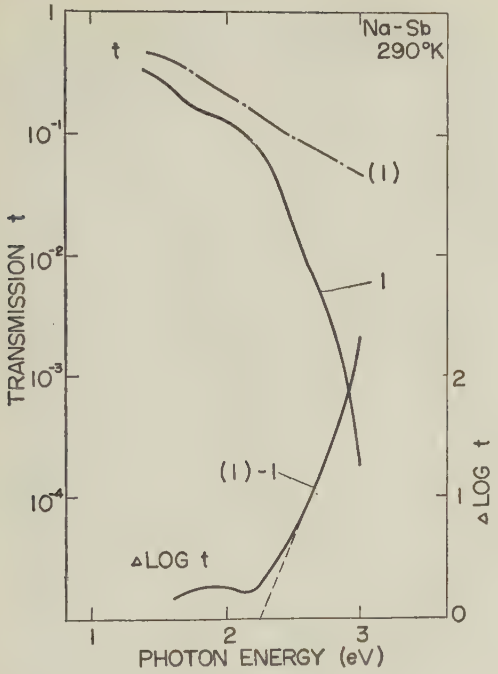

Fig. 2(d).

Fig. 2. Optical transmission spectra for the layers with different thickness, at 290°K. Thickness of initially deposited Sb layer is 100 to 120Å for chain curve and 150 to 170Å for solid curve. Degree of activation by alkali metal supply increases from 1 to 2. (a): Cs-Sb, (b): Rb-Sb, (c): K-Sb and (d): Na-Sb.

region cannot be considered to be intrinsic one.

During activation process, remarkable phenomena appeared in K-Sb and Rb-Sb. In Fig. 2 (c), for example, curves 1 and (1) represent the transmission in the state of high electric resistivity, curves 2 and (2) associate with the electrically degenerated state developed by addition of K atom to the states 1 and (1), and curves (1)–1 and (2)–2 give the difference of the transmission in these two states. As seen from curve 1–2, the absorption decreases remarkably in the higher photon energy region (hatched area), making a trough of absorption curve, and increases in the lower photon energy region, with alkali metal supply. In appearance, there were the color change from red to violet and an appreciable crystal growth, at this moment. Small hamp A of curve 1 suggests a partial proceeding of the color change at the initial stage of activation. These phenomena occure also in Rb-Sb (Fig. 2b), except some samples which retained high resistivity even though a large quantity of alkali atom was introduced. Consequently, abrupt color change and abrupt resistivity decrease occur at the same time. These phenomena were not distinct in Na-Sb and never occured in Cs-Sb. Since the absorption decrease takes place at the photon energies higher than the absorption edge, this is, at least, not caused by the excess alkali atoms, but considered to be due to a change in the energy band structure.

3.2 Photoemission

Fig. 3 shows the spectral quantum yields of photoemission. Degree of activation increases in suffixed numerical order. Since the absorption coefficient and the quantum yields are fairly large in this spectral region, the emission of all alkali antimonidies should be due to a volume effect. Then, the minimum energy for the transition from filled band to

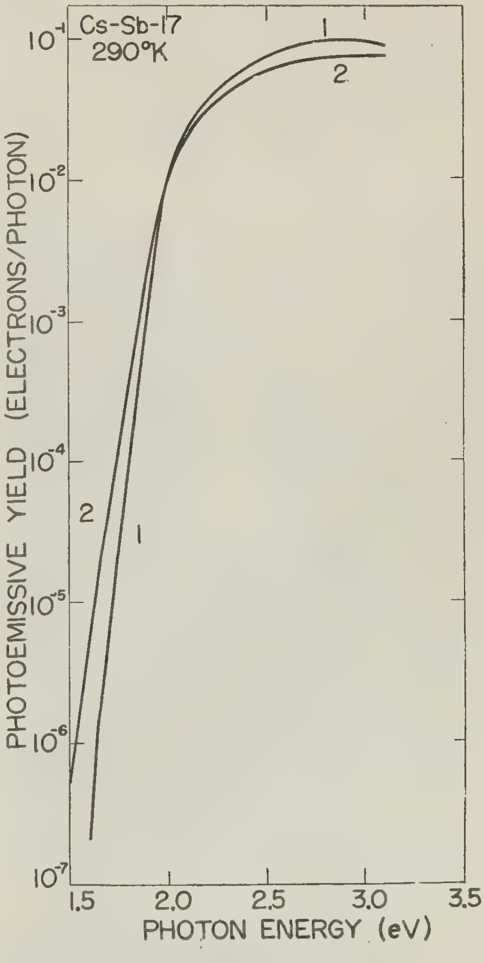

Fig. 3(a).

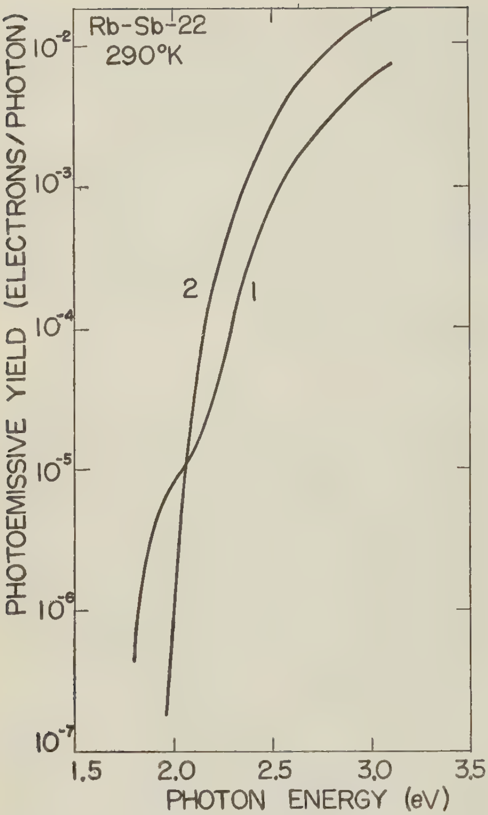

Fig. 3(b).

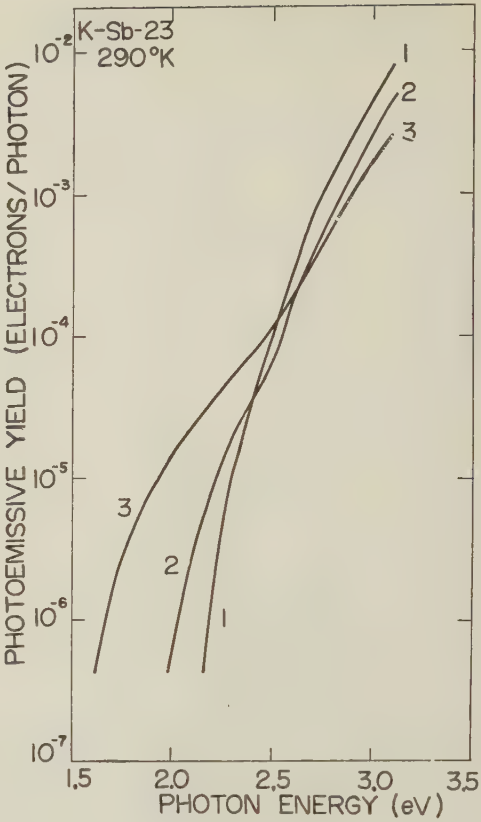

Fig. 3(c).

vacuum level can be approximately determined from the photoemission threshold energy. When a large quantity of alkali atom is introduced, the spectral yields increase at lower photon energy and decrease at higher photon energy. The increase is supposed to be due to the excitation of excess alkali atoms, which exist predominantly at the surface. However, the decrease of yields is considered to be more important and is attributed to the impurity scattering of the electrons excited by volume effect. The luminous sensitivity decreases also by excess alkali metal supply. In addition, it was observed that these changes are more remarkable in n-type Rb-Sb, K-Sb and Na-Sb, which are n-type compounds. It seems likely to deduce that n-type alkali antimonides are able to admit a large quantity of excess alkali atom than that p-type Cs-Sb does.

3.3 Photoconduction

Spectral response:

The measurement of the spectral distribution of photoconductivity was difficult, because magnitude of the photo-current was very small and unstable, and the noise current was large. Fig. 4 shows typical spectral response curves. No distinct change is found at the energy of absorption edge or the photoemission threshold. But, the value of the threshold of photoconductivity is fairly in agreement with the twice of the largest activation energy of electric conduction. Distinct change cannot be observed at the energy corresponding to the above mentioned absorption trough in K-Sb and Rb-Sb. If a small amount of Sb is deposited on the surface of these n-type alkali antimonides or infra-red light is overlapped, the response quenches especially in higher photon energy region as shown in Fig. 4d.

Temperature dependence:

Measurement of the temperature dependence of photoconductivity was carried out at the several stages in the course of preparation. Curve 1 in Fig. 5 was obtained at electrically degenerated state, which was developed by excess alkali atom supply and had low resistivity. The response is very low at room

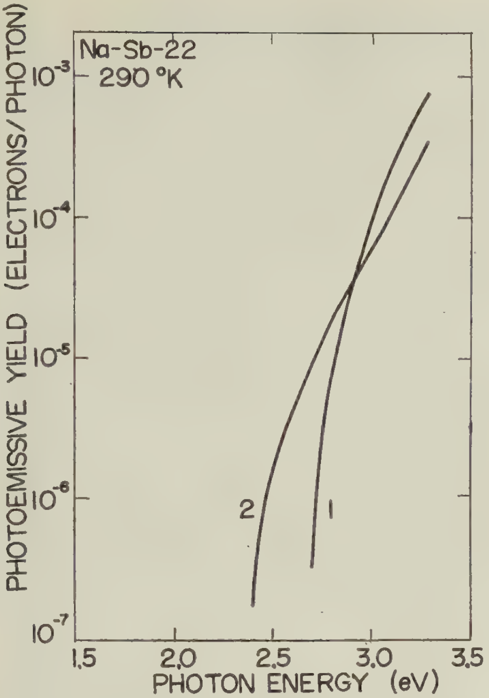

Fig. 3(d).

temperature, but increases rapidly with decreasing temperature. When a small amount of Sb is deposited, the sensitivity increases at room temperature and decreases at low temperatures (curves 2 and 3) in comparison to curve 1. The sensitivity of Cs-Sb is usually lower than those of other compounds by many factors, as shown in Fig. 5 (curve A).

Decay time:

Photoconductivity decay could not be expressed by a simple exponential curve. However, the time constant obtained from the fast decay at initial period is considered to give a measure of the life-time of the excess carriers. In a strongly n-type K-Sb sample the time constant was 300μ sec at 77°K and was 1.4μ sec at 290°K. This temperature dependence of time constant is in agreement with the tendency in the temperature dependence of photoconductivity. In the sample quoted above, the time constant decreased remarkably when infra-red light was overlapped, indicating that the trapped carriers (in this case, holes) were released on this occasion.

Light spot scanning measurement:

The area between electrodes was scanned by the thin light beam of 0.5 mm thick. It was found that the distribution of local photoconductivity was non-uniform and changed with time, in most samples of high resistivity. The rate of change depends on applied voltage and does not depend on illumination intensity, and finally a stationary state is established requiring several minutes or more. In n-type

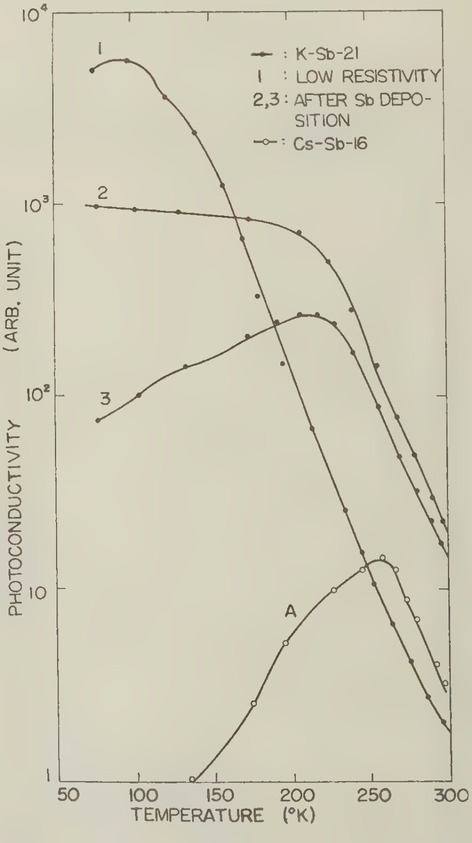

Fig. 5. Temperature dependence of photoconductivity. Curves 1, 2 and 3: for K-Sb, of which curve 1 was obtained at degenerated state and other curves were obtained by Sb deposition in suffixed numerical order. Curve A: Cs-Sb.

sample, the local photo-response in the stationary state is highest in the vicinity of the positive electrode, as shown in Fig. 6. These results indicate that the photo-sensitive point in high resistive n-type compound corresponds to a negatively charged center. Since during this change the color of layer was invariant, it could not be to relate to an electrolytic process[8].

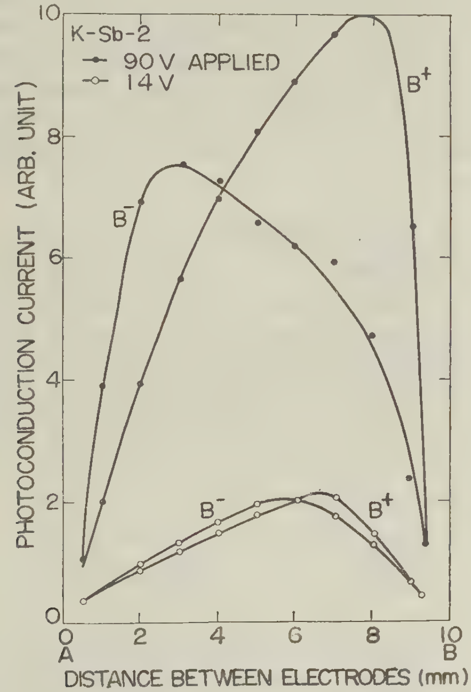

Fig. 6. Distribution of local photoconductivity in stationary state. B^+ and B^- denote the polarity of applied vollage at B side electrode.

Mechanism of photoconduction:

The donors and the acceptors are considered to be interstitial and substitutional alkali atoms respectively, as described in the preceding paper. In n-type compound, the donor concentration N_D is larger than the acceptor concentration N_A, and then the acceptors have been compensated negatively with donor electrons. If electron-hole pairs are produced by optical excitation of the filled band electrons as described in the next section, some of free holes are trapped by the negatively charged acceptors. As a result,

$$\Delta n = \Delta p_f + \Delta p_t\,, \tag{1}$$

when Δn, Δp_f and Δp_t are concentration of excess free electrons, free holes and trapped holes respectively (Fig. 7). The photo-sensitivity is related to the concentration and the life-time of free carriers. If the concentration and the life-time of the trapped holes are large, the corresponding excess free electrons are able to contribute to photoconduction.

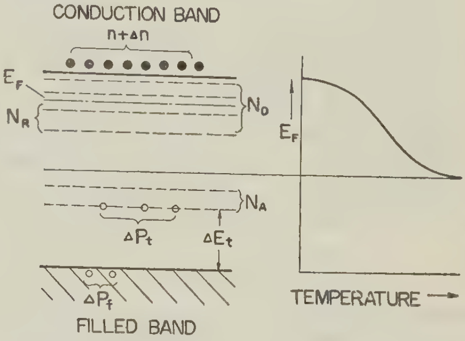

Fig. 7. Model of impurity states for illuminated *n* type compound.

Now, we consider the life-time. After the removal of optical excitation, the decay rate of hole and the time constant are given by

$$-\frac{d\Delta p_t}{dt} = q_t v n \Delta p_t + \Delta p_t \nu \exp\left(-\frac{\Delta E_t}{kT}\right)$$

$$\equiv \left(\frac{1}{\tau_t}\right)_1 \Delta p_t + \left(\frac{1}{\tau_t}\right)_2 \Delta p_t\,, \tag{2}$$

and

$$-\frac{d\Delta p_f}{dt} = q_f v N_R \Delta p_f$$

$$\equiv \left(\frac{1}{\tau_f}\right)\Delta p_f\,, \tag{3}$$

where q_t is the capture cross-section of acceptor for a free electron when occupied by a hole, v is the thermal velocity of free electron, n is the free electron concentration, ν is attempt-to-escape-frequency, ΔE_t is the energy difference between filled band and acceptor levels occupied by a hole, q_f is the recombination cross section of free electron and free hole through recombination center and N_R is the concentration of recombination centers. Eq. (2) represents the rates with which trapped hole density decreases by capture of free electrons and by thermal process. Eq. (3) represents the recombination rate of free carriers. Consequently, the life-time of excess carriers is controlled by three components;

$$\frac{1}{\tau} = \left(\frac{1}{\tau_t}\right)_1 + \left(\frac{1}{\tau_t}\right)_2 + \left(\frac{1}{\tau_f}\right).$$

Now, we assume that the donors below the Fermi level E_F act as the recombination centers. In the strongly n-type sample, temperature dependence of life-time is determined by the second term, because N_R is large and E_F, in this case, is temperature independent. Therefore, the sharp increase in photoconductivity with decreasing temperature (Curve 1 in Fig. 5) is understood. When a small amount of Sb is doposited, it combines with impurity alkali atom, and the sample becomes normally n-type. The decrease of impurity concentration implies the decrease of n, N_R and Δp_t. Then, the quenching of photoresponse is mainly due to the decrease of Δp_t, despite of increased life-time due to the decrease of n and N_R. In normally n-type sample, E_F shifts toward the middle of the forbidden gap with temperature rise. Therefore the density of the donors below E_F, which act as recombination centers, decreases with temperature rise, enhancing the photoresponse: temperature dependence is determined by the third term. At higher temperatures, the photoresponse decreases again with temperature rise, according to the first and the second terms. Thus, the fact, that the Sb deposition causes the enhancement of photoresponse at room temperature and makes the response peak at intermediate temperatures (Curve 3 in Fig. 5), may be understood.

The reverse may hold principally in p-type Cs-Sb. But, in this case, donor concentration is so small that the number of trapped electrons is smaller than that of trapped holes in n-type sample, though the acceptor concentration may be of the same order in both cases. Hence, the efficiency of photoconductivity in p-type sample is lower than that in n-type sample.

§ 4. Energy Band Structures in Alkali Antimonides

The energy values obtained from the different measurements are summarized in Table I, though they are not unique or highly accurate. The optical absorption edge coincides nearly with the photoemission threshold, indicating that the electron affinity should be small. The photoconduction threshold coincides nearely with the largest value of the electric conduction activation energy and does not coincide with the absorption edge. If the photoconductivity originates from impurity atoms, the photoemission is to be expected at the threshold energy of photoconductivity because of the small value of electron affinity, and the distinct absorption must be observed at this energy because of the large impurity concentration. But, these were not the cases. Hence, we postulate that the threshold energy of photoconductivity and the intrinsic dark conductivity is of an indirect transition between filled and conduction bands. The optical indirect transition is, of course, of small probability and produces the photoelectrons mostly in deep layer, so that appreciable photoconductivity and no photoemission should be observed. At the photon energies corresponding to direct transition, the both photo-electric effects should be observed though the photoconductivity may be quenched by surface recombination.

Table I. Excitation energies for different phenomena.

	Absorption edge $h\nu_a$ (eV)	Photoemission threshold $e\phi$ (eV)	Photoconduction threshold $h\nu_c$ (eV)	Max. activation energy for elec. cond. $\Delta E/2$ (eV)
Cs-Sb	1.6	1.6	0.9	0.4
Rb-Sb	1.8−1.6	1.9	0.9	0.5
K-Sb	1.9−1.7	2.1	1.0	0.5
Na-Sb	2.2	2.6	1.0	0.6

In these materials, filled band and conduction band are simply considered to be p-band associated with antimony and s-band associated with alkali atom respectively. So far it has been reported that K-Sb and Na-Sb take a hexagonal structure[9] and that Cs-Sb takes a cubic structure[10]. Since p-band of hexagonal structure splits into two bands, at least $\mathbf{k}=0$, whereas that of cubic structure does not split, at least $\mathbf{k}=0$[11], aforementioned absorption through may be attributed to the p-band splitting. Therefore the abrupt change of absorption spectra attendant upon increasing activation must correspond to the change from cubic to hexagonal structure or from amorphous to hexagonal one. In Cs-Sb, p-band splitting is absent and then the anomalous absorption change cannot be expected. Although the structure of Rb-Sb has not been investigated, the author supposes that this compound has two kinds of crystal structure (cubic and hexagonal).

Putting all accounts together, the energy band sheme can be tentatively given as illustrated in Fig. 8.

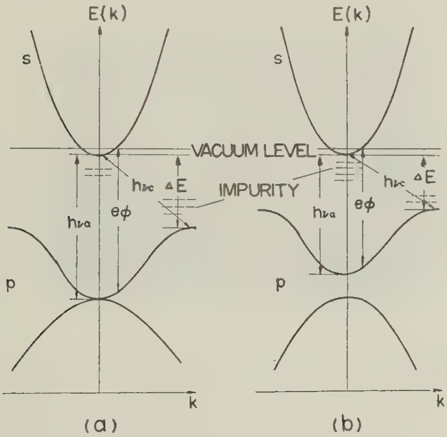

Fig. 8. Model of energies as a function of **k**. (a) for cubic and (b) for hexagonal structures of alkali antimonides.

§ 5. Conclusions

Optical absorption, photoemission and photoconduction of alkali antimonides were studied systematically during the preparation, as it was the case of the measurement of the electrical characteristics. Taking the ionic radius of alkali atom into consideration the preceding paper established a model which allowed to interprete the electric properties. The model was also feasible to interprete some of the photoelectrical properties. In addition, this paper proposed two kinds of energy band structure in **k**-space, depending on crystal structures. Abrupt changes in the spectral absorption and the electric conductivity during activation process were interpreted by considering the transition between these crystal structures.

In conclusion, the author wishes to express his appreciation to Dr. Hiroji Mitsuhashi, Dr. Jiro Yamashita and Dr. Ken'ichi Takeya for many helpful discussions and suggestions, to Mr. Mutsumu Kinoshita for experimental assistance, and to Dr, Akira Yamashita and Dr. Kohichi Miyaji for continuous encouragements.

Quenching Effect in KCl Crystals

By Masayoshi SAKAMOTO

Department of Physic, Tokyo College of Science
Tokyo, Japan

(Received June 5, 1959)

Effects of thermal quenching on KCl crystals were studied in both clear and colored specimens. These were subjected to two types of quenching, down- and up-quenching. The etching method was carried out to examine generated dislocations and the photoelastic method was used to see the distribution of the residual stresses.

The results of the experiments are as follows: (1) Generated dislocations, distributing from the crystal surface toward the interior, were perceived. (2) They ranged over a lunar area along the edges in the cross section of the specimen. (3) The range, in which the residual stresses exist, has also the same lunar form along the edges. Therefore, the residual stresses are considered as resulting from the thermal generation of slips. These experimental facts can be explained on the basis of thermal stresses.

§ 1. Introduction

In the research processes on colored alkali halide crystals, specimens are often subjected to thermal quenching. Therefore, it is interesting as well as necessary to study and and expound what kinds of effect thermal quenching will have in alkali halide crystals. As a typical sample, KCl was chosen among many alkali halides. This report deals with the experimental results obtained mainly by the etching method and partly by the photoelastic method with respect to the quenching effects on both clear and colored KCl crystals.

§ 2. Experimental Procedure

(i) Clear specimens were prepared through cleavage from the ingots produced by Kyropoulos method. Colored crystals were obtained through the usual additive coloring method. The density of color center was usually within $10^{16}\sim10^{17}$. Colored specimens were also prepared through cleavage from these crystals. The mean size of the specimens in both clear and colored specimens was $5\times5\times3$ mm^3.

(ii) Two types of quenching were performed. The one is the down-quenching, cooling down from high temperature (up to 500°C) to room temperature and the other the up-quenching, recovering from low temperature (liquid air temperature) to room temperature. In the case of down-quenching, two methods were used. The one, denoted A, was to cool the specimen through heat conduction on a metal plate after withdrawing from the crucible. The other, denoted B, was to air-cool the specimen within the crucible with a fan. These two methods were also used similarly but conversely in the case of up-quenching. The one, denoted B′, was to recover the temperature of the specimen keeping it within the container. The other, denoted C, was to recover its temperature by placing it in aceton just after withdrawing from the container.

(iii) In order to examine the generated dislocations and slip lines, the same etching method as in our previous reports[1,2] was applied. The increase in density of generated dislocations were visually observed by comparing the etch pattern within the same surface region of the specimen before and after subjecting them to thermal quenching.

(iv) The photoelectric method was also used in order to see the distribution of residual stresses within specimens. For this purpose, the polarization apparatus, attached to the Olympus universal type metal microscope, was employed.

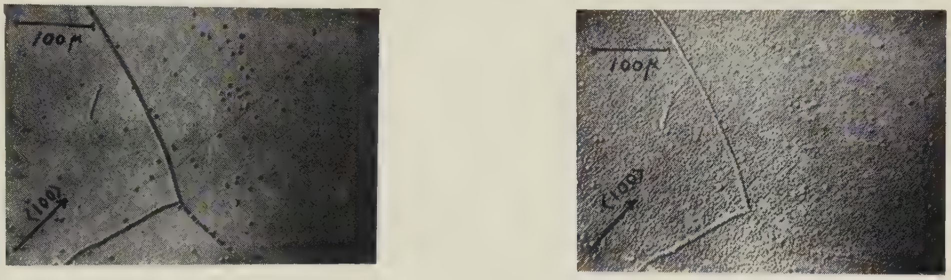
§ 3. Experimental Results

(i) *Etch patterns of the generated dislocations*

An etch pattern on the (001) plane of the clear specimen, quenched down from 500°C to room temperature by B method, is shown in Fig. 1(b) and compared with the one on the same region before quenching, Fig. 1(a).

The etch pits are seen to be aligned in ⟨100⟩ direction, showing that they correspond to screw type dislocation.[3)]

An etch pattern in the colored specimen, quenched down from 500°C to room temperature by A method, is shown in Fig. 2(b) and



a b

(b)

(c)

Fig. 6. A panoramic view of an etch pattern of a cleaved cross section in a "down-quenched" specimen; (a) a panoramic view, (b) a schematic diagram of (a) and (c) its horizontal perspective.

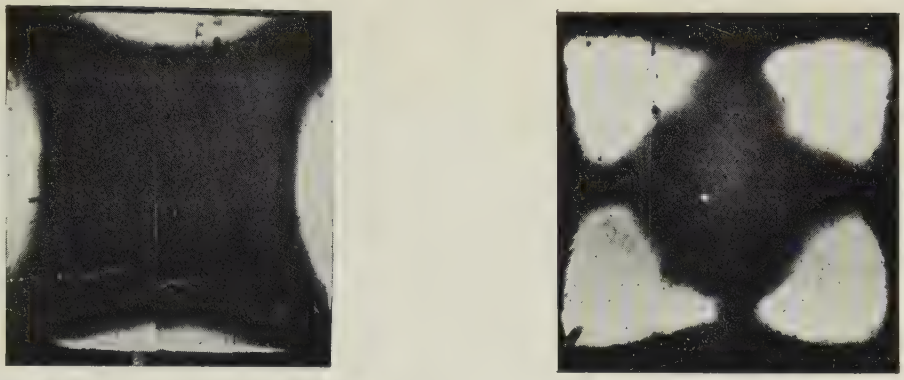
compared with that of the same region before quenching, Fig. 2(a). The alignment of etch pits is not so remarkable in the colored specimen as in the clear one.

In Fig. 3(b), an etch pattern of the (001) plane in the clear specimen, up-quenched from −183°C to room temperature by C method, is shown and compared with the one of the same region, Fig. 3(a), before quenching. It may be clearly seen that the etch pits are arranged in ⟨100⟩ type direction and consist of screw type dislocations.

Fig. 4(a) and (b) show the similar case in the colored specimen.

The distribution of the generated dislocations within specimens has been studied by etching of the cross section cleaved parallel to the surface of the specimen. The distribution of the generated dislocations on a cleaved plane parallel to and 800 μ in depth from the top surface of the specimen, down-quenched from 500°C to room temperature by A method, is shown in Fig. 5(a). It is seen that the generated dislocations are distributed over a range of 300 μ in distance from the edge of the specimen. Fig. 5(b) shows a central part of the same cleaved surface. The estimated density is almost equal to that before quenching showing that there was no appreciable plastic deformation in this region.

Inspecting several pictures indicated above, it may well be said that the thermal stresses by quenching make many slips from the surface toward the interior of the specimens



a b

Fig. 7. Photoelastic patterns of the "down-quenched" specimen in Fig. 6. Directions of the crossed nicols are (a) 45° or 135° against the edges of the square and (b) parallel to the latters.

and so the generated dislocations are related to these slips.

(ii) *Form the slipped area*

A panoramic view of the etched plane, cleaved parallel to the top surface of the clear specimen, is shown in Fig. (6)a. This specimen was down-quenched from 400°C by B method. In order to save time and effort, part of the square plane was not photographed as it in no way deters the experiment. Fig. 6(b) is its graphic diagram, in which the area of the generated dislocations has a lunar form along the edge of the square and there was no generation in the range between those areas. Slip lines, widely observed in the central part, are presumably originating from the top surface, as seen in Fig. 6(c).

(iii) *Photoelastic patterns*

Photoelastic patterns of the same specimen as the one in Fig. 6 are shown in Fig. 7. Fig. 7(a) is in case when the orthogonally crossed nicols make 45°C angle against $\langle 100 \rangle$ type directions and Fig. 7(b) in case they are parallel or at right angle to the same directions. It is considered that both pictures evince a distribution of the residual stresses resulting from the plastic deformation in the specimen. It should be noted that the lunar region, seen in Fig. 7(a), coincides with the same one, seen in Fig. 6(a). This fact strongly suggests that the residual stresses must have resulted from the plastic deformation by

Table on Densities of the Generated Dislocations.

	Starting temperature in °C	Estimated quenching rate in °C/min	Quenching method	Generated dislocation density in cm^{-3}	
				Clear crystal*	Colored crystal**

*,** Mean density of the background dislocations before quenching is $2 \sim 4 \times 10^4$ cm^{-2} in the clear specimen and $4 \sim 9 \times 10^4$ cm^{-2} in the colored one.

thermal quenching.

(iv) *Mean density of the generated dislocations*

Mean densities of the generated dislocations are shown in the following table. The quenching rates are estimated to show the order of magnitude. Densities are mean values of several results taken upon the same specimen, respectively.

(a) The primary characteristics, noted from the above table, is that no dislocations will be generated when the starting temperatures are low in the same quenching method. This fact may suggest that no slips will occur until thermal stresses reach critical value.

(b) Secondly, densities of the generated dislocations in the colored specimen are less than that in the clear specimen under the same quenching process.

(c) Thirdly, densities of the generated dislocations increase with the rate of quenching under the same starting temperature. This fact may be explained, as will be discussed later, from the character of the density which is proportional to the temperature gradient perpendicular to the crystal surface.

§ 4. Discussions

(i) *Interpretation of the photoelastic patterns*

Transmitted intensity of an incident monochromatic light is generally proportional to the factor, $(\sin\delta/2)\times(\sin 2\phi)$.[4] Here, δ is a phase difference between the two double-refracted beams which have two axes of principal stress on the specimen in the directions of vibrating plane and ϕ is an angle which the directions of the principal stress make against the polarizer's plane. The directions of the principal axes of the residual stresses are distributed as Fig. 8, from the symmetrical quality of the specimen (square). Speaking characteristically, three main parts can be discerned in Fig. 8: (a) part which is the periphery of the square along the edge, (b) part including the diagonal of the square and (c) part which is central in the square. In (a) part, ϕ will be 45° and therefore transmitted light will be maximum when the directions of the orthogonally crossed nicols make 45° to 135° against x axis. In (b) part, ϕ will be 45° and transmitted light will be maximum similarly when the directions of the orthogonally crossed nicols are parallel or at right angles to x axis. On the other hand, (c) part is dark in both Fig. 7(a) and (b). This fact may suggest that δ becomes very small, because δ is proportional to $\sigma_x\sim\sigma_y$ and also these two are almost equal in this region.

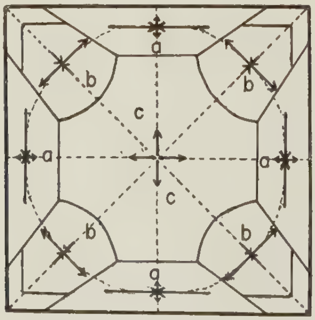

Fig. 8. A simple schematic diagram showing the directions of principal axes of the residual stress.

(ii) *Interpretation of the form of slipped area*

It is considered from the facts observed in § 3. (i), (ii) that the slips are generated from the surfaces toward the interior of the specimen by thermal stress. Therefore, let us delve into the problem of why the slipped area has a lunar form along the edge of the square (its cross section). At first, for simplicity's sake, assuming that the temperature variation along the axis perpendicular to the cross section is small, a two dimensional equation of the thermal stress may be considered as follows,[5] when the coordinates are taken as in Fig. 9,

$$\left.\begin{aligned}\frac{\partial\sigma_x}{\partial x}+\frac{\partial\tau_{xy}}{\partial y}-\frac{\alpha E}{1-2\nu}\frac{\partial T}{\partial x}=0\\ \frac{\partial\tau_{xy}}{\partial x}+\frac{\partial\sigma_y}{\partial y}-\frac{\alpha E}{1-2\nu}\frac{\partial T}{\partial y}=0\end{aligned}\right\} \qquad (1)$$

Here, σ_x, σ_y are normal components of stress parallel to x, y axis; τ_{xy}, α, E and ν are shearing stress, thermal expansion coefficient, elastic constant and Poisson's ratio, respectively. These equations can not be solved exactly. It is believed, however, that σ_y is proportional to the temperature distribution from the experimental situations.

Therefore, it is assumed that

$$\sigma_y=\frac{\alpha E}{1-2\nu}T. \qquad (2)$$

In the vicinity of the free end along x axis $\sigma_x \cong 0$ and also $|\partial\sigma_x/\partial x| \ll |\partial\sigma_y/\partial x|$,[6] so that it may suffice to discuss mainly σ_y's variation.

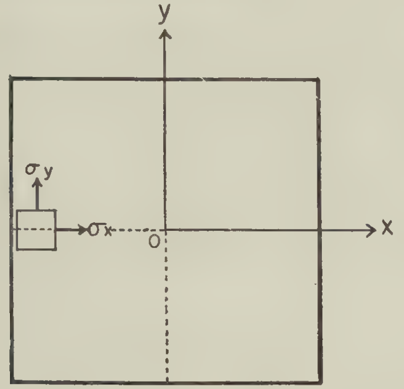

Fig. 9. Determination of the coordinate axes.

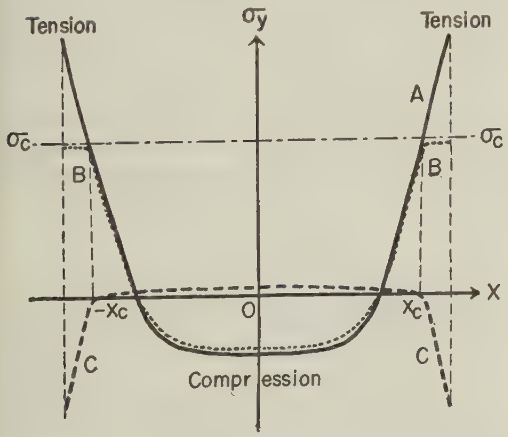

Fig. 10. σ_y's distribution along x-axis and its variation.

Considering σ_y's distribution just before the moment of slip generation qualitatively, it must extend along the substantial curve (A) as shown in Fig. 10. Denoting the critical stress value as σ_c and its position on x axis as x_c, yielding will occur in the whole part of $\sigma_y > \sigma_c$ and then the curve must move to the dotted line (B) in Fig. 10 in order to reach a new equilibrium. Now, in the region $|x| > x_c$, denoting σ_y's gradient just before the yielding as $(\partial\sigma_y/\sigma x)_{\text{bef.}}$, just after that as $(\partial\sigma_y/\partial x)_{\text{af.}}$, and the effective stress distribution due to the generated dislocations as $(\partial\sigma_y/\partial x)_{\text{disl.}}$, then

$$\left(\frac{\partial\sigma_y}{\partial x}\right)_{\text{af.}} = \left(\frac{\partial\sigma_y}{\partial x}\right)_{\text{bef.}} - \left(\frac{\partial\sigma_y}{\partial x}\right)_{\text{disl.}} . \tag{3}$$

Since the transposition of the curve is negligibly small, it can be said that $(\partial\sigma_y/\partial x)_{\text{af.}} \cong 0$ in this region.

As for the last term of equation (3), according to Read,[7]

$$\left(\frac{\partial\sigma_y}{\partial x}\right)_{\text{disl.}} = \frac{2G}{1-\nu} b_y N , \tag{4}$$

where G, b_y and N are shearing modulus, y component of Burgers vector and the density of pure edge-type dislocations, respectively. Therefore, in this region, it is

$$\left(\frac{\partial\sigma_y}{\partial x}\right)_{\text{bef.}} \simeq \frac{2G}{1-\nu} b_y N . \tag{5}$$

Substituting (2) into (5) in this region, then

$$N \cong \frac{\alpha}{(1-2\nu)b_y}\left(\frac{\partial T}{\partial x}\right) . \tag{6}$$

Next, to find the appropriate solution for the boundary conditions of this problem,[8] thus

$$T = \text{const.} \times [\sum_l f(p_l,\ t) \cos p_l x] \cdot [\sum_m g(q_m,\ t) \cos q_m y]$$

then,

$$\frac{\partial T}{\partial x} = \text{const.} \times [\sum_l f^*(p_l,\ t) \sin p_l x] \cdot [\sum_m g(q_m,\ t) \cos q_m y] . \tag{7}$$

Substituting (7) into (6), it will be easily understood that N's distribution approaches a lunar form along the edge of the square.

(iii) *Numerical evaluation of the generated dislocation density*

It is presumed that the quantitative reliability of equation (6), considering its introduction, is relatively poor. However, substituting the following experimental values

$$\alpha = 3 \times 10^{-5}\ [\text{deg}^{-1}]$$
$$b_y = 6 \times 10^{-8}\ [\text{cm}]$$
$$1-2\nu = 0.75$$

into (6),

$$N = 6.7 \times 10^2 \times \left(\frac{\partial T}{\partial x}\right) .$$

Considering $(\partial T/\partial x) \sim 10^3$, then N becomes $\sim 10^6$, which is not very far off from the results of the experiments.

(iv) *Results of the table*

(a) The fact that there was no generation of dislocations in the case of low starting temperature under the same quenching method may be understood when we note that σ_y did not reach σ_c in Fig. 10. But this is true only when the methods are indentical. Effects of the different quenching rates will be discussed later.

(b) The true reason why the generated dislocation densidity of the colored speciments is less than that of the clear ones is yet unknown. Perhaps, the difference in $(\partial T/\partial x)$ between the two types of specimens, resulting from the difference, in thermal conductivity, may not be the causative factor.

(c) Among three quenching methods, comparing A with B and C with B', the results show that the faster the quenching rate, the higher the density of the generated dislocations.

This fact may well be explained if we consider that a fast quenching rate gives rise to a large temperature gradient. It may be notable, however, that in one example of upquenching (−77°C, method) cited in the table, a plastic deformation occurred despite the fact that the difference between the starting and final temperatures was not so large. The reason may be that a large $(\partial T/\partial x)$ before the core is warmed brings $\sigma_y > \sigma_c$ in the peripheral part.

(v) *Quenching process of the specimen*

The fact that a lunar form of the photoelastic pattern (Fig. 7) coincides with that of the slipped area in the cross section (square) of the specimen (Fig. 6) forces us to believe that the residual stress results from the plastic deformation. This suggests that σ_y's distribution should extend along C-curve, shown as broken lines in Fig. 10, because of a new equilibrium in elastic conditions, when the temperature recovers to room temperature. That is, the peripheral part changes from tension field to compression one while, on the other hand, the core part from compression field to weak tension one. This explanation is consistent with the recent findings of Kear and Pratt,[9] qualitatively. A quantitative measurement of the residual stresses is hoped for, as their distribution correspond almost to $(\partial \sigma_y/\partial x)_{\text{disl.}}$.

§ 5. Conclusions

When KCl crystals were quenched thermally, both clear and colored specimens showed the following characteristics resulting mainly from thermal stresses.

(i) New dislocations, distributed from the crystal surface into the interior, were generated. They were considered closely allied to double slips of ⟨110⟩/(110) type.

(ii) The range of generated slips had a lunar form along the edge in the cross section of the specimen.

(iii) The photoelastic pattern also showed the same lunar pattern along the edge of the cross section and so the range of the residual stresses coincided with the one of the generated slips.

(iv) Qualitatively estimating, the concentration of generated dislocations is proportional to the temperature gradient perpendicular to the crystal surfaces.

Acknowledgement

The author wishes to express his thanks to Dr. T. Suzuki, Dr. H. Kanzaki of the Institute for Solid State Physics, University of Tokyo and Prof. A. Ookawa of Gakushuin University, for giving him valuable discussions and suggestions in this work.

He is much indebted to Dr. M. Nishida for his kind aid and also to Mr. K. Takahashi and Miss H. Muramoto for their constant assistance.

Application of Higher Order Born Approximation to Multiple Elastic Scattering of Electrons by Crystals

By Kunio FUJIWARA

The Institute for Solid State Physics,
Tokyo University, Tokyo, Japan

(Received June 30, 1959)

The calculation of Artmann (quoted in Raether's article in Hand. Phys. **32** 475) for the wave function of electrons in a crystal due to the first order Born approximation was extended to higher order approximations by iterated integrations. As the result, Cowley and Moodie's formula (Acta Cryst. **10** (1957) 609) for the multiple elastic scattering of electrons by crystal was reobtained in an improved form. The convergency of the higher order terms was illustrated by the numerical calculations on two simple examples. An elementary application was also made to the moiré patterns in electronmicrographs.

§1. Introduction

An essential feature which distinguishes the diffraction of electrons by crystals from those of X-ray and neutrons consists in the fact that numerous reflexions are excited simultaneously in a crystal owing to the strong interaction of electrons with crystals and the relative smallness of wave length of electrons. Under the ordinary experimental condition, these reflexions are in strong interactions to each other through the complicated multiple scattering processes. The kinematical theory of electron diffraction which is based on the first order Born approximation, describes the all waves excited by single scattering processes, but nothing about the interactions among them. Though, on the other hand, Bethe's dynamical theory[1] takes into account the interactions in the most general way, it is highly tedious to apply it to the cases where reflexions more than two or three are strongly excited. This makes almost impossible the quantitative comparison of the theoretical results with experimental data.

In 1957, an important diffraction theory was set up by Cowley and Moodie[2] on the basis of the theory of physical optics. They divided a crystal into a number of thin layers and calculated the wave field in a layer from that in the just prior to it by Huygens' principle. Thus, they succeeded in drawing out the vivid picture of multiple scattering processes, assuming that the scattering angles are small so that the wave fronts can be regarded as paraboloids. It is expected that their theory may solve many problems to which Bethe's theory is not applicable.

It is conceived that a quantum mechanical approach to their theory may be feasible by applying higher order Born approximation. To do this, the wave function of electron within a crystal must first be derived in the stage of the first order Born approximation. This had been done by Artmann[3]. In the present work, the extention of Born approximation is accomplished by starting from Artmann's calculation, and, as the results, Cowley and Moodie's formula is reobtained. The essential restriction in Cowley and Moodie's theory for the scattering angles is no longer necessary here. Though the mathematical proof hasn't yet been given on the convergency of wave function for general cases, the results of numerical calculations on simple examples shown in §6 give an instructive suggestion about it. The intensity in the short wave length limit and an approximate formula of scattering by finite crystals and an elementary application to moiré patterns have also been discussed in §§5 and 7, respectively.

§2. Method of Higher Order Born Approximation

In the beginning, the method of higher order Born approximation is outlined. As is well known, the wave equation for electrons scattered by a potential field $V(r)$ is given by

$$(\nabla^2+K^{0 2})\Psi(r)=-(2me/\hbar^2)V(r)\Psi(r)\,, \quad (2.1)$$

where K^0 represents the wave vector of the initial wave. The solution of Eq. (2.1) can be written in the form of integral equation

$$\Psi(\boldsymbol{r})=\psi^{(0)}(\boldsymbol{r})-(2me/\hbar^2)\int G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)V(\boldsymbol{r}_i)\Psi(\boldsymbol{r}_i)\,d\boldsymbol{r}_i\,, \tag{2.2}$$

where $\psi^{(0)}(\boldsymbol{r})$ is a solution of the homogeneous equation corresponding to Eq. (2.1) and $G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)$ is Green function.

Substituting the right hand side of (2.2) into the integrand in itself, we obtain

$$\begin{aligned}\Psi(\boldsymbol{r})=\psi^{(0)}(\boldsymbol{r})&-(2me/\hbar^2)\int G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)V(\boldsymbol{r}_i)\psi^{(0)}(\boldsymbol{r}_i)\,d\boldsymbol{r}_i\\&+(-2me/\hbar^2)^2\int G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)V(\boldsymbol{r}_i)\int G_{K^0}(\boldsymbol{r}_i,\boldsymbol{r}_j)V(\boldsymbol{r}_j)\Psi(\boldsymbol{r}_j)\,d\boldsymbol{r}_i\,d\boldsymbol{r}_j\,.\end{aligned} \tag{2.3}$$

In the first order Born approximation, the last term of Eq. (2.3) is neglected as a small quantity, while the second term, which we denote as $\psi^{(1)}(\boldsymbol{r})$, is interpreted as describing the wave field generated by single scattering. If Eq. (2.3) retaining the last integral term is substituted further into the same integral, we may improve Born approximation. After iterating similar substitutions, we shall finally obtain

$$\Psi(\boldsymbol{r})=\psi^{(0)}(\boldsymbol{r})+\psi^{(1)}(\boldsymbol{r})+\psi^{(2)}(\boldsymbol{r})+\cdots+\psi^{(m)}(\boldsymbol{r})+\cdots\,, \tag{2.4}$$

where $\psi^{(m)}(\boldsymbol{r})$ is given by

$$\psi^{(m)}(\boldsymbol{r})=-(2me/\hbar^2)\int G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)V(\boldsymbol{r}_i)\psi^{(m-1)}(\boldsymbol{r}_i)\,d\boldsymbol{r}_i\,. \tag{2.4a}$$

$\psi^{(m)}(\boldsymbol{r})$ may be interpreted as the amplitude of the wave field generated by the m-ple scattering. If

$$|\psi^{(n)}(\boldsymbol{r})|\ll|\psi^{(n-1)}(\boldsymbol{r})|\,, \tag{2.5}$$

the series (2.4) may be terminated at $\psi^{(n)}(\boldsymbol{r})$. In this case we have the solution of the n-th order Born approximation.

§ 3. Evaluation of $\psi^{(1)}(\boldsymbol{r})$

As is clear from Eq. (2.4a), all $\psi^{(m)}(\boldsymbol{r})$'s may be derived, once the form of $\psi^{(1)}(\boldsymbol{r})$ within the crystal is known. As mentioned before, $\psi^{(1)}(\boldsymbol{r})$ was already calculated by Artmann[3]. However, his calculation, the detail of which has not been published, was performed assuming that only the waves scattered in forward directions are appreciable. In what follows, his result is amended by allowing for the backward scattering as well as the forward scattering, although his approximation will be adopted again in the later discussions.

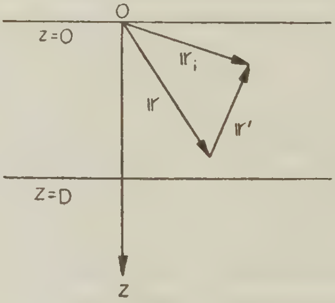

Fig. 1.

Let us assume the crystal be an infinite plate with thickness D, and choose the z-axis normal to the surface as shown in Fig. 1. Then

$$V(\boldsymbol{r})=\sum_h v_h\exp(2\pi i\boldsymbol{h}\boldsymbol{r})\qquad\text{for}\quad 0\leq z\leq D\,. \tag{3.1}$$

If a beam of electrons enters the crystal through the surface $z=0$ with wave number K^i, the wave equation in the crystal can be written as

$$(\nabla^2+K^{0^2})\Psi(\boldsymbol{r})=-(2me/\hbar^2)\cdot(\sum_h{}' v_h e^{2\pi i\boldsymbol{h}\boldsymbol{r}})\Psi(\boldsymbol{r})\,, \tag{3.2}$$

where

$$K^{0^2}=K^{i^2}+(2me/\hbar^2)\cdot v_0 \tag{3.3}$$

and the prime on $\sum$ indicates the absence of the term $\boldsymbol{h}=0$. We ask the solution of Eq. (3.2) under the following boundary conditions:

1) The amplitudes of the scattered waves whose wave vectors have positive z-components should be zero at the surface $z=0$.

2) The amplitudes of the waves whose wave vectors have negative z-components should be zero at the surface $z=D$.

The unperturbed wave function is taken as

$$\psi^{(0)}(\boldsymbol{r})=A_0\exp(i\boldsymbol{K}^0\boldsymbol{r})\ , \tag{3.4}$$

where $\boldsymbol{K}^0$ denotes the wave vector of the initial wave in the crystal. Evidently, the above conditions cannot take into account the refraction of the waves at the boundaries. Though for the rigorous treatment, therefore, we should take the incident wave in vacuum instead of (3.4) as the unperturbed state, we shall avoid it here on account of slow convergency of the series in the required calculation.

Using the Fourier integral form of the Green function

$$G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)=\frac{-1}{(2\pi)^3}\int\frac{\exp[-i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r})]}{\boldsymbol{k}^2-\boldsymbol{K}^{0^2}}\,d\boldsymbol{k}\ , \tag{3.5}$$

we obtain for $\psi^{(1)}(\boldsymbol{r})$

$$\psi^{(1)}(\boldsymbol{r})=A_0\left(\frac{2me}{\hbar^2}\right)\sum_{\boldsymbol{h}}{}' v_h\iint\frac{\exp[-i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r})]}{(2\pi)^3(\boldsymbol{k}^2-\boldsymbol{K}^{0^2})}\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}_i]\,d\boldsymbol{k}\,d\boldsymbol{r}_i\ . \tag{3.6}$$

Putting $\boldsymbol{r}_i-\boldsymbol{r}\equiv\boldsymbol{r}'$, we have

$$\psi^{(1)}(\boldsymbol{r})=A_0(2me/\hbar^2)\sum_{\boldsymbol{h}}{}' v_h\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}]\cdot I(\boldsymbol{h})\ , \tag{3.7}$$

where

$$I(\boldsymbol{h})=\frac{1}{(2\pi)^3}\iint\frac{\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h}-\boldsymbol{k})\boldsymbol{r}']}{\boldsymbol{k}^2-\boldsymbol{K}^{0^2}}\,d\boldsymbol{r}'d\boldsymbol{k}\ . \tag{3.8}$$

$I(\boldsymbol{h})$ can be calculated in the following way:

$$\begin{aligned}I(\boldsymbol{h})=&\frac{1}{(2\pi)^3}\int\frac{d\boldsymbol{k}}{\boldsymbol{k}^2-\boldsymbol{K}^{0^2}}\int_{-\infty}^{\infty}\exp[i(K_x{}^0+2\pi h_x-k_x)x']\,dx'\int_{-\infty}^{\infty}\exp[i(K_y{}^0+2\pi h_y-k_y)y']\,dy'\\&\times\left[\int_{-z}^{0}\exp[i(K_z{}^0+2\pi h_z-k_z)z']\,dz'+\int_{0}^{D-z}\exp[i(K_z{}^0+2\pi h_z-k_z)z']\,dz'\right].\end{aligned} \tag{3.9}$$

The integrals over x' and y' are reduced to $2\pi\cdot\delta(K_x{}^0+2\pi h_x-k_x)$ and $2\pi\cdot\delta(K_y{}^0+2\pi h_y-k_y)$, respectively, and those over z' are also easy to carry out. After performing the integrations over k_x and k_y, we obtain

$$\begin{aligned}I(\boldsymbol{h})=&\frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{1}{[(K_x{}^0+2\pi h_x)^2+(K_y{}^0+2\pi h_y)^2+k_z{}^2]-(K_x{}^{0^2}+K_y{}^{0^2}+K_z{}^{0^2})}\\&\times\left[\frac{1-\exp[-i(K_z{}^0+2\pi h_z-k_z)z]}{K_z{}^0+2\pi h_z-k_z}+\frac{\exp[i(K_z{}^0+2\pi h_z-k_z)(D-z)]-1}{K_z{}^0+2\pi h_z-k_z}\right]dk_z\ .\end{aligned}$$

When the wave vectors $\boldsymbol{K}^h(K_x{}^h, K_y{}^h, K_z{}^h)$ and ${}^h\boldsymbol{K}({}^hK_x, {}^hK_y, {}^hK_z)$ are introduced as shown in Fig. 2, $I(\boldsymbol{h})$ is reduced to

$$\begin{aligned}I(\boldsymbol{h})=&\frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{1-\exp[-i(K_z{}^0+2\pi h_z-k_z)z]}{(k_z{}^2-K_z{}^{h^2})(K_z{}^0+2\pi h_z-k_z)}\,dk_z\\&+\frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{\exp[i(K_z{}^0+2\pi h_z-k_z)(D-z)]-1}{(k_z{}^2-{}^hK_z{}^2)(K_z{}^0+2\pi h_z-k_z)}\,dk_z\ ,\end{aligned} \tag{3.10}$$

where use has been made of the relations

$$K_x{}^0+2\pi h_x=K_x{}^h={}^hK_x\ ,$$
$$K_y{}^0+2\pi h_y=K_y{}^h={}^hK_y$$

and

$$K_x{}^{0^2}+K_y{}^{0^2}+K_z{}^{0^2}=K_x{}^{h2}+K_y{}^{h2}+K_z{}^{h2}={}^hK_x{}^2+{}^hK_y{}^2+{}^hK_z{}^2\ .$$

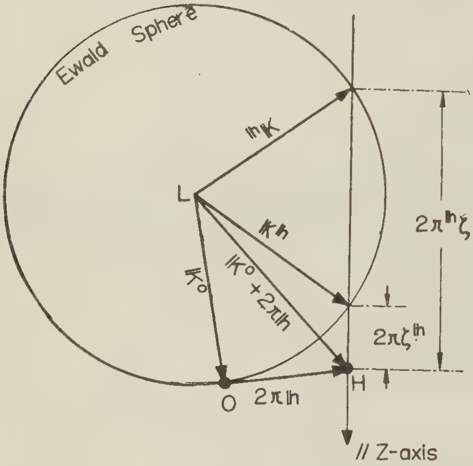

Fig. 2.

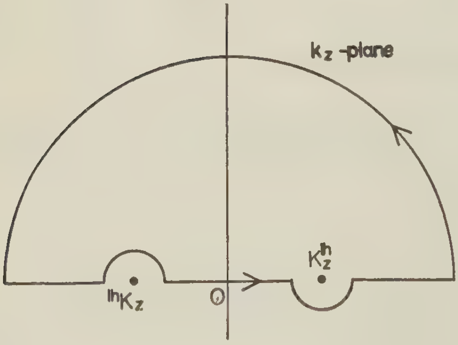
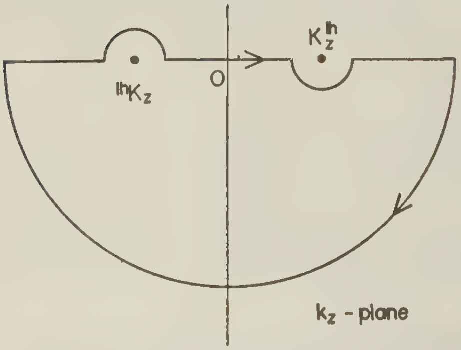


(a) Contour C_1.



(b) Contour C_2.

Fig. 3. Contours for the evaluation of the integrals in Eq. (3.10).

The integrals in (3.10) may be evaluated by contour integrals on the complex k_z-plane, since the integrands have simple poles at $k_z=\pm K_z{}^h=\mp{}^hK_z$. The contour C_1 for the first integral and C_2 for the second should be chosen as shown in Fig. 3 in accordance with the boundary conditions mentioned above.* Using the theorem of residues and defining the excitation errors, ζ^h and ${}^h\zeta$, as (Cf. Fig. 2)

$$-2\pi\zeta^h=K_z{}^0+2\pi h_z-K_z{}^h \qquad (3.11a)$$
$$-2\pi\,{}^h\zeta=K_z{}^0+2\pi h_z-{}^hK_z\ , \qquad (3.11b)$$

we have

$$I(\boldsymbol{h})=\frac{1}{4\pi K_z{}^h}\left[\exp(2\pi i\zeta^h z)\cdot\left(\frac{\exp(-2\pi i\zeta^h z)-1}{-\zeta^h}\right)\right.$$
$$+\exp(2\pi i\,{}^h\zeta\cdot z)$$
$$\left.\cdot\left(\frac{\exp(-2\pi i\,{}^h\zeta D)-\exp(-2\pi i\,{}^h\zeta z)}{-{}^h\zeta}\right)\right]. \qquad (3.12)$$

Allowing for the relations

$$\boldsymbol{K}^h\boldsymbol{r}=(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}+2\pi\zeta^h\cdot z$$
$${}^h\boldsymbol{K}\boldsymbol{r}=(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}+2\pi\,{}^h\zeta\cdot z\ ,$$

we obtain

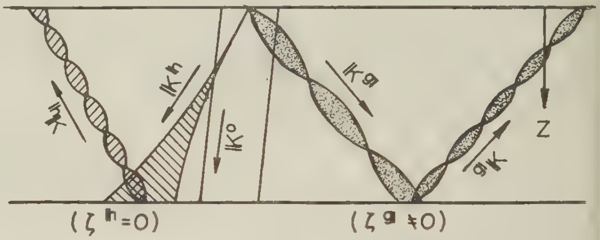


Fig. 4. Illustration of the Intensities of the waves given by Eq. (3.13).

---

* The validity of the adoption of these contours can easily be verified by the more detailed treatment which introduces the Green function in the form

$$G_{K^0}(\boldsymbol{r},\boldsymbol{r}_i)=-\int\frac{d\boldsymbol{k}}{(2\pi)^3}\left[\frac{\mathrm{P}}{\boldsymbol{k}^2-K^{0^2}}\right.$$
$$\left.+\lambda(\boldsymbol{k})\cdot\delta(\boldsymbol{k}^2-K^{0^2})\right]\exp[i\boldsymbol{k}(\boldsymbol{r}-\boldsymbol{r}_i)]\ ,$$

where $\lambda(\boldsymbol{k})$ is the factor which should be determined to satisfy the boundary conditions.

$$\psi^{(1)}(\boldsymbol{r})=A_0\left(\frac{me}{2\pi\hbar^2}\right)\sum_{h}{}'\frac{v_{\boldsymbol{h}}}{K_z{}^{\boldsymbol{h}}}\left[\exp(i\boldsymbol{K}^{\boldsymbol{h}}\boldsymbol{r})\cdot\left(\frac{\exp(-2\pi i\zeta^{\boldsymbol{h}}z)-1}{-\zeta^{\boldsymbol{h}}}\right)\right.$$
$$\left.+\exp(i\,{}^{\boldsymbol{h}}\boldsymbol{K}\boldsymbol{r})\cdot\left(\frac{\exp(-2\pi i\,{}^{\boldsymbol{h}}\zeta D)-\exp(-2\pi i\,{}^{\boldsymbol{h}}\zeta z)}{-{}^{\boldsymbol{h}}\zeta}\right)\right]. \tag{3.13}$$

The first term in (3.13), which came from the first integral over z' in (3.9), is that previously derived by Artmann[3)] taking account of the forward scattering only. The second term which was newly added corresponds to the backward reflection. The intensities of the waves calculated by Eq. (3.13) vary with z in the manners as illustrated in Fig. 4.

§ 4. Calculation of $\psi^{(n)}(\boldsymbol{r})$

It should be noticed that $\psi^{(1)}(\boldsymbol{r})$, which has been derived from the plane wave $\psi^{(0)}(\boldsymbol{r})$, is a superposition of plane waves owing to the fact that $V(\boldsymbol{r})$ can be written in the form of Fourier series. Such a result suggests that all $\psi^{(m)}(\boldsymbol{r})$'s may be evaluated from Eq. (2.4a) in similar way as the derivation of $\psi^{(1)}(\boldsymbol{r})$ from $\psi^{(0)}(\boldsymbol{r})$. Thus, it is expected, in principle, that the complicated multiple scattering phenomena can be dealt with for any reflecting condition. However, in Bragg case, where we have strong reflected waves propagating in the directions more or less nearly parallel to the surface under the usual experimental conditions, the convergency of $\psi^{(m)}(\boldsymbol{r})$ is expected to be so slow with increasing m that the application of the present method cannot be practicable. We, therefore, will hereafter restrict ourselves to Laue case, where most of strong reflections transmit the crystal. We further assume that only the waves scattered in forward directions are appreciable. This assumption which has been adopted by Bethe[1)], Artmann[3)] and Cowley and Moodie[2)], seems to be reasonable provided that the glancing angle of the incidence is not extremely small.

We, first of all, calculate the function $\psi^{(2)}(\boldsymbol{r})$ from $\psi^{(1)}(\boldsymbol{r})$. Substituting the first term of (3.13) and (3.5) into (2.4a) for $m=2$, we obtain

$$\psi^{(2)}(\boldsymbol{r})=4\pi A_0\left(\frac{me}{2\pi\hbar^2}\right)^2\sum_{h}{}'\sum_{g}{}'\frac{v_{\boldsymbol{h}-\boldsymbol{g}}\cdot v_{\boldsymbol{g}}}{K_z{}^{\boldsymbol{g}}}\iint\frac{\exp[-i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r})]}{(2\pi)^3(\boldsymbol{k}^2-\boldsymbol{K}^{0^2})}$$
$$\times\exp[i\{\boldsymbol{K}^{\boldsymbol{g}}+2\pi(\boldsymbol{h}-\boldsymbol{g})\}\boldsymbol{r}_i]\cdot\left(\frac{\exp(-2\pi i\zeta^{\boldsymbol{g}}z_i)-1}{-\zeta^{\boldsymbol{g}}}\right)d\boldsymbol{k}\,d\boldsymbol{r}_i\,.$$

Taking account of

$$\boldsymbol{K}^{\boldsymbol{g}}\boldsymbol{r}_i+2\pi(\boldsymbol{h}-\boldsymbol{g})\boldsymbol{r}_i-2\pi\zeta^{\boldsymbol{g}}z_i=[(\boldsymbol{K}^0+2\pi\boldsymbol{g})\boldsymbol{r}_i+2\pi\zeta^{\boldsymbol{g}}z_i]+2\pi(\boldsymbol{h}-\boldsymbol{g})\boldsymbol{r}_i-2\pi\zeta^{\boldsymbol{g}}z_i$$
$$=(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}_i\,,$$

we have

$$\psi^{(2)}(\boldsymbol{r})=4\pi A_0\left(\frac{me}{2\pi\hbar^2}\right)^2\sum_{h}{}'\sum_{g}{}'\frac{v_{\boldsymbol{h}-\boldsymbol{g}}\cdot v_{\boldsymbol{g}}}{K_z{}^{\boldsymbol{g}}\cdot\zeta^{\boldsymbol{g}}}$$
$$\times\left[\exp[i\{\boldsymbol{K}^{\boldsymbol{g}}+2\pi(\boldsymbol{h}-\boldsymbol{g})\}\boldsymbol{r}]\iint\frac{\exp[i\{\boldsymbol{K}^{\boldsymbol{g}}+2\pi(\boldsymbol{h}-\boldsymbol{g})-\boldsymbol{k}\}\boldsymbol{r}']}{(2\pi)^3(\boldsymbol{k}^2-\boldsymbol{K}^{0^2})}\,d\boldsymbol{k}\,d\boldsymbol{r}'\right.$$
$$\left.-\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}]\iint\frac{\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h}-\boldsymbol{k})\boldsymbol{r}']}{(2\pi)^3(\boldsymbol{k}^2-\boldsymbol{K}^{0^2})}\,d\boldsymbol{k}\,d\boldsymbol{r}'\right]. \tag{4.1}$$

The second integral in (4.1) is nothing but (3.8), and the first integral may also be reduced to the same integral, if $\boldsymbol{K}^{\boldsymbol{g}}-2\pi\boldsymbol{g}$ in the exponent is replaced by $\boldsymbol{K}^0$. Then, consulting the first term of (3.12), we obtain

$$\psi^{(2)}(\boldsymbol{r})=A_0\left(\frac{me}{2\pi\hbar^2}\right)^2\sum_{h}{}'\sum_{g}{}'\frac{v_{\boldsymbol{h}-\boldsymbol{g}}\cdot v_{\boldsymbol{g}}}{K_z{}^{\boldsymbol{h}}\cdot K_z{}^{\boldsymbol{g}}}\exp(i\boldsymbol{K}^{\boldsymbol{h}}\boldsymbol{r})$$
$$\times\left[\frac{\exp[2\pi i(\zeta^{\boldsymbol{g}}-\zeta^{\boldsymbol{h}})z]-1}{\zeta^{\boldsymbol{g}}(\zeta^{\boldsymbol{g}}-\zeta^{\boldsymbol{h}})}+\frac{\exp(-2\pi i\zeta^{\boldsymbol{h}}z)-1}{\zeta^{\boldsymbol{h}}\cdot\zeta^{\boldsymbol{g}}}\right]. \tag{4.2}$$

For the simple evaluation of $\psi^{(3)}(\boldsymbol{r})$, we rearrange the terms in the square bracket in (4.2) as

$$\exp(i\boldsymbol{K}^h\boldsymbol{r})\left[\frac{\exp[2\pi i(\zeta^g-\zeta^h)z]-1}{\zeta^g(\zeta^g-\zeta^h)}+\frac{\exp(-2\pi i\zeta^h z)-1}{\zeta^h\cdot\zeta^g}\right]$$
$$=\left[\frac{\exp[i\{\boldsymbol{K}^g+2\pi(\boldsymbol{h}-\boldsymbol{g})\}\boldsymbol{r}]}{\zeta^g(\zeta^g-\zeta^h)}+\frac{\exp(i\boldsymbol{K}^h\boldsymbol{r})}{\zeta^h(\zeta^h-\zeta^g)}+\frac{\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}]}{\zeta^h\cdot\zeta^g}\right]. \tag{4.3}$$

Substituting (4.2) with (4.3) into (2.4a) for $m=3$ and rewriting $\boldsymbol{g}$ and $\boldsymbol{h}$ as $\boldsymbol{g}_1$ and $\boldsymbol{g}_1+\boldsymbol{g}_2$ respectively, we have

$$\psi^{(3)}(\boldsymbol{r})=4\pi A_0\left(\frac{me}{2\pi\hbar^2}\right)^3\sum_{\boldsymbol{h}}{}'\sum_{g_2}{}'\sum_{g_1}{}'\frac{v_{\boldsymbol{h}-(g_1+g_2)}\cdot v_{g_2}\cdot v_{g_1}}{K_z{}^{g_1+g_2}\cdot K_z{}^{g_1}}\iint\frac{\exp[-i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r})]}{(2\pi)^3(\boldsymbol{k}^2-\boldsymbol{K}^{0^2})}$$
$$\times\exp[2\pi i\{\boldsymbol{h}-(\boldsymbol{g}_1+\boldsymbol{g}_2)\}\boldsymbol{r}]\left[\frac{\exp[i(\boldsymbol{K}^{g_1}+2\pi\boldsymbol{g}_2)\boldsymbol{r}_i]}{\zeta^{g_1}(\zeta^{g_1}-\zeta^{g_1+g_2})}\right.$$
$$\left.+\frac{\exp(i\boldsymbol{K}^{g_1+g_2}\boldsymbol{r}_i)}{\zeta^{g_1+g_2}(\zeta^{g_1+g_2}-\zeta^{g_1})}+\frac{\exp[i\{\boldsymbol{K}^0+2\pi(\boldsymbol{g}_1+\boldsymbol{g}_2)\}\boldsymbol{r}_i]}{\zeta^{g_1+g_2}\cdot\zeta^{g_1}}\right]d\boldsymbol{r}_i\,d\boldsymbol{k}\,. \tag{4.4}$$

Since the integrals contained in (4.4) have the forms similar to that in (3.8), we obtain

$$\psi^{(3)}(\boldsymbol{r})=A_0\left(\frac{me}{2\pi\hbar^2}\right)^3\sum_{\boldsymbol{h}}{}'\sum_{g_2}{}'\sum_{g_1}{}'\frac{v_{\boldsymbol{h}-(g_1+g_2)}\cdot v_{g_2}\cdot v_{g_1}}{K_z{}^h\cdot K_z{}^{g_1+g_2}\cdot K_z{}^{g_1}}\cdot\exp(i\boldsymbol{K}^h\boldsymbol{r})\left[\frac{\exp[2\pi i(\zeta^{g_1}-\zeta^h)z]-1}{\zeta^{g_1}(\zeta^{g_1}-\zeta^{g_1+g_2})(\zeta^{g_1}-\zeta^h)}\right.$$
$$\left.+\frac{\exp[2\pi i(\zeta^{g_1+g_2}-\zeta^h)z]-1}{\zeta^{g_1+g_2}(\zeta^{g_1+g_2}-\zeta^{g_1})(\zeta^{g_1+g_2}-\zeta^h)}-\frac{\exp(-2\pi i\zeta^h z)-1}{\zeta^h\cdot\zeta^{g_1+g_2}\cdot\zeta^{g_1}}\right]. \tag{4.5}$$

For the evaluation of $\psi^{(4)}(\boldsymbol{r})$ from $\psi^{(3)}(\boldsymbol{r})$, it is again advantageous to rearrange the terms in the square bracket in (4.5) as

$$\exp(-i\boldsymbol{K}^h\boldsymbol{r})\cdot\left[\frac{\exp[i\{\boldsymbol{K}^{g_1}+2\pi(\boldsymbol{h}-\boldsymbol{g}_1)\}\boldsymbol{r}]}{\zeta^{g_1}(\zeta^{g_1}-\zeta^{g_1+g_2})(\zeta^{g_1}-\zeta^h)}+\frac{\exp[i\{\boldsymbol{K}^{g_1+g_2}+2\pi(\boldsymbol{h}-\boldsymbol{g}_1-\boldsymbol{g}_2)\}\boldsymbol{r}]}{\zeta^{g_1+g_2}(\zeta^{g_1+g_2}-\zeta^{g_1})(\zeta^{g_1+g_2}-\zeta^h)}\right.$$
$$\left.+\frac{\exp(i\boldsymbol{K}^h\boldsymbol{r})}{\zeta^h(\zeta^h-\zeta^{g_1})(\zeta^h-\zeta^{g_1+g_2})}-\frac{\exp[i(\boldsymbol{K}^0+2\pi\boldsymbol{h})\boldsymbol{r}]}{\zeta^h\cdot\zeta^{g_1+g_2}\cdot\zeta^{g_1}}\right]. \tag{4.6}$$

Without the rearrangement we have six integrals to evaluate and the expression for $\psi^{(4)}(\boldsymbol{r})$ becomes much lengthy, while the number of integrals can be reduced to four when (4.6) is taken into account. The calculations of higher $\psi^{(n)}(\boldsymbol{r})$ are also much simplified by making the similar rearrangements of calculated terms. Thus, we have a general expression for $\psi^{(n)}(\boldsymbol{r})$:

$$\psi^{(n)}(\boldsymbol{r})=A_0\left(\frac{me}{2\pi\hbar^2}\right)^n\sum_{\boldsymbol{h}}{}'\sum_{g_{n-1}}{}'\sum_{g_{n-2}}{}'\cdots\sum_{g_2}{}'\sum_{g_1}{}'$$
$$\times\frac{v_{\boldsymbol{h}-(g_1+g_2+\cdots+g_{n-1})}\cdot v_{g_{n-1}}\cdot v_{g_{n-2}}\cdot\;\cdots\;\cdot v_{g_2}\cdot v_{g_1}}{K_z{}^h\cdot K_z{}^{g_1+\cdots+g_{n-1}}\cdot K_z{}^{g_1+\cdots+g_{n-2}}\cdot\;\cdots\;\cdot K_z{}^{g_1+g_2}\cdot K_z{}^{g_1}}$$
$$\times\exp(i\boldsymbol{K}^h\boldsymbol{r})\cdot Z_n(\zeta_1,\zeta_2,\cdots,\zeta_{n-1},\zeta^h;z)\,, \tag{4.7}$$

where

$$Z_n(\zeta_1,\zeta_2,\cdots,\zeta_{n-1},\zeta^h;z)$$
$$=\sum_{m=1}^{n-1}\frac{\exp[2\pi i(\zeta_m-\zeta^h)z]-1}{\zeta_m(\zeta_m-\zeta^h)\prod\limits_{\substack{k=1\\k\neq m}}^{n-1}(\zeta_m-\zeta_k)}+(-1)^n\frac{\exp(-2\pi i\zeta^h z)-1}{\zeta^h\cdot\prod\limits_{k=1}^{n-1}\zeta_k}\,. \tag{4.8}$$

In (4.8), ζ_m is the abbreviated notation of $\zeta^{g_1+g_2+\cdots+g_m}$ and means the excitation error of the reciprocal lattice point corresponding to the vector $2\pi(\boldsymbol{g}_1+\boldsymbol{g}_2+\cdots+\boldsymbol{g}_m)$, as shown in Fig. 5.

The formula (4.7) with (4.8) is essentially similar to that previously derived by Cowley and

Moodie[2]. Particularly, the factor $Z_n(\zeta_1, \zeta_2, \cdots, \zeta_{n-1}, \zeta^h; z)$ given by (4.8) coincides exactly with the result of their calculations. However, the essential assumption in their theory that all scattering angles should be small is no longer necessary here, so long as only the forward scattering is appreciable. Under the same condition, (4.7) is applicable also to the cases of oblique incidence without any revision, since K_z's are adopted instead of K's. The formula (4.7) as well as Cowley and Moodie's gives the pictorial image of the n-ple scattering process in which the incident wave $\boldsymbol{K}^0$ turns to $\boldsymbol{K}^h$ through the $n-1$ intermediate states characterised by $\boldsymbol{K}^{g_1}, \boldsymbol{K}^{g_1+g_2}, \cdots, \boldsymbol{K}^{g_1+\cdots+g_{n-1}}$.

The expansion of $Z_n(\zeta_1, \zeta_2, \cdots, \zeta_{n-1}, \zeta^h; z)$ into power series of ζ's gives another useful expression for Z_n:

$$
\begin{aligned}
&Z_n(\zeta_1, \zeta_2, \cdots, \zeta_{n-1}, \zeta^h; z) \\
&=\sum_{k=n}^{\infty} \frac{(2\pi i z)^k}{k!} \sum_{m_1=0}^{k-n} (-1)^{m_1} \cdot \binom{k-1}{m_1} \cdot \sum_{m_2=0}^{k-n-m_1} \; \sum_{m_3=0}^{k-n-(m_1+m_2)} \cdots \sum_{m_{n-1}=0}^{k-n-(m_1+\cdots+m_{n-2})} \\
&\quad \times [(\zeta^h)^{m_1} \cdot (\zeta_{n-1})^{m_2} \cdot (\zeta_{n-2})^{m_3} \cdots (\zeta_3)^{m_{n-2}} \cdot (\zeta_2)^{m_{n-1}} \cdot (\zeta_1)^{k-n-(m_1+\cdots+m_{n-1})}] \, .
\end{aligned}
\tag{4.9}
$$

If all ζ's are zero, (4.9) is reduced to

$$Z_n = (2\pi i z)^n / n! \, . \tag{4.10}$$

Other special forms of Z_n are given in Appendix.

§ 5. Intensities in the Short Wave Length Limit

Miyake[4] has recently pointed out that the well-known treatment of the two-wave approximation of dynamical theory is not legitimate for calculating the intensities of reflexion in the short wave length or small crystal size limit. In this connection, it may be significant to study the behavior of the intensity of reflexion in the limit $K \to \infty$ with the present theory, assuming that the relativistic effects could be taken into account by the mass correction in wave length.

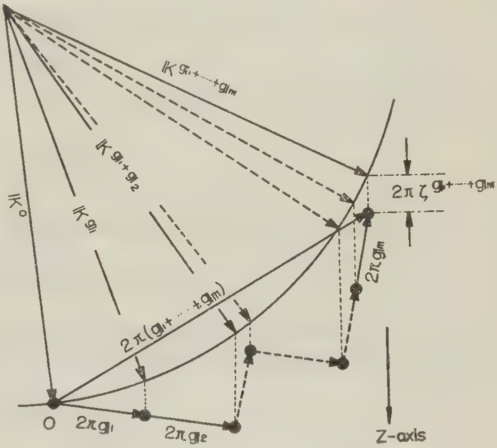

Fig. 5. Illustration of $\boldsymbol{K}^{g_1+\cdots+g_m}$ and $\zeta^{g_1+\cdots+g_m}$.

The expression (4.9) shows that Z_n approaches to the constant value $(2\pi i z)^n/n!$ as $K \to \infty$, since all ζ's, in which we are interested, tend to $O(1/K)$. Then, from (4.7), we obtain

$$\phi^{(n)}(\boldsymbol{r}) \to O(1/K^n) \qquad \text{as} \quad K \to \infty \, .$$

It can be concluded, therefore, that

$$\Psi(\boldsymbol{r}) - \phi^{(0)}(\boldsymbol{r}) \to A_0 \left(\frac{ime}{\hbar^2} \right) \cdot z \cdot \sum_h{}' \frac{v_h}{K_z^h} \cdot \exp(i\boldsymbol{K}^h \boldsymbol{r}) \qquad \text{as} \quad K \to \infty \, .$$

In other words, the intensity of reflexion in the short wave length limit is equal to the exact excitation value of kinematical intensity. It appears that this result is the same as that due to the usual method of two-wave approximation (Pinsker, Blackman). However, it should be noticed that the simultaneous occurence of many reflexions in a crystal is taken into account here. Thus, the present result amounts to a more general theoretical confirmation than before to the experimental method developed by Honjo and Kitamura[5] for obtaining the kinematical value of reflected intensity by varying the wave length of electrons.

§ 6. Convergence Test of Wave Function for Simple Examples

Concerning the method of higher order Born approximation, a question may arise as to whether the wave functions derived successively from low order approximations do converge or not. Though no conclusive answer has yet been obtained to this question, two simple examples quoted below may be instructive to show how the wave functions converge and to suggest the convergency in more general cases.

(a) *Free electron model* (v_0*-scattering*)

Now we consider that a beam of electron enters the hypothetical crystal whose potential field is

$$V(r)=\begin{cases} v_0 & \text{for} \quad 0\leq z\leq D \\ 0 & \text{otherwise.}\end{cases} \tag{6.1}$$

For further simplification, the direction of the incident beam is assumed to be normal to the surface. Neglecting the reflection at the surfaces of crystal, we may write immediately the wave function in the form

$$\Psi(\boldsymbol{r})=\begin{cases} \exp(i\boldsymbol{K}^i\boldsymbol{r}) & \text{in vacuum} \\ \exp(i\boldsymbol{K}^0\boldsymbol{r}) & \text{in crystal ,}\end{cases} \tag{6.2}$$

where the wave number vector $\boldsymbol{K}^0$ in crystal is defined as

$$\boldsymbol{K}^{02}=\boldsymbol{K}^{i2}+(2me/\hbar^2)\cdot v_0 \,. \tag{6.3}$$

When K^i is large enough we have

$$K^0\simeq K^i+\frac{mev_0}{\hbar^2K^i} \,,$$

so that the wave function in the crystal is approximately given by

$$\Psi(\boldsymbol{r})\simeq\exp(i\boldsymbol{K}^i\boldsymbol{r})\cdot\exp[i(mev_0/\hbar^2K^i)z] \,. \tag{6.4}$$

We show below that the power series obtained by the application of the higher order Born approximation also gives the same result. Adopting $\exp(i\boldsymbol{K}^i\boldsymbol{r})$ as $\psi^{(0)}(\boldsymbol{r})$, we obtain from (4.7)

$$\psi^{(n)}(\boldsymbol{r})=\frac{(imev_0z/\hbar^2K^i)^n}{n!}\cdot\exp(i\boldsymbol{K}^i\boldsymbol{r}) \,.$$

Here use has been made of (4.10), since all ζ's in Z_n should be equal to ζ^0 (the excitation error of the origin of reciprocal space) and apparently $\zeta^0=0$. It is easily shown that

$$\begin{aligned}\sum_{n=0}^{\infty}\psi^{(n)}(\boldsymbol{r})&=\exp(i\boldsymbol{K}^i\boldsymbol{r})\cdot\left(1+i\alpha z-\frac{\alpha^2}{2}z^2-i\,\frac{\alpha^3}{6}z^3+\cdots\right)\\ &=\exp(i\boldsymbol{K}^i\boldsymbol{r})\cdot\exp(i\alpha z) \,,\end{aligned} \tag{6.5}$$

where

$$\alpha=mev_0/\hbar^2K^i \,.$$

In Fig. 6, $|\psi^{(n)}(\boldsymbol{r})|$ is plotted against n for two cases. The open circles in the figure correspond to the case where $v_0=10$ volts, $\lambda=0.048$ Å and $z=50$ Å, and the full circles to the case where $v_0=20$ volts, $\lambda=0.048$ Å and $z=200$ Å. The former shows the monotonous decrease of $|\psi^{(n)}(\boldsymbol{r})|$ with increasing n. In the latter case, on the other hand, $|\psi^{(n)}(\boldsymbol{r})|$ increases until n reaches 3, and then turns to decrease with increasing n. It should be noticed that the wave function converges ultimately despite that a tendency of divergence was observed for the first two or three terms.

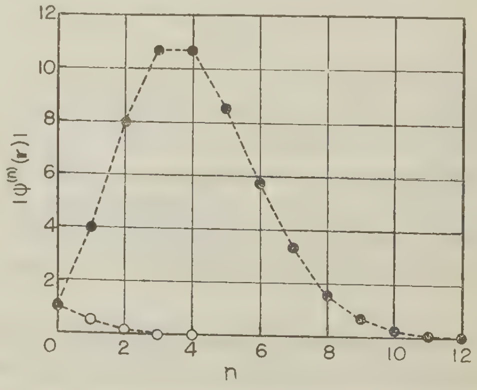

Fig. 6. $|\psi^{(n)}(\ )|$ versus n curves for v_0-scattering

(b) *The pendulum solution of Bethe*

It has been proved by Cowley and Moodie that their theory gives Bethe's pendulum solution[1] when the same condition of the two-wave approximation as in the usual dynamical theory is assumed. Their result is most easily confirmed for the condition of the exact excitation of the reflexion $\boldsymbol{h}$. Using (4,7) and (4.10) and taking into account only the interactions between waves $\boldsymbol{o}$ and $\boldsymbol{h}$, we may write the amplitude of the reflected wave $\boldsymbol{h}$ as follows:

$$\psi_h = A_0\left(\frac{me}{2\pi\hbar^2}\right)\frac{v_h}{K_z^h}(2\pi iz) + A_0\left(\frac{me}{2\pi\hbar^2}\right)^3 \frac{v_h v_{-h} v_h}{K_z^h K_z^0 K_z^h}\cdot\frac{(2\pi iz)^3}{3!}$$
$$+ A_0\left(\frac{me}{2\pi\hbar^2}\right)^5 \frac{v_h v_{-h} v_h v_{-h} v_h}{K_z^h K_z^0 K_z^h K_z^0 K_z^h}\cdot\frac{(2\pi iz)^5}{5!} + \cdots .$$

Assuming $v_h = v_{-h}$ and $K_z^0 = K_z^h$ and putting $mev_h/\hbar^2 K_z^0 = \alpha$, we have

$$\psi_h \propto \alpha\cdot z - \frac{(\alpha z)^3}{3!} + \frac{(\alpha z)^5}{5!} - \cdots = \sin(\alpha z) .$$

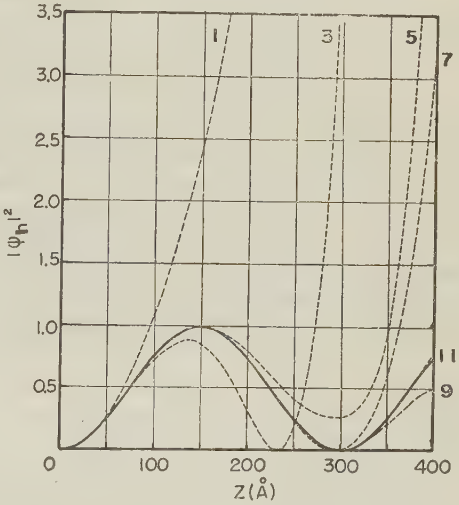

Fig. 7. A numerical calculation on the pendulum solution of Bethe. $v_h = 10$ volts and $\lambda = 0.0502$ Å (56 KeV) are adopted. The solid curve represents the pendulum solution. The dotted curve with index n shows the result in n-th order Born approximation. For the 200 KeV-electron, values of z should be doubled.

This is nothing but the pendulum solution. Fig. 7 shows a result of numerical calculation for $v_h = 10$ volts and $\lambda = 0.0502$ Å (56 KeV). In the figure, the solid curve represents Bethe's pendulum solution $\sin^2(\alpha z)$, and the dotted curves with index n show the intensities of reflection $\boldsymbol{h}$ of the n-th order Born approximations, respectively. We see here how the range where Born approximation is valid is extended with increasing n.

§ 7. Extensions of the Present Theory

In this paragraph we treat the diffraction by finite crystals and overlapping crystals as the extended applications of the present theory.

(a) *Approximate asymptotic form of the wave scattered by a finite crystal*

In the derivation of $\psi^{(1)}(r)$ in § 3, we had a great advantage that the integrals over x' and y' in (3.9) are reduced to δ-functions because of the assumption of infinite plate crystal. It seems to be difficult to treat rigorously the scattering from a finite crystal by the present theory, since such an advantage is no longer available now. Therefore, we shall content ourselves with deriving the following approximate result.

We consider a crystal of parallelepiped with the side lengths L_1, L_2 and L_3 as shown in Fig. 8 (a). The asymptotic form of wave function at a point r far away from the crystal is given by

$$\Psi(r) \sim \psi^{(0)}(r) + \frac{me}{2\pi\hbar^2}\cdot\frac{\exp(iK^0 r)}{r}\iiint\limits_{crystal}\exp[-iK^0(r\cdot r_i)/r]\cdot V(r_i)\Psi(r_i)\,dr_i . \tag{7.1}$$

Strictly speaking, the wave number in vacuum K^i must be taken instead of the wave number in crystal K^0. However, for simplicity of calculation, we adopt K^0 and omit the zero term from $V(r)$. If L_1 and L_2 are large compared with L_3 and the direction of the incident beam is nearly perpendicular to the xy-plane, we may neglect the edge effect and substitute (4.7) for the infinite crystal into $\Psi(\boldsymbol{r}_i)$ in the integrand of (7.1) as the approximation. Then, we shall have the wave function in the form of spherical wave:

$$\Psi(\boldsymbol{r})\sim\phi^{(0)}(\boldsymbol{r})+\phi^{(1)}(\boldsymbol{r})+\phi^{(2)}(\boldsymbol{r})+\cdots+\phi^{(n)}(\boldsymbol{r})+\cdots, \tag{7.2}$$

where

$$\begin{aligned}\phi^{(n)}(\boldsymbol{r})=&A_0\left(\frac{me}{2\pi\hbar^2}\right)^n\cdot\frac{\exp(iK^0r)}{2\pi ir}\\&\times\sum_{\boldsymbol{h}}{}'\sum_{\boldsymbol{g}_{n-1}}{}'\cdots\sum_{\boldsymbol{g}_2}{}'\sum_{\boldsymbol{g}_1}{}'\frac{v_{\boldsymbol{h}-(\boldsymbol{g}_1+\cdots+\boldsymbol{g}_{n-1})}\cdot v_{\boldsymbol{g}_{n-1}}\cdot\cdots\cdot v_{\boldsymbol{g}_2}v_{\boldsymbol{g}_1}}{K_z^{\boldsymbol{g}_1+\cdots+\boldsymbol{g}_{n-1}}\cdot\cdots\cdot K_z^{\boldsymbol{g}_1+\boldsymbol{g}_2}\cdot K_z^{\boldsymbol{g}_1}}\\&\times[\sin(\pi\eta_x^{\boldsymbol{h}}L_1)/\pi\eta_x^{\boldsymbol{h}}]\cdot[\sin(\pi\eta_y^{\boldsymbol{h}}L_2)/\pi\eta_y^{\boldsymbol{h}}]\\&\times\left[\sum_{m=1}^{n-1}\frac{\exp[2\pi i(\zeta_m-\eta_z^{\boldsymbol{h}})L_3]-1}{\zeta_m(\zeta_m-\eta_z^{\boldsymbol{h}})\prod\limits_{\substack{k=1\\k\neq m}}^{n-1}(\zeta_m-\zeta_k)}+(-1)^n\frac{\exp(-2\pi i\eta_z^{\boldsymbol{h}}L_3)-1}{\eta_z^{\boldsymbol{h}}\prod\limits_{k=1}^{n-1}\zeta_k}\right].\end{aligned} \tag{7.3}$$

$\eta^{\boldsymbol{h}}$ in (7.3) is the excitation error vector defined as

$$2\pi\eta^{\boldsymbol{h}}=\frac{K^0\boldsymbol{r}}{r}-(\boldsymbol{K}^0+2\pi\boldsymbol{h})$$

and is illustrated in Fig. 8(b). It is clear that the formula (7.3), which contains Laue functions, gives diffraction spots of finite sizes. As to the Fraunhofer diffraction of electrons by a finite crystal, a more detailed theory which takes into account the refraction phenomena at the surfaces of crystal has been developped by Kato[6] by using the two-wave approximation. The formula (7.3) may be regarded as the rough extension of his formula to the cases containing many reflexions.

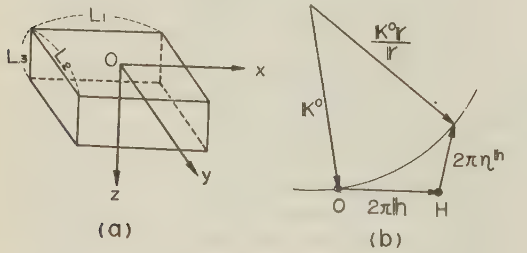

Fig. 8(a). Illustration of a finite crystal. (b) Definition of the excitation error vector $2\pi\eta^{\boldsymbol{h}}$.

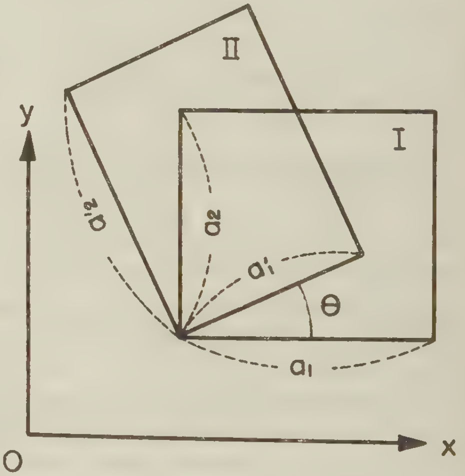

Fig. 9. An arrangement of the unit cells of overlapping crystals.

(b) *Elementary application to Moiré patterns*

Let us consider the overlapping crystals, the potential field within which is given by

$$V(\boldsymbol{r})=\begin{cases}\sum\limits_{\boldsymbol{h}}v_{\boldsymbol{h}}\exp(2\pi i\boldsymbol{hr}) & \text{for}\quad 0\leq z\leq D\\ \sum\limits_{\boldsymbol{h}'}v_{\boldsymbol{h}'}\exp(2\pi i\boldsymbol{h}'\boldsymbol{r}) & \text{for}\quad D\leq z\leq D+D'\\ 0 & \text{otherwise.}\end{cases} \tag{7.4}$$

In the case when the both crystals have orthorhombic cells, whose fundamental vectors are $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, $\boldsymbol{a}_3$ and $\boldsymbol{a}_1'$, $\boldsymbol{a}_2'$, $\boldsymbol{a}_3'$, respectively, and $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, $\boldsymbol{a}_1'$ and $\boldsymbol{a}_2'$ lie in the xy-plane (parallel to the surface) as shown in Fig. 9 (7.4) can be written by using Miller's indices (l, m, n) and (l', m', n') as follows:

$$V(\boldsymbol{r})\begin{cases}\sum V_{lmn}\cdot\exp\left[2\pi i\left(\dfrac{l}{a_1}x+\dfrac{m}{a_2}y+\dfrac{n}{a_3}z\right)\right] & \text{for}\quad 0\leq z\leq D\\ \sum V_{l'm'n'}\cdot\exp\left[2\pi i\left\{\left(\dfrac{l'}{a_1'}\cos\theta-\dfrac{m'}{a_2'}\sin\theta\right)x+\left(\dfrac{l'}{a_1'}\sin\theta+\dfrac{m'}{a_2'}\cos\theta\right)y+\dfrac{n'}{a_3'}z\right\}\right] & \\ & \text{for}\quad D\leq z\leq D+D'\,.\end{cases}\tag{7.5}$$

The amplitude of the waves scattered by these crystals may easily be calculated by following the same procedure as before. Using (2.4a) for $m=1$ and (7.4), we obtain

$$\phi^{(1)}(\boldsymbol{r})=\begin{cases}-A_0\left(\dfrac{me}{2\pi\hbar^2}\right)\sum\limits_{g}\dfrac{v_g}{K_z^g}\left[\dfrac{\exp(-2\pi i\zeta^g z)-1}{\zeta^g}\right]\exp(i\boldsymbol{K}^g\boldsymbol{r}) & \text{for}\quad 0\leq z\leq D\\ -A_0\left(\dfrac{me}{2\pi\hbar^2}\right)\cdot\left[\sum\limits_{g}\dfrac{v_g}{K_z^g}\left\{\dfrac{\exp(-2\pi i\zeta^g D)-1}{\zeta^g}\right\}\exp(i\boldsymbol{K}^g\boldsymbol{r})\right. & \\ \qquad\left.+\sum\limits_{g'}\dfrac{v_{g'}}{K_z^{g'}}\left\{\dfrac{\exp(-2\pi i\zeta^{g'}z)-\exp(-2\pi i\zeta^{g'}D)}{\zeta^{g'}}\right\}\exp(i\boldsymbol{K}^{g'}\boldsymbol{r})\right] & \\ & \text{for}\quad D\leq z\leq D+D'\,.\end{cases}\tag{7.6}$$

The first term of $\phi^{(1)}(\boldsymbol{r})$ for $D\leq z\leq D+D'$ describes the waves which came into the second crystal after having been scattered once in the first crystal. By substituting (7.6) into (2.4a) for $m=2$, this term will produce the following field in the second crystal:

$$\frac{v_{h'}\cdot v_g}{K_z^{g+h'}K_z^g}\left(\frac{\exp(-2\pi i\zeta^g D)-1}{\zeta^g}\right)\cdot\exp(i\boldsymbol{K}^{g+h'}\boldsymbol{r})$$
$$\times\left[\frac{\exp[2\pi i(\zeta^g-\zeta^{g+h'})D]-\exp[2\pi i(\zeta^g-\zeta^{g+h'})z]}{\zeta^g-\zeta^{g+h'}}\right],\tag{7.7}$$

which represents the wave scattered once in each of the crystals. The interference of $\phi^{(0)}(\boldsymbol{r})$ with (7.7) at the exist surface $z=D+D'$ may be expressed simply as

$$A_0\exp[i\{K_x^0x+K_y^0y+K_z^0(D+D')\}]$$
$$\times[1+C\cdot\exp[2\pi i\{(g_x+h_x')x+(g_y+h_y')y\}]]\,,\tag{7.8}$$

and will give the moiré pattern. The factor C, which determines the contrast of the image, can be calculated from (7.7). The spacings of the parallel and rotation moiré patterns are easily given by using (7.5).

The result mentioned above contains nothing new, since Cowley[7)] and other authors have dealt with the theory of moiré patterns up to date. It may be expected, however, that the present theory will prove its true merits, if it is applied to some complicated problems, *e.g.*, those of the moiré patterns produced by more than three waves, the dependence of the contrasts of moiré patterns on the other waves excited simultaneously and so on.

In conclusion the author wishes to express his sincere thanks to Prof. Shizuo Miyake for his kind guidance and encouragement throughout the present work.

Appendix

The expressions for $Z_n(\zeta_1,\cdots,\zeta_{n-1},\zeta^h;\,z)$ in the cases, where (4.8) is no longer available, are given below for $n\leq3$. It should be noticed that the formula (4.8) is symmetric as to ζ's except ζ^h.

[I]. If only ζ^h is zero, $Z_n(\zeta_1,\cdots,\zeta^h;\,z)$ should be written as

$$Z_n=\sum_{m=1}^{n-1}\frac{\exp(2\pi i\zeta_m z)-1}{\zeta_m^2\prod\limits_{\substack{k=1\\k\neq m}}^{n-1}(\zeta_m-\zeta_k)}+(-1)^n\frac{(-2\pi iz)}{\prod\limits_{k=1}^{n-1}\zeta_k}\,.$$

[II]. $Z_2(\zeta_1, \zeta^h; z)$

(1) $\zeta_1=0$

$$Z_2=[1-(2\pi iz\zeta^h+1)\cdot\exp(-2\pi i\zeta^h z)]/(\zeta^h)^2 \,.$$

(2) $\zeta_1=\zeta^h$

$$Z_2=[2\pi iz\cdot\zeta^h+\exp(-2\pi i\zeta^h z)-1]/(\zeta^h)^2 \,.$$

[III]. $Z_3(\zeta_1, \zeta_2, \zeta^h; z)$

(1) $\zeta_1=0$

$$Z_3=\frac{\exp[2\pi i(\zeta_2-\zeta^h)z]-1}{\zeta_2^2(\zeta_2-\zeta^h)}+\frac{2\pi iz\cdot\exp(-2\pi i\zeta^h z)}{\zeta_2\zeta^h}+\frac{(\zeta_2+\zeta^h)\cdot[\exp(-2\pi i\zeta^h z)-1]}{(\zeta_2\zeta^h)^2} \,.$$

(2) $\zeta_1=\zeta_2$

$$Z_3=\frac{(\zeta^h-2\zeta_1)[\exp[2\pi i(\zeta_1-\zeta^h)z]-1]}{\zeta_1^2(\zeta_1-\zeta^h)^2}+\frac{2\pi iz\cdot\exp[2\pi i(\zeta_1-\zeta^h)z]}{\zeta_1(\zeta_1-\zeta^h)}-\frac{\exp(-2\pi i\zeta^h z)-1}{\zeta_1^2\zeta^h} \,.$$

(3) $\zeta_1=\zeta^h$

$$Z_3=\frac{2\pi iz}{\zeta^h(\zeta^h-\zeta_2)}+\frac{\exp[2\pi i(\zeta_2-\zeta^h)z]-1}{\zeta_2(\zeta_2-\zeta^h)^2}-\frac{\exp(-2\pi i\zeta^h z)-1}{\zeta_2(\zeta^h)^2} \,.$$

(4) $\zeta_1=\zeta_2=0$

$$Z_3=\frac{-1}{(\zeta^h)^3}\left[\exp(-2\pi i\zeta^h z)\left\{\frac{1}{2}(2\pi iz)^2(\zeta^h)^2+2\pi iz\zeta^h+1\right\}-1\right].$$

(5) $\zeta_1=\zeta^h=0$

$$Z_3=\frac{-1}{\zeta_2^3}\left[\frac{1}{2}(2\pi iz)^2\zeta_2^2+(2\pi iz)\zeta_2-\exp(2\pi i\zeta_2 z)+1\right].$$

(6) $\zeta_1=\zeta_2,\ \zeta^h=0$

$$Z_3=\frac{1}{\zeta_1^3}[\exp(2\pi i\zeta_1 z)\cdot(2\pi iz\zeta_1-2)+2\pi iz\cdot\zeta_1+2] \,.$$

(7) $\zeta_1=\zeta^h,\ \zeta_2=0$

$$Z_3=\frac{1}{(\zeta^h)^3}[2\pi iz\zeta^h\{\exp(-2\pi i\zeta^h z)+1\}+2\{\exp(-2\pi i\zeta^h z)-1\}] \,.$$

(8) $\zeta_1=\zeta_2=\zeta^h$

$$Z_3=\frac{1}{(\zeta^h)^3}\left[\frac{1}{2}(2\pi iz)^2(\zeta^h)^2-(2\pi iz)\zeta^h-\exp(-2\pi i\zeta^h z)+1\right].$$

To the numerical evaluation of the relatively high order terms, the use of (4.9) seems to be convenient, if we terminate the summation over k at a sufficient large number N.

A Theoretical Treatment of the Excess Energies of Binary Metallic Solutions

By Mitsuo SHIMOJI

Faculty of Science, Hokkaido University, Sapporo

(Received July 4, 1959)

A simplified theoretical treatment of the excess energy of a binary metallic solution, which is based upon a principle of the cellular approximation, is presented. The average size of the atomic polyhedron of a metallic solution, corresponding to the boundary correction of the metallic state, is determined under the condition of a minimum of the total energy of the system. This calculation contains many factors such as the effects of the lowest energy of the valence electrons, the Fermi energy, the interelectronic energy, the ion-core repulsive energy, the van der Waals energy etc. As the purpose of any theory of metallic solutions is to predict the excess quantities from the knowledge of the properties of the pure components, a semi-empirical expression determined only from the quantities of the pure metals is employed in some parts for the estimation of the above factors quantitatively. The present calculation is free from the classical elasticity theory which has been used in the theories of solid solutions, some difficulties having been pointed out. Furthermore, the energetic asymmetry of most metallic solutions can qualitatively or quantitatively be explained by the present treatment.

§ 1. Introduction

In recent years thermodynamic data of metallic solutions have extensively been reviewed by Lumsden¹⁾, Wagner²⁾ and Kubaschewski et al³⁾. However, the quantitative theoretical works on these experimental results have been rather limited. Statistical thermodynamics of metallic solutions has been discussed by many authors¹⁾,⁴⁾⁻⁹⁾, but the statistical theory is not sufficient to predict the excess properties of the metallic solutions except when each component has the same electronegativity. A satisfactory treatment of the calculation of the excess functions of metallic solutions needs a quantum mechanical consideration. Of course it is very difficult to obtain an exact solution of Schroedinger's equation for any metallic solution as well as for any pure metal. Thus a simplified model is necessary to enable one to treat the problem easily. As is well known the cellular method developed by Wigner and Seitz¹⁰⁾ is very useful to estimate the cohesive energy, the lattice constant and the compressibility of simple pure metals, as reviewed in Seitz's¹¹⁾ and Mott-Jones'¹²⁾ text books and others¹³⁾⁻¹⁵⁾.

Quantum mechanical calculations of the excess energies of the dilute metallic solutions have been made by Huang¹⁶⁾ for Au–Ag alloys and by Arafa¹⁷⁾ for Cu–Ag and Ag–Au. For the systems of the finite concentrations and of multivalent metals, Varley¹⁸⁾ has made progress in calculating the excess energy and obtained a reasonable order of magnitude of the energy etc., though the calculation of the strain energy has been based on the classical elasticity theory. This elastic model, which has been used by many investigators, has the difficulties to obey a vague idea of atomic sizes and other concepts, pointed out by Oriani⁵⁾,¹⁹⁾. Then it is desirable for an atomic theory of metallic solutions to be free from the elastic model. Friedel²⁰⁾ has investigated the screening effects in the alloys from the point of view of a modification of the Thomas-Fermi method. It is to be noted that Friedel's theory gives no effect for a system, where both components have the same valency, and no absolute value of the excess energy, though it does give the curvature of the heat of solution determined by the sign of the excess valency, etc.

The aim of this paper is to devise a simple procedure for calculation of the excess energy of the concentrated metallic solutions from the view point of the cellular method without using the classical elasticity theory in order to predict the thermodynamic properties of metallic solutions in terms of properties of pure components.

§ 2. Average Size of Atomic Sphere

In the quantum mechanical calculation of the cohesive energy of pure metals there are three important factors. The first is the boundary correction associated with the change of the state from the free atomic state to its crystalline one. In other words, the boundary correction gives the lowest energy of electrons in the metal relative to the energy of valence electrons in the free atom. The second is the kinetic energy of the conduction electrons or Fermi energy. The third is the interelectronic energy composed of Coulomb, exchange, correlation energy etc. This last factor is very small in total compared with the other two factors. Thus the effects of the boundary correction and of Fermi energy determine the cohesive forces of metals to first approximation. Furthermore, the effects of ionic (exchange) repulsion emphasized by Fuchs[21] and the van der Waals force stressed by Friedel[22] can not be neglected in such a metal as the noble metals. The cohesive forces of both pure metals and metallic solutions may be explained qualitatively, or quantitatively to some extent, if the above effects are adequately calculated.

In a theory concerning metallic solutions it is not always necessary to calculate the "total" cohesive energy of the solution. The aim of the theory of metallic solutions is to understand the change of cohesive energy due to mixing process. Then it is worth emphasizing that the calculation of the excess energy of a metallic solution could be done by using a semi-empirical result of the pure metals to a certain extent. Such a semi-empirical relation might independently be achieved to a complete calculation of pure metals in the future, though the satisfactory results have not yet been gained except in a few cases such as monovalent metals[15]. A calculation for metallic solutions may be impossible now without some semi-empirical relations of pure components, since the calculated results for pure metals are rarely obtained now except for simple systems.

The atomic polyhedron in the cellular approximation can be replaced by a sphere of the same volume.[10]–[12] Thus the energy of a pure metal has been calculated as a function of the size of the atomic sphere mentioned above. The lattice parameter is determined from the point of a minimum of the energy in the relation between the energy and the size of the atomic sphere. This means that the size of an atomic polyhedron corresponds to the minimum of the total energy in any metal. If this principle is extended also to metallic solutions, an average atomic polyhedron should have a size corresponding to the minimum of the total energy of the solution. From this extended principle the size of the atomic sphere, r_m, could be determined. Thus

$$(\partial E(r)/\partial r)_{r_m}=0 \qquad (2.1)$$

is the fundamental equation in the present theory of metallic solutions. $E(r)$ is the total interaction energy of the solution. In a binary system one can put

$$E(r)=x_A E_{AA}(r)+x_B E_{BB}(r)+\varDelta E^* \qquad (2.2)$$

where x_A and x_B are atomic fractions of A and B, E_{AA} and E_{BB} and the interaction energies of the pure states respectively. $\varDelta E^*$ denotes the energy due to the electrochemical effect or electronegativity effect, the effect of the change of van der Waals forces between the unlike atoms, and others.

$$E(r)\approx x_A E_{AA}(r)+x_B E_{BB}(r) \qquad (2.2')$$

determines the average size of the atomic sphere to first approximation, when $\varDelta E^*$ is small. In a later section § 4, a consideration will be given in the case of taking into account the value of $\varDelta E^*$.

A semi-empirical equation of state for each pure component may be employed in solving (2.1) and (2.2). If an exact solution is obtained for any pure metal in the future, this equation will be able to be confirmed theoretically, as explained in the following section. The present principle will hold as it stands for any result of pure metals. According to Slater[23] the semi-empirical equation of state of a pure metal is given by

$$\begin{aligned} E_{ii}(r)+\varDelta I=&-L_i+L_i a_i^2(r_{ii}-r)^2 \\ &+L_i a_i^3(r_{ii}-r)^3+\cdots, \end{aligned} \qquad (2.3)$$

where L_i is the energy of sublimation at 0°K, r_{ii} is the interatomic distance at 0°K and the parameter a_i is connected with the Grüneisen constant, γ_i, by

$$\gamma_i = a_i r_{ii}/2 - 1/3 \,. \tag{2.4}$$

The difference of the energy between the state of the free atom and that of the ionized ion, where the valence electrons are removed to an infinite distance is shown by ΔI. Putting $L_i a_i^2 = l_i$, substituting (2.3) into (2.2′) and solving (2.1) and (2.2′), one obtains from the first order expression of (2.3)

$$r_m^{(1)} = (x_A l_A r_{0A} + x_B l_B r_{0B})/(x_A l_A + x_B l_B) \,, \tag{2.5}$$

where r_{0A} is the radius of the atomic sphere of pure A, easily deduced from the interatomic distance r_{AA}. The term r_{0B} has the corresponding meaning for B. If the crystalline forms of pure metals are different from each other, (2.5) should be slightly modified. From (2.5) Vegard's law is obtained, if $l_A = l_B$.

$$r_m^{(0)} = x_A r_{0A} + x_B r_{0B} \,. \tag{2.6}$$

It should be noted that (2.5) has a corresponding form to Varley's recent calculation[24)], in which the effect of hydrostatic work due to the size factor in liquid alloys has been studied. The present result is, however, based upon such a generalized equation as (2.1); more detailed expression of r_m than (2.5) can be obtained numerically, provided the higher order expression is adopted in (2.3). Interpretation of equation of state, (2.3), will be given in the following section.

§ 3. Excess Energy with Non-Redistribution of Electrons

The first step to calculate the change of the total energy of a metallic solution is to evaluate the lowest energy of electrons at the bottom of the Brillouin zone of the crystal as a function of the radius of the atomic sphere.[11),12)] The size of the atomic sphere has to satisfy the condition of the total energy minimum as described in the foregoing section. In other words the size of the atomic sphere changes, on the average, from r_{0A} and r_{0B} to r_m in accordance with (2.1). Then the lowest energy of valence electrons for the metal A, $\mathcal{E}_{0A}$, may be written as follows:

$$\mathcal{E}_{0A}(r_m) = \mathcal{E}_{0A}(r_{0A}) + (r_m - r_{0A})\left(\frac{\partial \mathcal{E}_{0A}}{\partial r}\right)_{r=r_{0A}} + \frac{(r_m - r_{0A})^2}{2}\left(\frac{\partial^2 \mathcal{E}_{0A}}{\partial r^2}\right)_{r=r_{0A}} + \cdots \,, \tag{3.1}$$

where $\mathcal{E}_{0A}(r_{0A})$ denotes the value for the pure state and $\mathcal{E}_{0A}(r_m)$ for the solution. This may be evaluated in principle by making use of the familiar procedures in the cellular approximation, for example by the Wigner and Seitz method or the quantum defect method, computed from the spectroscopic data of the free atom.

The second step is to calculate the effect of the average Fermi energy. As is well known, this is given by

$$\mathcal{E}_{FA}(r_m) = \frac{3}{5}\,\frac{K Z_A^{2/3}}{r_m^2} \,, \tag{3.2}$$

and

$$K = \frac{h^2}{8m^*}\left(\frac{9}{4\pi^2}\right)^{2/3} , \tag{3.3}$$

where h is Planck's constant, m^* is the effective mass of electrons, Z_A is the valency of A. In a rigorous treatment the effective mass should be employed, but, in a first approximation, the normal mass of the electrons may be used, when an exact solution of the electronic zone structure in alloys has not been obtained. It is instructive to note the recent development for a non-rigid band model of alloys investigated by Cohen and Heine[25)] as well as Jones' work for a rigid band model[26)]. Future developments for the band structures of metals will be available for improving the present discussion. Furthermore, (3.2) assumes that the electron wave functions have a characteristic of the periodicity of the non-perturbed lattice in spite of the fact that the potential in the metallic solution is no longer periodic owing to the existence of the different kinds of the atoms. Though more rigorous consideration for the electron wave function may be necessary in order to know the correct change of the Fermi energy of the solution, the approximation of the nearly free electrons may be permitted as an approach to the goal as in Varley's paper.[18)]

It is known that the interelectronic energy (Coulomb-, exchange- and correlation energy etc.) is small compared to the effects of the boundary correction and of the Fermi energy.[11)–15)] Then the latter two factors determine mainly the amount of the cohesive energy of metals. In the following discussion for the sake of brevity the effect of the interelectronic energy is not taken into account.

The ionic repulsive energy and the van der Waals energy originating from the field of the ion-core must be influenced by this mixing process, since the change in the radius of the atomic sphere causes variation of the exchange energies and dispersion energies due to a synchronized motion of the bounded electrons of each ion. E^{RV} is defined as the energy due to these effects of the ions.

The energy of pure monovalent metals at 0°K is thus given by[11),12)]

$$E_{AA}(r_{AA})=\mathcal{E}_{0A}(r_{0A})+\mathcal{E}_{FA}(r_{0A})+E_A{}^{RV}=-L_A-I_A\ , \tag{3.4}$$

where I_A is the first ionization potential of A. For the atomic sphere A in solutions one has

$$E_A(r_{mm})=\mathcal{E}_{0A}(r_m)+\mathcal{E}_{FA}(r_m)+E_A{}^{RV}(r_m)=-I_A-L_A+\{l_A(r_{AA}-r_{mm})^2+\cdots\}\ . \tag{3.5}$$

From (3.4) and (3.5) one can calculate the change of the interaction energy of the atomic sphere A on mixing, when there are no charge transfer between the unlike atoms and no appreciable change of the van der Waals force constants between them.

$$\begin{aligned}E_A(r_{mm})-E_A(r_{AA})=\mathcal{E}_{0A}(r_m)-\mathcal{E}_{0A}(r_{0A})+\mathcal{E}_{FA}(r_m-)-\mathcal{E}_{FA}(r_{0A})\\ +E_A{}^{RV}(r_m)-E_A{}^{RV}(r_{0A})=\{l_A(r_{AA}-r_{mm})^2+\cdots\}\ .\end{aligned} \tag{3.6}$$

When use is made of (3.2), (3.6) becomes

$$\mathcal{E}_{0A}(r_m)-\mathcal{E}_{0A}(r_{0A})=-\frac{3K}{5}\left(\frac{1}{r_m{}^2}-\frac{1}{r_{0A}{}^2}\right)-\{E_A{}^{RV}(r_m)-E_A{}^{RV}(r_{0A})\}+\{l_A(r_{AA}-r_{mm})^2+\cdots\}. \tag{3.7}$$

In this way one can calculate the effect of the boundary or so in the case of monovalent metals.

The above consideration can be extended to the case of polyvalent metals. Corresponding to (3.5), one has for the Z_A valence

$$E_A(r_{mm})=Z_A[\mathcal{E}_{0A}(r_m)+\mathcal{E}_{FA}(r_m)]+E_A{}^{RV}(r_m)=-\sum_{i=1}^{Z_A}I_i-\Delta Q-L_A+l_A(r_{AA}-r_{mm})^2+\cdots\ , \tag{3.8}$$

where I_i is the i-th ionization potential, ΔQ is the difference of the interelectronic energy between that in the free atom and that in the metal. By extending the method used to derive (3.7), one obtains

$$\begin{aligned}&Z_A[\mathcal{E}_{0A}(r_m)-\mathcal{E}_{0A}(r_{0A})]\\ &\quad=-\frac{3KZ_A{}^{5/3}}{5}\left(\frac{1}{r_m{}^2}-\frac{1}{r_{0A}{}^2}\right)+\{l_A(r_{AA}-r_{mm})^2+\cdots\}-\{E_A{}^{RV}(r_m)-E_A{}^{RV}(r_{0A})\}\ ,\end{aligned} \tag{3.9}$$

corresponding to (3.7).

Thus one can calculate the change of the total interaction energy of a binary metallic solution on mixing without reference to a direct calculation of the lowest energy of the valence electrons by making use of (3.9), when l_A and $E_A{}^{RV}$ are determined from the experimental data of pure metals only. The detailed study of each term in these equations should be developed, though these empirical expressions are enough for the present purpose.

The change of the total energy of binary solutions (excess energy) on mixing is, if there is no charge transfer,

$$\begin{aligned}\Delta E=&\,x_A\{E_A(r_{mm})-E_{AA}(r_{AA})\}+x_B\{E_B(r_{mm})-E_{BB}(r_{BB})\}+\Delta E^{RV}\\ =&\,x_A\{Z_A[\mathcal{E}_{0A}(r_m)+\mathcal{E}_{FA}(r_m)-\mathcal{E}_{0A}(r_{0A})-\mathcal{E}_{FA}(r_{0A})]+E_A{}^{RV}(r_m)-E_A{}^{RV}(r_{0A})\}\\ &+x_B\{Z_B[\mathcal{E}_{0B}(r_m)+\mathcal{E}_{FB}(r_m)-\mathcal{E}_{0B}(r_{0B})-\mathcal{E}_{FB}(r_{0B})]+E_B{}^{RV}(r_m)-E_B{}^{RV}(r_{0B})\}+\Delta E^{RV}\end{aligned} \tag{3.10}$$

where ΔE^{RV} is the correction due to the forces of the ions on mixing. For example the effect associated with the difference between the force constants of the van der Waals energy of the unlike atoms. Making use of (3.8) and (3.9), (3.10) is rewritten as follows.

$$\Delta E = x_A\{l_A(r_{AA}-r_{mm})^2+\cdots\}+x_B\{l_B(r_{BB}-r_{mm})^2+\cdots\}+\Delta E^{RV}\,. \tag{3.11}$$

If r_m is given by (2.5), (3.11) is

$$\Delta E = x_A x_B (r_{AA}-r_{BB})^2/(x_A/l_B+x_B/l_A)+\Delta E^{RV}. \tag{3.12}$$

More detailed expressions than the quadratic equation will be found also by solving the higher order equations in (2.1), (2.3) and (3.10).

The contents of ΔE^{RV} include the deviation of exchange repulsive energy from the expression such as (3.9) and the effect due to the difference of the van der Waals force constants. The former may be evaluated by some method of Born and Mayer type[27] or Fuchs type[21], but the correction based upon these methods may have no detailed formula except for copper. Then only the latter correction is taken into account. It may be very important, especially when there are easily polarizable d-electrons of different degrees in each ion as in noble and transition metals.[30] This effect can be represented by means of the geometric mean rule for the force constants as in the usual non-electrolyte solutions[4]. From London's consideration[7][8], one can write roughly[4]

$$\Delta E^{RV} = x_A x_B c(f_A-f_B)^2/r_m^3 \tag{3.13}$$

where c is the number of the interaction pairs depending upon the crystal structure, f_A and f_B are the force constants appropriately defined respectively. It is readily found that no effect of this type exists if both components have the same value of van der Waals forces.

It is to be noted that ΔE, (3.12), shows always a positive excess energy due to the disparity of atomic radii and the difference of the van der Waals forces. The former corresponds to the terms of the size factor based on the classical elasticity theory, but it has more sound base than in the elastic model because of its derivation from the equation of state to be explained in principle by quantum mechanics. Furthermore one should remember the effect of the van der Waals forces always provides a positive quantity to the excess energy, even if there is no size factor.

It is of interest that there is a possibility of applicability of the geometric mean rule such as (3.13) in Pauling's view, taking into account the effect of d-electrons in a form of the spd hybrid metallic resonance.[29],[30]

§ 4. Excess Energy with Redistribution of Electrons

In this section the effect of the electronic redistribution on mixing is considered. This effect called the electrochemical effect gives always the negative excess energy, corresponding to a tendency to form a stable alloy phase. If one of the components of the metallic solution has a greater attraction for electrons than the other, an increased probability of finding the electrons near the first may be expected. In the extreme case this tendency means an ionic bonding in ionic crystals. As is well known this effect in molecules can be explained by the concept of electronegativity which depends upon the ionization potential as well as upon the electron affinity.[31],[32] This approach may be extended to metallic solutions,[6],[8],[33] but a more improved approach based upon the cellular approximation is employed here.

The main reason why the electrons in metallic solutions accumulate near one of the atoms in comparison with the other may be found in the fact that the ionization potential of the former is greater than that of the latter, and briefly the large electron affinity of the former. The theoretical investigation of the cohesive energy of metallic solutions has been developed so as to evaluate the effect of the charge transfer qualitatively or quantitatively. In the present treatment this effect is estimated by means of a modification of Varley's method. The difference between the present theory and Varley's is in the point that the height of the maximum of the electronic energy is measured at the average atomic size of metallic solutions or at the respective pure atomic sizes, in addition to the fact that the classical elasticity theory was used in Varley's paper.

If the charge n leaves from one cell, A, and distributes itself uniformly over the other cell, B, the latter accepts on the average $x_A n/x_B$ charge. Hence the average energy of the binary metallic solution which corresponds to (2.2) can be expressed by

$$E(r_m)=x_A[Z_A-n]\mathcal{E}_{0A}(r_m)+x_B[Z_B+x_A n/x_B]\mathcal{E}_{0B}(r_m)+x_A E_A{}^{RV}(r_m)+x_B E_B{}^{RV}(r_m)+\Delta E^{RV}$$
$$+\frac{3x_A K Z_A{}^{5/3}}{5r_m{}^2}\left(1-\frac{n}{Z_A}\right)^{5/3}+\frac{3x_B K Z_B{}^{5/3}}{5r_m{}^2}\left(1-\frac{x_A n}{x_B Z_B}\right)^{5/3}. \tag{4.1}$$

Expanding (4.1) to the second power in n, one obtains

$$E(r_m)=x_A\left\{Z_A\mathcal{E}_{0A}(r_m)+\frac{3}{5}\frac{KZ_A{}^{5/3}}{r_m{}^2}\right\}+x_B\left\{Z_B\mathcal{E}_{0B}(r_m)+\frac{3}{5}\frac{KZ_B{}^{5/3}}{r_m{}^2}\right\}$$
$$+x_A E_A{}^{RV}(r_m)+x_B E_B{}^{RV}(r_m)+\Delta E^{RV}$$
$$+n x_A\{\mathcal{E}_{0B}(r_m)+KZ_B{}^{2/3}/r_m{}^2-\mathcal{E}_{0A}(r_m)-KZ_A{}^{2/3}/r_m{}^2\}$$
$$+n^2 x_A/x_B\{x_B K/3Z_A{}^{1/3}r_m{}^2+x_A K/3Z_B{}^{1/3}r_m{}^2\}\,. \tag{4.2}$$

The simplified equation (4.2) holds, when the amount of charge transfer is small compared to the valency of the pure state. In principle n in (4.1) or (4.2) can be determined from the condition

$$\partial E(n)/\partial n=0\,. \tag{4.3}$$

This equation can be easily calculated if (4.2) is used. As a result the excess energy, corresponding to (3.10), is given by

$$\Delta E=[x_A\{l_A(r_{AA}-r_{mm})^2+\cdots\}+x_B\{l_B(r_{BB}-r_{mm})^2+\cdots\}]$$
$$+x_A x_B c(f_A-f_B)^2/r_m{}^3$$
$$-x_A\,x_B\frac{3r_m{}^2\{\mathcal{E}_{0B}(r_m)-\mathcal{E}_{0A}(r_m)+K(Z_B{}^{2/3}-Z_B{}^{2/3})/r_m{}^2\}^2}{4K(x_A/Z_A{}^{1/3}+x_A/Z_B{}^{1/3})}\,, \tag{4.4}$$

where r_m should satisfy the condition of the energy minimum such as (2.1). However, an analytical expression for r_m is not easily obtained in contrast to (2.6) deduced from the condition of non-redistribution for the electronic charge. Then one had better calculate the energy of the system in a given r_m and, from the graphical relation between the size of the atomic cell and the energy, the most probable size of the system can be obtained.

As the first approximation, Vegard's law for the interatomic distance may be useful in view of the fact that the deviation from this law is not appreciable in most alloys. If this approximation is adopted, (4.4) can readily be calculated. Of course a numerical calculation based upon the above described procedure can evaluate the difference of the energy due to the deviation from this simplification. Thus an approximate expression of (4.4) is given by

$$\Delta E/x_A x_B=(x_B l_A+x_A l_B)(r_{BB}-r_{AA})^2+c(f_A-f_B)^2/r_m{}^{(0)3}$$
$$-\frac{3}{4}\frac{r_m{}^{(0)2}\{\mathcal{E}_{0B}(r_m{}^{(0)})-\mathcal{E}_{0A}(r_m{}^{(0)})+K(Z_B{}^{2/3}-Z_A{}^{2/3})/r_m{}^{(0)2}\}^2}{K(x_B/Z_A{}^{1/3}+x_A/Z_B{}^{1/3})}, \tag{4.5}$$

where for $r_m{}^{(0)}$ one is referred to (2.6), i.e. Vegard's law. The first two terms of the right hand side of equations (4.4) or (4.5) corresponds to (3.10) obtained in the foregoing section. The second term means, of course, ΔE^{RV}. However, the last term due to the charge redistribution gives always a negative value for the excess energy and shows a tendency of compound formation i.e. attraction between unlike atoms. In other words, this last term corresponds to the electrochemical effect caused from the difference of the electronegativities of both components. The effect due to the electrostatic effect originating from the above process may be negligibly small except for the superlattice formation.[18]

The compiled values of L_i, $\mathcal{E}_{0i}(r_{0i})$, $KZ_i^{2/3}/r_{0i}^2$, a_i and r_{ii} for some pure metals, which are necessary to evaluate (2.6), (4.4) and (4.5), are given in Table I. Using these values with (2.7) and (3.9), one can calculate the excess energies of solutions on basis of (4.3) or (4.4) except the factor of the van der Waals force, which has to be considered only qualitatively.

Comparisons of the theory with experiment may be made by making use of Kopp-Neumann's law for the specific heat of an alloy, since the deviation from this law is very small in most alloys at high temperatures, where the observed data are often obtained.

Table I. Fundamental constans of pure metals useful in calculation of the excess energies of metallic solutions.

Metal	L_i (eV)	$-\varepsilon_{0i}(r_{0i})$ (eV)	$KZ_i^{2/3}/r_{0i}^2$ (eV)	a_i (Å^{-1})	r_{ii} (Å)

L_i, $\varepsilon_{0i}(r_{0i})$ and $KZ^{2/3}/r_{0i}^2$: taken from Varley's table.
a_i: taken from Slater's table, and* calculated from the Grüneisen constant. The values in parentheses correspond to those in liquid states.
r_{ii}: the Goldshmidt atomic diameter. (c.n. 12)

§ 5. Energetic Asymmetry of Liquid Solutions

The properties of infinitely or moderately dilute mixtures are often of interest in the studies of metallic solutions, since in such solutions the complication due to the presence of the solute may considerably be reduced. The excess heat can be expanded in power series of the atomic fraction of the solute, x_B,

$$\Delta H=\alpha x_B+\beta x_B^2+\gamma x_B^3+\cdots \qquad (5.1)$$

at a dilute concentration. From this one readily obtains the partial molar excess heat of the solute B or the solvent A as follows.

$$\Delta\overline{H}_B=\alpha+2\beta x_B+\cdots\,, \qquad (5.2)$$

$$\Delta\overline{H}_A=-\beta x_B^2\,. \qquad (5.3)$$

The constant α in these equations denotes the partial molar excess heat of the solute in an infinitely dilute solution, as may be seen in (5.2). On the other hand, the constant, β, may determine the curvature of the excess heat at the dilute concentration.

These constants can be evaluated on the basis of the present theory, because the excess heat may nearly be equal to the excess energy in condensed phases. Thus one obtains, for example from the simplified expression (4.5),

$$\begin{aligned}\alpha=&(r_{BB}-r_{AA})^2 l_B+c(f_A-f_B)^2/r_{0A}^3\\&-3\{\mathcal{E}_{0B}(r_{0A})-\mathcal{E}_{0A}(r_{0A})\\&+K(Z_B^{2/3}-Z_A^{2/3})/r^2_{0A}\}^2 r^2_{0A}Z_B^{1/3}/4K\,, \qquad (5.4)\end{aligned}$$

and

$$\begin{aligned}\beta=&(r_{BB}-r_{AA})^2(l_A-2l_B)+c(f_A-f_B)^2 r_{0B}^3/r_{0A}^6\\&-3\{\mathcal{E}_{0B}(r_{0A})-\mathcal{E}_{0A}(r_{0A})\\&+K(Z_B^{2/3}-Z_A^{2/3})/r^2_{0A}\}^2(r^2_{0A}Z_B^{1/3}/4K)\\&\times\{-(Z_B/Z_A)^{1/3}+2(r_{BB}/r_{AA})-1\}\,. \qquad (5.5)\end{aligned}$$

Positive values of α may be obtained from the prominence of the first and the second terms or the effects of the size factor and the van der Waals force, while negative values may indicate the prominent contribution of the electrochemical factor.

If the component A is regarded as the solute, i.e. in the opposite side of (5.1), the constants, α', β' and $\gamma'\cdots$ may be introduced.

$$\Delta H' = \alpha' x_A + \beta' x_A^2 + \gamma' x_A^3 + \cdots . \tag{5.1'}$$

Corresponding to (5.4),

$$\begin{aligned}\alpha' = {} & (r_{BB} - r_{AA})^2 l_A + c(f_A - f_B)^2 / r_{0B}^3 \\ & -3\{\mathcal{E}_{0B}(r_{0B}) - \mathcal{E}_{0A}(r_{0B}) + K(Z_B^{2/3} - Z_A^{2/3})/r_{0B}^2\}^2 r_{0B}^2 Z_A^{1/3}/4K .\end{aligned} \tag{5.4'}$$

Table II. Energetic asymmetry of binary liquid metallic solutions at extremely high dilution.

Systems observed as $2\alpha' \approx \alpha$	Zn–Sn	Zn–In	Zn–Ga	Cd–Pb	Cd–Sn	Cd–Tl	Cd–In
Calculated ratio from (5.7)	1.6	1.4	1.6	1.5	1.9	1.2*	1.7

Systems observed as $\alpha' \approx \alpha$	Cd–Zn	Ga–In	Ga–Sn	In–Pb	Tl–Sn	Pb–Sn	Cd–Ga
Calculated ratio from (5.7)	1.2	0.9	1.0	0.9	1.6*	1.3	1.8*

* In these systems the electrochemical factor must be taken into account in addition to the size factor.

If $r_{AA} = r_{BB}$ and $Z_A = Z_B$, the relation $\alpha = \alpha'$ can readily be found. For $r_{AA} \neq r_{BB}$ and $Z_A = Z_B$ the asymmetric relation $\alpha \neq \alpha'$ is obtained generally, but $\alpha = \alpha'$ may hold for special systems.

Firstly one considers the case of the positive excess energies ($\alpha > 0$. $\alpha' > 0$), such as in the liquid mixture of divalent metals. These systems (Cd–Tl. Cd–Pb, Cd–Sn, Zn–In, Zn–Sn etc.) show, according to Kleppa's observation,[34]

$$2\alpha' \approx \alpha \qquad \text{for } Z_A < Z_B. \tag{5.6}$$

In order to examine the above experimental relation, the following simplification is adopted for convenience, since the size factor predominates at least over the electrochemical factor, as long as $\alpha > 0$. From (5.4) and (5.4')

$$\frac{\alpha}{\alpha'} = \frac{l_B}{l_A} = \frac{L_B a_B^2}{L_A a_B^2} . \tag{5.7}$$

Of course this approximate expression shows only the most effective factor in (5.4) or (5.4'), but may be suitable for a qualitative discussion. As long as l_B and l_A are known, the relation between α and α' may be examined by using (5.7). Calculated values of l_B/l_A are shown in Table II. It is readily found that the ratio of l_B (higher valence) to l_B (divalence) exceeds at least 1.4, but that the ratio of l_B (tetravalence) to l_A (trivalence) shows values below 1.3 except Tl–Sn alloys. In most cases the prediction of (5.7) or (5.7') is in good agreement with the experimental results on the energetic asymmetry of the excess energy. It is thus to be noted that the relation between α and α' is not always only due to the valence electron effects but due to mixed effects of the boundary correction, Fermi energy and so on. It is of interest to note that some systems do not obey the above condition (5.7), as seen in Table II. To these systems a more rigorous condition than (5.7) should be applied.

Secondly similar consideration can be given to the case of the negative excess energy ($\alpha < 0$), as seen in the mixture of noble metals with multivalent metals. For example, the rule of the relative valence effect proposed by Hume-Rothery[35] indicates that the solid solubility of the alloy of monovalent metals with those of higher valence is smaller in the side of those having higher valence than in those of having lower valence. In other words, the excess energy at high dilution has, in the case of noble metals being the solvent, a steep slope against the concentration compared with that in the opposite case. Thus the relative valence effect requires

$$\alpha<\alpha' \text{ or } |\alpha|>|\alpha'| \qquad \text{for } Z_A<Z_B. \tag{5.8}$$

Apparently (5.8) contradicts (5.6). However, this may be explained, since the electrochemical factor predominates over the size factor as long as the excess energy is negative. For example from (5.4) and (5.4′)

$$|\alpha|/|\alpha'|\approx(Z_B/Z_A)^{1/3} \qquad \text{for } r_{0A}\approx r_{0B}. \tag{5.9}$$

For the relative valence effects,[18] (5.9) is in agreement with Varley's result since the present treatment should be coincident in principle with Varley's especially for $r_{0A}\approx r_{0B}$. Thus the discrepancy of experimental data with the relative valence effects may occur owing to (5.7), if the excess energy is positive. However, this rule may be associated with a condition such as (5.9). which holds only for the negative excess energy. Furthermore, it is worth noting that a complete explanation of solid solubility of an alloy requires knowledge of the band structure, which depends on the crystal structure, the excited electronic state of the components and the boundary correction etc., since the transformation of alloy phases is accompanied with touching of Fermi surfaces at the Brillouin zone of the alloy.[12] In liquid alloys this correction may be less important than in solid alloys, because the Brillouin zone in liquid state has not very definite meaning compared with that in solid state.

Thirdlly the relation between α and β in (5.1) and (5.2) is considered as the properties of moderately dilute mixtures. According to the theory of regular solutions,

$$-\beta/\alpha=1 \tag{5.10}$$

is obtained because of random mixing. However, it is found experimentally that in most system, such as solutions of divalent metals with metals of higher valence $|\beta|$ differs considerably from $|\alpha|$, e.g. $-\beta/\alpha\approx2$. These experimental results can not be explained by the quasi-chemical theory even if deviations from randomness are taken into account. This behavior is probably on account of the fact that these systems must be represented by more refined model than the regular solution model, for example Hardy's sub-regular solution model,[36] Oriani and Murphy's approach[37] and others.[38]

The present theory can immediately be applied to the discussion of the ratio of β/α as well as that of α/α'. For brevity the same assumptions used in the foregoing discussion

Table III. Energetic asymmetry of binary liquid metallic solutions at moderate dilution.

Solvent	Solute	Calc. (5.11)	Obs. Relation	Solvent	Solute	Calc. (5.11)	Obs. Relation
Zn	Cd	0.8	*	In	Zn	0.6	*

* means an observed relation $-\beta/\alpha\approx1$, while ** does $-\beta/\alpha\geq2$. For noble metals the calculated ratio is obtained from solid a_t. It should be noted that the expansion such as (5.11) is inadequate if $|l_B-l_A|\ll l_B$ is not satisfied. Of course the tendency of the prediction is reasonable.

concerning the ratio of α and α' are employed in accordance with $\alpha>0$ and $\alpha<0$. Then

$$-\frac{\beta}{\alpha}=1+\frac{l_B-l_A}{l_B} \quad \text{for } \alpha>0, \tag{5.11}$$

while

$$-\frac{\beta}{\alpha}=1+\frac{Z_A^{1/3}-Z_B^{1/3}}{Z_A^{1/3}} \quad \text{for } \alpha<0 \text{ and } r_{0A}\approx r_{0B}. \tag{5.12}$$

The comparisons (5.11) and (5.12) with experimental results are shown in Table III. The agreement is reasonably good in most systems in spite of the crude approximation. $\beta=-\alpha$ $(\alpha>0)$ could hold, if l_B of the solute B is equal to, or less than l_A of the sovent A. $-\beta/\alpha\approx 2$ $(\alpha>0)$, if l_B is larger than l_A. On the other hand, the valence of the solvent has to be larger than that of the solute, in order to make it hold that $\alpha<0$ and $-\beta/\alpha>1$. If more detailed equations, (5.4) and (5.5), than (5.11) or (5.12) are used, disagreements found in some systems could be removed.

Thus the behaviour of the excess energy of a metallic solution at dilute concentrations can be predicted by using the present theoretical results, (5.4), (5.5), or more simply (5.7), (5.9), (5.11) and (5.12). These equations indicate that the factors due to boundary corrections and Fermi energies etc. of components, being indirectly related to their valences, determine the excess energies of metallic solutions. The influence of the formal valence effect cannot simply be concluded owing to the more fundamental effect mentioned above, as may be seen in the case of the solutions of the divalent metals with metals of higher valence contradictory to the relative valence effect.

§ 6. Application to Solid Solutions

The numerical calculation based on the present equation (4.5) is applied to solid solutions of the monovalent noble metals, since thermodynamic data of these alloys have been well established. In obtaining the calculated values shown in Table IV it is assumed that $\mathcal{E}_0$ and $\mathcal{E}_F$ of monovalent metals in alloys are equal to those in the pure metals respectively, because E^{RV} cannot be calculated accurately. The values are due to neglection of the effect of the van der Waals energy, being, probably reasonable for Au–Cu alloys. However, this omission may not hold in both Ag–Au and Cu–Ag systems because of the presence of the less polarizable d-electrons of Ag. For example, theoretical sublimation energies (upper limit) for monovalent noble metals based on the quantum defect method by Kambe[39] show 59.3 kcal./mole for Cu, 55.8 kcal./mole for Ag and 48.9 kcal/mole for Au, while experimental values 81.2, 68.0 and 92.0 kcal./mole are found respectively. The most important discrepancy of these results is that the minimum sublimation energy occurs experimentally for Ag, while the calculated values decrease from Cu to Ag to Au. One of the reasons for this discrepancy may be due to the van der Waals force of d-electrons, though other factors may, of course, be taken into account. If the energy of the van der Waals forces of d-electrons is much greater in Cu and Au (the order of magnitude is assumed 1 eV for both metals, and the energy of Au slightly greater than that of Cu) than in Ag (for example roughly 0.1 eV), the minimum sublimation energy could be found in Ag. The correction due to the effects of d-electrons seems to be reasonable to improve the calculated results in these solid solutions.

Table IV. Excess heats of noble metal solid solutions at equiatomic fraction (kcal./mole).

System	Present	Varley	Obs.[3]
Au–Cu	0.9	1.6	−0.90
Au–Ag	−5.7	−1.7	−0.95, −1.07
Cu–Ag	4.6	1.3	no solution

A very different approach based on the concept of the existence of resonating covalent bonds in metals proposed by Pauling, has been applied to the calculation of the misfit strain energy of Au–Cu solid alloys by Hultgren.[40] As a feature of the theory of Pauling, the strain energy is reduced by redistribution of electrons, causing the favour of the size factor. This effect could be discussed from the present point of view, if (4.4) is used.

As pointed out in the discussion of the foregoing section, the excess heats of most solutions does not always indicate the symmetric behaviour. In other words, the definition of the regular solutions does not always hold except for a few special systems. Cu-Au alloys, the well known example of superlattices, cannot be explained by the term of the interchange energy independent of the composition being the basic assumption of the regular solution.[41),42)] This fact could be explained by the present theory, if one calculates (4.5). However, $\varepsilon_{0\mathrm{Au}}$ and $\varepsilon_{0\mathrm{Cu}}$ in (4.5) are not obtained accurately, since E^{RV} in (3.7) has not been investigated in detail in this system. Then a somewhat different approach based on Frölich's simple treatment[43)] for alkali metals is extended to a discussion of the energy of the lowest electronic state of this system. According to Frölich's work, the lowest energy of the electrons in simple metals can be expressed in the form

$$\varepsilon_{0i}=-\frac{3e^2}{r_{0i}}+\frac{e^2R_{0i}^2}{r_{0i}^3}, \qquad (6.1)$$

where the first term represents the potential energy, and the second the kinetic energy of the lowest electronic state. The constant R_{0i} in the second term can be estimated from the ionization energy and varies from one metal to another. On the other hand, the first term always gives the same value to monovalent metals, if there is no difference of the atomic sizes. Then one can calculate the electrochemical factor in the solution of the monovalent metals such as Au–Cu alloys from (4.5) and (6.1). Thus the excess energy is

$$\Delta E=x_{\mathrm{Au}}x_{\mathrm{Cu}}\left\{(x_{\mathrm{Au}}l_{\mathrm{Cu}}+x_{\mathrm{Cu}}l_{\mathrm{Au}})(r_{\mathrm{AuAu}}-r_{\mathrm{CuCu}})^2 -\frac{3}{4}\frac{(R_{0\mathrm{Au}}{}^2-R_{0\mathrm{Cu}}{}^2)^2}{Kr_m{}^{(0)4}}\right\}. \qquad (6.2)$$

This equation shows that the electrochemical energy between monovalent metals is inversely proportional to the fourth power of the average atomic sizes. The concentration dependance of the excess energy of Au–Cu alloys may be calculated, if the constants in (6.1) are given. As the present theory gives qualitatively the reasonable value for the excess energy, these constants are provisionally determined so as to satisfy the experimental data at equiatomic fraction. The calculated values at other concentrations are in agreement with experimental ones as seen in Table V. Of course the above method for the determination of constants in (6.1) or (6.2) can be improved, but the direction of the change of the excess energy, that increases with the increases of the concentration of Cu, may hold as it stands, aside from the minor difference of the absolute magnitude.

The metallic solutions of multivalent metals dissolved monovalent metals are of interest to examine for the valence effect on mixing, as seen in the foregoing section. Though the qualitative explanation for the excess energy of liquid solutions may be satisfactory, more detailed calculation for that of solid solutions is given. As the solute, zinc and cadmium are chosen, since the equations of state of these metals have been studied in detail com-

Table V. The concentration dependence of $\Delta H/x_{\mathrm{Cu}}x_{\mathrm{Au}}$ in the Au–Cu solid solutions.

pared with those of other multivalent metals. Typical examples of the calculation in the dilute range of α alloys are presented in Table VI. The order of magnitude of calculated values is in agreement with the observed data.

Thus one can calculate the excess energy of metallic solutions at any concentration as long as each term in (4.4) or (4.5) is known. Most calculated results may qualitatively be reasonable, but quantitative agreement with experimental values will not be obtained without detailed knowledge of $\mathcal{E}_{0i}$, $\mathcal{E}_{Fi}$, E_i^{RV}, and l_i of each pure metal. The present stage of both theoretical and experimental investigations of theses terms of pure metals is not satisfactory except for simple alkali metals. It is necessary to ascertain the properties of pure metal in order to understand those of metallic solutions.

Furthermore, it is a weak point that the present treatment is based upon the free electron approximation as is also the case in Varley's work. To understand the deviation from the free electron approximation is very important in order to understand the change of the excess energy due to the phase transformation of alloys, as expected from works of Jones and Cohen-Heine. The Fermi energy having a central position in the sublimation energy of a metal is very sensitive to the changes of the Brillouin zone structure and the number of the conduction electrons. However, the free electron approximation may be rather suitable in liquid phases, since there is no definite structure of the zone in liquid state except in a physical meaning as an average structure. For solid solutions this approximation should be carefully improved.

Lastly it should be noted that the small corrections for correlations between free electrons considered in Varley's work are disregarded here. Such corrections may, however, yield no appreciable change of the present conclusion, if theoretical results concerning pure metals are taken into account. However, this conclusion may be doubtful in some complex metals.[13)]

§7. Conclusion

i) The semi-empirical equation of state of a pure metals is applicable to the calculation of the excess energy. The interatomic distance giving a minimum of the total energy should correspond to the average size of the atomic cells (polyhedra) in the metallic solutions. In this way, one part of the excess energy, i.e., the size factor can be calculated in any desired degree of approximations beyond the quadratic representation without reference to the classical elasticity theory.

ii) There is a possibility that a positive excess energy is yielded without the negligible size factor, when the difference between the van der Waals forces of both components is strong. This will be the case, as in the mixture of the transition metals with the noble metals, both having polarizable *d*-electrons. The same conclusion may be obtained from the Pauling scheme of the *spd* hybrid resonance.

iii) The effect of charge transfer is obtained in the present treatment from the point of view of taking into account the change of the total energy at the "average size" of the atomic polyhedra of the solution, but in Varley's treatment from that at the respective pure atomic sizes. As a result, for example, the lowest energy of electrons, $\mathcal{E}_0$, in the former theory is kept constant except the effect of charge transfer throughout the whole concentration, but in the present treatment it varies, as seen in (4.4). The present treatment may be suitable for a discussion concerning the dependence of the excess energy upon concentration. Of course both approaches may coincide, if each component has the same atomic sizes.

iv) The order of magnitude of the calculated excess energy may be reasonable in spite of the crude approximation. However, the points to be improved in the future are the change of the Brillouin zone, that of the interelectronic energy, and that of wave functions due to the disturbance of the periodic field etc. The present treatment should be regarded as the first approximation for the excess energy of a metallic solution.

Algebraic Method to obtain Irreducible Representations of Space Groups with an Application to White Tin

By Shoichi MASE

Department of General Education, Nagoya University

(Received July 14, 1959)

Algebraic method to construct irreducible representations of space groups is presented by making an example of white tin having screw axes and glide planes in the symmetry operations. In present method it is enough to treat explicitly at most only symmetry elements equal in number to the operations of the point group to which concerned lattice belongs, regardless of the cases with or without spin and also of interior points or the points of the Brillouin zone boundary. This becomes very simplification compared to usual group-theoretical method.

§ 1. Introduction.

In the study of electronic structure of solids, the group theory plays an important role and many results have been published. The pioneering works by Seitz[1)] and Bouckaert-Smoluchowski-Wigner[2)] were extended by Herring[3)] to the case of complex crystals containing screw axes and glide planes in their symmetry operations, and recently the construction of the representations of the so-called double space group in the case with spin was discussed by Elliott.[4)] The theory of the representations of space groups is purely mathematical and it is group-theoretically completed. For practical object to obtain the representations, however, there is far simpler way to perform the calculation. We study the symmetry properties of the Brillouin zone of white tin with use of the theory of hypercomplex number or algebra. Though, as is expressed in later section, we can obtain not a few knowledges for the symmetry properties of white tin from the references on the studies of diamond lattice[3),4),5)], it may be not unuseful to derive partly the same results by different method, since much of 230 space groups contain the screw axes and glide planes in their symmetry operations and the advantage of algebraic method is in the case of such complex crystals.*

Generally a crystal is kept at invariance by rotations, translations proper to the crystal and also their combination. The assembly of all these operations makes a group and we designate this group, the space group, by $\mathfrak{G}$. Following to Seitz's notation the elements of $\mathfrak{G}$ are expressed by

$$\{\varepsilon|\boldsymbol{t}\}\{A|\tau_A\}\in\mathfrak{G}\,.$$

$\{A|\boldsymbol{\tau}_A\}$ means the rotation A about certain fixed point followed by the translation $\boldsymbol{\tau}_A$. $\boldsymbol{t}$ is a linear combination of the basic primitive translation vectors $\boldsymbol{t}_1, \boldsymbol{t}_2$ and $\boldsymbol{t}_3$ of the crystal, i.e.

$$\boldsymbol{t}=l\boldsymbol{t}_1+m\boldsymbol{t}_2+n\boldsymbol{t}_3\,,$$

$$-\frac{N}{2}\leq l,\, m,\, n\,(\text{integer})\leq\frac{N}{2}\,,$$

and τ_A the non-primitive translation vector determined by A. The assembly of N^3 elements composed of only pure translations $\{\varepsilon/\boldsymbol{t}\}$, which is called as the translation group $\mathfrak{T}$, is an invariant subgroup of the space group and the factor group (mod $\mathfrak{T}$) is composed of the elements

$$\mathfrak{T}\{A|\tau_A\},\ \mathfrak{T}\{B|\tau_B\},\ \cdots\ \mathfrak{T}\{X|\tau_X\}\,. \quad (1)$$

The order of this factor group is 48 in grey tin and 16 in white tin. We call N^3 elements $\mathfrak{T}\{A|\boldsymbol{\tau}_A\}$ etc as coset and the element $\{A|\boldsymbol{\tau}_A\}$ etc as coset representative (we abbreviate this as C.R.). The group $\mathfrak{G}(\boldsymbol{k})$ of wave number $\boldsymbol{k}$ is composed of the elements in $\mathfrak{G}/\mathfrak{T}$ satisfing the condition

$$\boldsymbol{ak}=\boldsymbol{k}+\boldsymbol{h}\,(\boldsymbol{h}\text{: reciprocal lattice vector})\,. \quad (2)$$

We denote all these as

$$\mathfrak{T}\{\alpha|\tau_\alpha\},\ \mathfrak{T}\{\beta|\tau_\beta\},\cdots\mathfrak{T}\{\partial|\tau_\delta\}\in\mathfrak{G}(\boldsymbol{k})\,,\quad (3)$$

---

* Dr. C. Herring has kindly called to the author's attention a work by O. V. Kovalev and G. Ya. Lyubarskii: Zh. tekh. Fiz. **28** (1958) 1151, which uses some similar concept. Since, however, its translation could not be in hand during the preparation of this paper, the author wishes to discuss of their results in later opportunity.

and we assume the order of the factor group of $\mathfrak{G}(\boldsymbol{k}) (\mathrm{mod}\, \mathfrak{T})$ to be $c(\boldsymbol{k})$.

In the consideration of the representations of $\mathfrak{G}(\boldsymbol{k})$ on the basis of Bloch functions, it is not always necessary to take account of all elements of $\mathfrak{T}$. (i) At certain $\boldsymbol{k}$, just only C. R. s may make a subgroup of $\mathfrak{G}(\boldsymbol{k})$. (ii) On certain symmetry lines in the Brillouin zone the assembly of the product of C. R. and unity or inverse square root of the representation of some translation $T_x=\{\boldsymbol{\varepsilon}|\boldsymbol{t}_x\}$, whichever is determined by the corresponding C.R., may make a group. (iii) At some symmetry points on the zone boundary we can find a group composed of the combination of C.R.s and the elements $\mathfrak{T}_0\{\boldsymbol{\varepsilon}|o\}, \mathfrak{T}_0\{\boldsymbol{\varepsilon}|\boldsymbol{t}_a\}\cdots\mathfrak{T}_0\{\boldsymbol{\varepsilon}|\boldsymbol{t}_d\}$, where $\mathfrak{T}_0$ is the assembly of the translations such that the elements give the representation as $\exp(-2\pi i\boldsymbol{k}\boldsymbol{t})=1$ and where $\{\boldsymbol{\varepsilon}|o\}, \{\boldsymbol{\varepsilon}|\boldsymbol{t}_a\}\cdots \{\boldsymbol{\varepsilon}|\boldsymbol{t}_d\}$ are pure translations generated by the combination between C. R. s, giving essentially different representations. (iv) On certain symmetry lines on the zone boundary there is the case to need the combination of (ii) and (iii). In order to obtain the representations group-theoretically, it is necessary to find such group in $\mathfrak{G}(\boldsymbol{k})$. Since, however, we know that the representation of an element $\{\boldsymbol{\varepsilon}|\boldsymbol{t}\}$ of $\mathfrak{T}$ on the basis of the Bloch function is $\exp(-2\pi i\boldsymbol{k}\boldsymbol{t})$, we can immediately obtain the representations of $\mathfrak{G}(\boldsymbol{k})$ if we can obtain the representations of C. R. s, and then it is not always necessary to construct such groups. This can be made possible by the use of the theory of algebra.

We designate the assembly of the linear combination of C. R. s of $\mathfrak{G}(\boldsymbol{k})$ with coefficients of complex number as $\mathfrak{A}(\boldsymbol{k})$ in which addition of the elements is defined. The multiplication rule between C. R. s is

$$\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}=T_{\alpha\beta}\{\boldsymbol{\gamma}|\boldsymbol{\tau}_\gamma\}\,, \tag{4}$$

where $\{\boldsymbol{\gamma}|\boldsymbol{\tau}_\gamma\}$ is also a C. R. of $\mathfrak{G}(\boldsymbol{k})$ and $T_{\alpha\beta}$ is a pure translation determined by $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. Since the representation of $\mathfrak{T}$ is a constant times the diagonal matrix, we treat $T_{\alpha\beta}$ not as matrix but as the combination parameter of complex number when considering representation (the unit matrix is absorbed into the matrix of $\{\boldsymbol{\gamma}|\boldsymbol{\tau}_\gamma\}$). Then $\mathfrak{A}(\boldsymbol{k})$ is an algebra of the order $c(\boldsymbol{k})$ over the field of complex number, i. e. $c(\boldsymbol{k})$ C. R. s of $\mathfrak{G}(\boldsymbol{k})$ are the bases of $\mathfrak{A}(\boldsymbol{k})$. (On the definition of algebra and related terminology, see Appendix A). If $T_{\alpha\beta}=1$ for all $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$, $\mathfrak{A}(\boldsymbol{k})$ is equal to a group ring. We refer to several theorems of algebra necessary for obtaining irreducible representations (we abbreviate as I. R.):[6]

a) If the unit element $\boldsymbol{e}$ of the centrum $\mathfrak{z}(\boldsymbol{k})$ of $\mathfrak{A}(\boldsymbol{k})$ is expressed as

$$\boldsymbol{e}=\sum_{l=1}^{q}\boldsymbol{e}^{(l)},\ \boldsymbol{e}^{(l)}\boldsymbol{e}^{(m)}=\delta_{lm}\boldsymbol{e}^{(l)}\,,$$

(actually the orthogonal idempotents $\boldsymbol{e}^{(l)}$ can be expressed uniquely by making use of $q(\boldsymbol{k})$ bases of the centrum, when the order of $\mathfrak{z}(\boldsymbol{k})$ being assumed to be $q(\boldsymbol{k})$), $\mathfrak{z}(\boldsymbol{k})$ is expressed by the direct sum of $q(\boldsymbol{k})$ orthogonal ideals

$$\mathfrak{z}(\boldsymbol{k})=\sum_{l=1}^{q}\mathfrak{z}^{(l)}(\boldsymbol{k})\,,\ \mathfrak{z}^{(l)}(\boldsymbol{k})\mathfrak{z}^{(m)}(\boldsymbol{k})=\delta_{lm}\mathfrak{z}^{(l)}(\boldsymbol{k})\,.$$

b) $\mathfrak{A}(\boldsymbol{k})$ satisfing a) is decomposed into $q(\boldsymbol{k})$ orthogonal ideals

$$\mathfrak{A}(\boldsymbol{k})=\sum_{l=1}^{q}\mathfrak{A}\boldsymbol{e}^{(l)}=\sum_{l=1}^{q}\mathfrak{A}\mathfrak{z}^{(l)}=\sum_{l=1}^{q}\mathfrak{A}_l(\boldsymbol{k})\,,$$

$$\mathfrak{A}_l(\boldsymbol{k})\mathfrak{A}_m(\boldsymbol{k})=\delta_{lm}\mathfrak{A}_l(\boldsymbol{k})\,.$$

Therefore

$$\mathfrak{A}(\boldsymbol{k})\boldsymbol{e}^{(l)}=\mathfrak{A}_l(\boldsymbol{k})=\boldsymbol{e}^{(l)}\mathfrak{A}(\boldsymbol{k})$$

and then $\boldsymbol{e}^{(l)}$ is also the orthogonal idempotent of $\mathfrak{A}_l(\boldsymbol{k})$. If the order of simple ideal $\mathfrak{A}_l$ is N_l,

$$c(\boldsymbol{k})=\sum_{l=1}^{q}N_l\,.$$

c) From N_l independent elements of $\mathfrak{A}_l(\boldsymbol{k})$, by proper transformation of the bases we can obtain n_l^2 matrixes, the dimension be n_l, such that

$$\boldsymbol{e}_{ii}^{(l)}\boldsymbol{e}_{ii}^{(l)}=\boldsymbol{e}_{ii}^{(l)},\ \boldsymbol{e}_{ij}^{(l)}\boldsymbol{e}_{mk}^{(l)}=\delta_{jm}\boldsymbol{e}_{ik}^{(l)}\,,$$

(Wedderburn's theorem). Therefore $N_l=n_l^2$.

d) The l-th I. R. of any element of $\mathfrak{A}(\boldsymbol{k})$ can be obtained by taking the basis of any one of n_l left ideals of $\mathfrak{A}_l(\boldsymbol{k})$, $\{\boldsymbol{e}_{1j}^{(l)}, \boldsymbol{e}_{2j}^{(l)},\cdots\boldsymbol{e}_{n_lj}^{(l)}\}$ $j=1\sim n_l$, as the representation module:

$$\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}\{\boldsymbol{e}_{1j}^{(l)}, \boldsymbol{e}_{2j}^{(l)},\ \cdots\boldsymbol{e}_{n_lj}^{(l)}\}$$

$$=\{\boldsymbol{e}_{1j}^{(l)}, \boldsymbol{e}_{2j}^{(l)},\ \cdots\boldsymbol{e}_{n_lj}^{(l)}\}\begin{pmatrix} a_{11}^{(l)}\cdots a_{1n_l}^{(l)} \\ \vdots \qquad \vdots \\ a_{n_l1}^{(l)}\cdots a_{n_ln}^{(l)} \end{pmatrix},$$

$$\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}\in\mathfrak{A}(\boldsymbol{k})\,.$$

The n_l representations occurred from different j are isomorphic. Then it is enough to take only $j=1$. Though the bases $\boldsymbol{e}_{ij}^{(l)}$ satisfing *c*) are not determined uniquely, the representations by different bases are isomorphic.

This procedure to obtain the representations is essentially the same in both cases with and without spin, except that in the former case the multiplication for the elements operating on spin part must be made by the spin representation of the rotation group. In order to construct the representation, the introduction of independent element $\bar{\boldsymbol{E}}$ corresponding to 2π-rotation is unnecessary in algebraic theory. Then the order of the algebra we must treat is at most 24 (by making use of direct product) even in diamond lattice.

In order to calculate the electronic states, we construct the basis functions belonging to the irreducible representations. This is easily performed by means of the representation module $\{\boldsymbol{e}_{11}^{(l)}, \boldsymbol{e}_{21}^{(l)}, \cdots \boldsymbol{e}_{n_l 1}^{(l)}\}$. For example, if we wish to obtain the tight binding Bloch functions belonging to the representation X_l, we operate $\boldsymbol{e}_{i1}(X_l)$ to the Bloch function of type $u, w, \sigma (u = s, p, d, \cdots; w = s_1, s_2, \cdots s_n,$ n the number of sublattices; $\sigma = \pm$, i.e. two spin states):[7]

$$\psi_i(X_l) = \boldsymbol{e}_{i1}(X_l)\chi_{u,w,\sigma}(\boldsymbol{k}) \quad i = 1 \cdots n_l \, .$$

ψ_i corresponding to different i are mutually orthogonal and we obtain n_l sets of functions, corresponding to n_l fold degeneracy. Of course, it is enough to take up only one set. In other type of approximation, we can do similarly. In this paper, however, we do not try to apply our results in concrete calculation.

§ 2. The Symmetry Operations in White Tin

White tin lattice has the space group $D_{4h}^{19} \frac{4_1}{a} \frac{2}{m} \frac{2}{d}$ symmetry. The lattice is composed of two sublattices and one atom is surrounded by four nearest neighbours (Fig. 1). We choose a four fold rotation reflection axis as z-axis and bisect lines of two binary axes as x- and y-axis. The primitive translations are

$$T_1 = (x+a, y+a, z-c) \, ,$$
$$T_2 = (x+a, y-a, z+c) \, , \qquad (5)$$
$$T_3 = (x-a, y+a, z+c) \, .$$

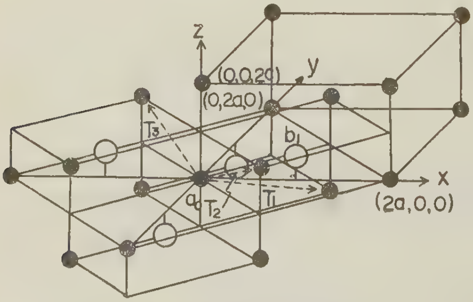

Fig. 1. White tin lattice.

The values of a and c are

$$2a = 5.82 \text{ Å}, \ 2c = 3.18 \text{ Å} \, .$$

C. R. s of $\mathfrak{G}$ are 16 elements as follows:

(i) $\boldsymbol{E}$ is the unit element,

(ii) $\boldsymbol{C}_2$ is the rotation by π about z-axis,

(iii) $\boldsymbol{S}_4^+$ and $\boldsymbol{S}_4^-$ are the rotations by $\pm\pi/2$ about z-axis followed by the reflection at the plane through the origin and perpendicular to the rotation axis,

(iv) $\boldsymbol{U}_{xy}$ and $\boldsymbol{U}_{x\bar{y}}$ are the rotations by π about the bisecting lines between x-, y-axis and x-, $\bar{y}$-axis respectively, i. e. about the binary axes,

(v) $\boldsymbol{M}_x$ and $\boldsymbol{M}_y$ are the mirror planes which contain x-, z-axis and y-, z-axis respectively,

(vi) $\boldsymbol{J}$ is the inversion at the origin followed by the non-primitive translation $\overrightarrow{a_0 b_1} \equiv \tau(a, 0, c/2)$,

(vii) $\boldsymbol{JC}_2$, (viii) $\boldsymbol{JS}_4^+$ and $\boldsymbol{JS}_4^-$, (ix) $\boldsymbol{JU}_{xy}$ and $\boldsymbol{JU}_{x\bar{y}}$, (x) $\boldsymbol{JM}_x$ and $\boldsymbol{JM}_y$.

The operations (i)$\sim$(v) are represented by $\{A|0\}$ and the operations (vi)$\sim$(x) by $\{A|\tau\}$. By $\{A|0\}$ and $\{A|\tau\}$, the atom of a-site is transformed into an atom of a-site and that of b-site respectively. The multiplication of some element $\boldsymbol{P}$ in (i)$\sim$(v) and $\boldsymbol{JQ}$ in (vi)$\sim$(x) is

$$\boldsymbol{P} \cdot \boldsymbol{JQ} = \{\varepsilon | p\tau - \tau\} \boldsymbol{J} \cdot \boldsymbol{PQ} \equiv T(P) \boldsymbol{J} \cdot \boldsymbol{PQ} \, , \quad (6)$$

and also the multiplication of $\boldsymbol{JP}$ and $\boldsymbol{JQ}$ is

$$\boldsymbol{JP} \cdot \boldsymbol{JQ} = \{\varepsilon | -p\tau + \tau\} \boldsymbol{PQ} \equiv T^{-1}(P) \boldsymbol{PQ} \, . \quad (6)'$$

Therefore, if we know only the multiplication rules between $\boldsymbol{P}$ and $\boldsymbol{Q}$ and also $\boldsymbol{P}$ and $\boldsymbol{J}$, we can obtain immediately the multiplication between all other elements by taking account of $T(P)$ and $T^{-1}(P)$. The result is shown in Table I.

By using (5), we can obtain primitive reciprocal lattice vectors

$$b_1 = \left(\frac{1}{2a}, \frac{1}{2a}, 0\right) ,$$
$$b_2 = \left(\frac{1}{2a}, 0, \frac{1}{2c}\right) , \qquad (7)$$
$$b_3 = \left(0, \frac{1}{2a}, \frac{1}{2c}\right) .$$

The general vector $\boldsymbol{h}$ is

$$\boldsymbol{h}=n_1\boldsymbol{b}_1+n_2\boldsymbol{b}_2+n_3\boldsymbol{b}_3\ .$$

Thus we can obtain first Brillouin zone (Fig. 2) surrounded by the planes of the types (100) and (1$\bar{1}$0). In Table II we give the bases of $\mathfrak{A}(\boldsymbol{k})$ and the representations of T_1, T_2 and T_3. Before we close this section, we show the value of $\boldsymbol{k}$ of the points A and C (though these are not special points):

$$A=\left(0,0,\frac{1}{4c}\left(1+\frac{c^2}{a^2}\right)\right),$$

$$C=\left(\frac{1}{2a},0,\frac{1}{4c}\left(1-\frac{c^2}{{}^2a}\right)\right).$$

§ 3. The Representations for Algebras of k-vectors. Case without Spin

Following to the principle outlined in § 1,

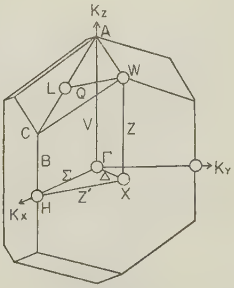

Fig. 2. First Brillouin zone for white tin lattice.

we calculate the representations of algebra $\mathfrak{A}(\boldsymbol{k})$ of wave number $\boldsymbol{k}$. In this section we concern with the spinless case, then the structure of $\mathfrak{A}(\boldsymbol{k})$ can be seen by combining Table I and II.

We begin with the point Γ. In this point every translations give the same representation as the identity. Then $\mathfrak{A}(\Gamma)$ is equivalent to the direct product of subalgebras {(i)∼(v)} and $\{\boldsymbol{E}, \boldsymbol{J}\}$. The algebra $\mathfrak{A}'(\Gamma)$ composed of (i)∼(v) has the centrum, the bases of which being the following elements

$$\boldsymbol{E},\ \boldsymbol{C}_2,\ (\boldsymbol{S}_4{}^+ + \boldsymbol{S}_4{}^-),\ (\boldsymbol{U}_{xy} + \boldsymbol{U}_{x\bar{y}}),\ (\boldsymbol{M}_x + \boldsymbol{M}_y)\ . \tag{8}$$

Then we should have four I. R. of one dimension and one I. R. of two dimensions. The unit elements $\boldsymbol{e}^{(l)}$ of five orthogonal ideals are

$$\begin{aligned}
\boldsymbol{e}^{(1)} &= \frac{1}{8}\{\boldsymbol{E} + \boldsymbol{C}_2 + (\boldsymbol{S}_4{}^+ + \boldsymbol{S}_4{}^-) + (\boldsymbol{U}_{xy} + \boldsymbol{U}_{x\bar{y}}) \\
&\qquad + (\boldsymbol{M}_x + \boldsymbol{M}_y)\}\ , \\
\boldsymbol{e}^{(2)} &= \frac{1}{8}\{\boldsymbol{E} + \boldsymbol{C}_2 + (\boldsymbol{S}_4{}^+ + \boldsymbol{S}_4{}^-) - (\boldsymbol{U}_{xy} + \boldsymbol{U}_{x\bar{y}}) \\
&\qquad - (\boldsymbol{M}_x + \boldsymbol{M}_y)\}\ , \\
\boldsymbol{e}^{(3)} &= \frac{1}{8}\{\boldsymbol{E} + \boldsymbol{C}_2 - (\boldsymbol{S}_4{}^+ + \boldsymbol{S}_4{}^-) + (\boldsymbol{U}_{xy} + \boldsymbol{U}_{x\bar{y}}) \\
&\qquad - (\boldsymbol{M}_x + \boldsymbol{M}_y)\}\ , \\
\boldsymbol{e}^{(4)} &= \frac{1}{8}\{\boldsymbol{E} + \boldsymbol{C}_2 - (\boldsymbol{S}_4{}^+ + \boldsymbol{S}_4{}^-) - (\boldsymbol{U}_{xy} + \boldsymbol{U}_{x\bar{y}}) \\
&\qquad + (\boldsymbol{M}_x + \boldsymbol{M}_y)\}\ , \\
\boldsymbol{e}^{(5)} &= \frac{1}{2}\{\boldsymbol{E} - \boldsymbol{C}_2\}\ ,
\end{aligned} \tag{9}$$

where $\boldsymbol{e}^{(5)}$ gives two dimensional representation. From four independent elements of ideal $\mathfrak{A}'(\Gamma)\boldsymbol{e}^{(5)}$, we construct new bases of the ideal

$$\begin{aligned}
\left.\begin{matrix}\boldsymbol{e}^{(5)}_{11} \\ \boldsymbol{e}^{(5)}_{22}\end{matrix}\right\} &= \frac{1}{4}\{\boldsymbol{E} - \boldsymbol{C}_2 \pm (\boldsymbol{M}_x - \boldsymbol{M}_y)\}\ , \\
\left.\begin{matrix}\boldsymbol{e}^{(5)}_{21} \\ \boldsymbol{e}^{(5)}_{12}\end{matrix}\right\} &= \frac{1}{4}\{\boldsymbol{U}_{xy} - \boldsymbol{U}_{x\bar{y}} \pm (\boldsymbol{S}_4{}^+ - \boldsymbol{S}_4{}^-)\}\ .
\end{aligned} \tag{10}$$

It is easily seen that these equations satisfy the theorem (c) in § 1. The representation of $\mathfrak{A}'(\Gamma)$ is obtained by theorem (d) in § 1. On the other hand algebra $\{\boldsymbol{E}, \boldsymbol{J}\}$ has two idempotents

$$\left.\begin{matrix}\boldsymbol{e}^{(1)} \\ \boldsymbol{e}^{(2)}\end{matrix}\right\} = \frac{1}{2}(\boldsymbol{E} \pm \boldsymbol{J})\ . \tag{11}$$

Final representation is the direct product of two I. R. of subalgebras. This and other important results are listed in the table in next section and Appendix B and C.

The point H has the same C. R. s as the point Γ. The translations, however, give distinct representations. Because of it, the structure of the centrum $\mathfrak{z}(H)$ becomes essentially different from that of $\mathfrak{z}(\Gamma)$. The elements commutative to all elements of $\mathfrak{A}(H)$ are the following four:

$$\boldsymbol{E},\ \boldsymbol{C}_2,\ \boldsymbol{M}_x + \boldsymbol{M}_y,\ \boldsymbol{J}\boldsymbol{M}_x - \boldsymbol{J}\boldsymbol{M}_y\ . \tag{12}$$

Then we obtain four orthogonal idempotents

$$\begin{aligned}
\left.\begin{matrix}\boldsymbol{e}({}^2H_1) \\ \boldsymbol{e}({}^2H_2)\end{matrix}\right\} &= \frac{1}{4}(\boldsymbol{E} + \boldsymbol{C}_2 \pm \boldsymbol{M}_x \pm \boldsymbol{M}_y)\ , \\
\left.\begin{matrix}\boldsymbol{e}({}^2H_3) \\ \boldsymbol{e}({}^2H_4)\end{matrix}\right\} &= \frac{1}{4}(\boldsymbol{E} - \boldsymbol{C}_2 \pm \boldsymbol{J}\boldsymbol{M}_x \mp \boldsymbol{J}\boldsymbol{M}_y)\ .
\end{aligned} \tag{13}$$

All these give two dimensional representations. We can calculate new bases $\boldsymbol{e}_{ij}({}^2H_i)$ from each ideal $\mathfrak{A}(\boldsymbol{k})\boldsymbol{e}({}^2H_i)$, and then I. R.

In other points, lines and planes, the method is the same and we give only the bases of centrums $\mathfrak{z}$, from which we can obtain orthogonal idempotents of each centrum, and and then bases of representations:

$$\begin{aligned}
&\mathfrak{z}(X) : \{\boldsymbol{E},\ \boldsymbol{U}_{xy}\}\ , \\
&\mathfrak{z}(W) : \{\boldsymbol{E},\ (\boldsymbol{S}_4{}^+ + i\boldsymbol{S}_4{}^-)\}\ , \\
&\mathfrak{z}(V) : \{\boldsymbol{E},\ \boldsymbol{C}_2,\ (\boldsymbol{M}_x + \boldsymbol{M}_y),\ (\boldsymbol{J}\boldsymbol{S}_4{}^+ + \boldsymbol{J}\boldsymbol{S}_4{}^-), \\
&\qquad (\boldsymbol{J}\boldsymbol{U}_{xy} + \boldsymbol{J}\boldsymbol{U}_{x\bar{y}})\}\ , \\
&\mathfrak{z}(B) : \{\boldsymbol{E},\ \boldsymbol{C}_2,\ (\boldsymbol{M}_x + \boldsymbol{M}_y),\ (\boldsymbol{J}\boldsymbol{S}_4{}^+ + \boldsymbol{J}\boldsymbol{S}_4{}^-), \\
&\qquad (\boldsymbol{J}\boldsymbol{U}_{xy} + \boldsymbol{J}\boldsymbol{U}_{x\bar{y}})\}\ , \\
&\mathfrak{z}(\varDelta) : \{\boldsymbol{E},\ \boldsymbol{U}_{xy},\ \boldsymbol{J}\boldsymbol{U}_{x\bar{y}},\ \boldsymbol{J}\boldsymbol{C}_2\} \equiv \mathfrak{A}(\varDelta)\ , \\
&\mathfrak{z}(\varSigma) : \{\boldsymbol{E},\ \boldsymbol{M}_x,\ \boldsymbol{J}\boldsymbol{M}_y,\ \boldsymbol{J}\boldsymbol{C}_2\} \equiv \mathfrak{A}(\varSigma)\ , \\
&\mathfrak{z}(Z) : \{\boldsymbol{E}\}\ , \\
&\mathfrak{z}(Z') : \{\boldsymbol{E}\}\ , \\
&\mathfrak{z}(L) : \{\boldsymbol{E},\ \boldsymbol{M}_x,\ \boldsymbol{J},\ \boldsymbol{J}\boldsymbol{M}_x\} \equiv \mathfrak{A}(L)\ , \\
&\mathfrak{z}(Q) : \{\boldsymbol{E},\ \boldsymbol{J}\boldsymbol{M}_x\} \equiv \mathfrak{A}(Q)\ , \\
&\mathfrak{z}(P) : \{\boldsymbol{E},\ \boldsymbol{M}_x\} \equiv \mathfrak{A}(P)\ , \\
&\mathfrak{z}(S) : \{\boldsymbol{E},\ \boldsymbol{J}\boldsymbol{C}_2\} \equiv \mathfrak{A}(S)\ , \\
&\mathfrak{z}(R) : \{\boldsymbol{E},\ \boldsymbol{J}\boldsymbol{U}_{x\bar{y}}\} \equiv \mathfrak{A}(R)\ , \\
&\mathfrak{z}(T) : \{\boldsymbol{E},\ \boldsymbol{J}\boldsymbol{U}_{xy}\} \equiv \mathfrak{A}(T)\ .
\end{aligned} \tag{14}$$

We see the commutation relation of certain elements $\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}$ and $\sum_\beta\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}$, where all $\boldsymbol{\tau}_\beta$ is assumed to be the same in the summation, of $\mathfrak{A}(\boldsymbol{k})$ corresponding to interior points of the Brillouin zone.

$$\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}\cdot\sum_\beta\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}=\sum_\beta\{\boldsymbol{\varepsilon}|\boldsymbol{\alpha}\boldsymbol{\tau}_\beta+\boldsymbol{\tau}_\alpha-\boldsymbol{\tau}_{\alpha\beta}\}\cdot\{\boldsymbol{\alpha}\boldsymbol{\beta}|\boldsymbol{\tau}_{\alpha\beta}\}\,, \tag{15a}$$

$$\sum_\beta\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}\cdot\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}=\sum_\beta\{\boldsymbol{\varepsilon}|\boldsymbol{\beta}\boldsymbol{\tau}_\alpha+\boldsymbol{\tau}_\beta-\boldsymbol{\tau}_{\alpha\beta}\}\{\boldsymbol{\beta}\boldsymbol{\alpha}|\boldsymbol{\tau}_{\alpha\beta}\}\,, \tag{15b}$$

where $\boldsymbol{\tau}_{\alpha\beta}$ is 0 or $\boldsymbol{\tau}$, whichever is determined by the element $\boldsymbol{\alpha}\boldsymbol{\beta}_0$, where $\boldsymbol{\beta}_0$ being any one of the elements in the summation. In other word it is assumed that $\{\boldsymbol{\alpha}\boldsymbol{\beta}|\boldsymbol{\tau}_{\alpha\beta}\}$ and $\{\boldsymbol{\beta}\boldsymbol{\alpha}|\boldsymbol{\tau}_{\alpha\beta}\}$ are the bases of $\mathfrak{A}(\boldsymbol{k})$. Since $\{\boldsymbol{\varepsilon}|\boldsymbol{\alpha}\boldsymbol{\tau}_\beta+\boldsymbol{\tau}_\alpha-\boldsymbol{\tau}_{\alpha\beta}\}$ and $\{\boldsymbol{\varepsilon}|\boldsymbol{\beta}\boldsymbol{\tau}_\alpha+\boldsymbol{\tau}_\beta-\boldsymbol{\tau}_{\alpha\beta}\}$ give the same representation $\exp(-2\pi i\boldsymbol{k}(\boldsymbol{\tau}_\alpha+\boldsymbol{\tau}_\beta-\boldsymbol{\tau}_{\alpha\beta}))$, $\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}\cdot\sum_\beta\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}$ and $\sum\{\boldsymbol{\beta}|\boldsymbol{\tau}_\beta\}\cdot\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}$ are equivalent, if

$$\boldsymbol{\alpha}\cdot\sum_\beta\boldsymbol{\beta}=\sum_\beta\boldsymbol{\beta}\cdot\boldsymbol{\alpha}\,. \tag{16}$$

This fact means that the structure of $\mathfrak{z}(\boldsymbol{k})$ is determined by only the rotational part. Since $\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}=\{\boldsymbol{\varepsilon}|\boldsymbol{\tau}_\alpha\}\{\boldsymbol{\alpha}|o\}$, the representation of any element $\{\boldsymbol{\alpha}|\boldsymbol{\tau}_\alpha\}$ of $\mathfrak{A}(\boldsymbol{k})$ is expressed by the product of the representation of $\{\boldsymbol{\alpha}|o\}$ and $\exp(-2\pi i\boldsymbol{k}\boldsymbol{\tau}_\alpha)$. This fact was derived group-theoretically by Koster[8]. $\sum_\beta\boldsymbol{\beta}$ satisfing (16) is the summation of the elements belonging to some class of the point group. Above result is unchanged even when considering the spin. In the interior points of Brillouin zone, the labour for obtaining the representations is almost the same in group-theoretical and present methods, because the procedure to classify into classes in group theory and that to search for the bases of the centrum in algebraic theory need nearly the same labour. At the points on the Brillouin zone boundary, however, present method is very often superior to group theory, as we can see if we calculate group-theoretically the representation, for example, of the point W.

§ 4. The Representations. Case with Spin

In this section we take account of the spin. Since spin space and ordinary space are distinct, the effect to the spatial part due to symmetry operations is the same as expressed in the previous section. Since the spin part is invariant by the translation, we may consider for the operations on spin part only that of the point group to which the space group belongs. These rotational parts are expressed by the spin representation of the rotation group. For example the rotations by θ about x-, y- and z-axis are expressed by

$$R_x(\theta)=\begin{pmatrix}\cos\dfrac{\theta}{2} & -i\cdot\sin\dfrac{\theta}{2}\\ -i\cdot\sin\dfrac{\theta}{2} & \cos\dfrac{\theta}{2}\end{pmatrix},$$

$$R_y(\theta)=\begin{pmatrix}\cos\dfrac{\theta}{2} & -\sin\dfrac{\theta}{2}\\ \sin\dfrac{\theta}{2} & \cos\dfrac{\theta}{2}\end{pmatrix},$$

$$R_z(\theta)=\begin{pmatrix}\exp\left(-i\,\dfrac{\theta}{2}\right) & 0\\ 0 & \exp\left(i\,\dfrac{\theta}{2}\right)\end{pmatrix}.$$

Improper rotation is expressed by taking the unit matrix for the inversion. The multiplication between spin representations gives clearly the same results as that of usual representations of three dimensional rotation group except that negative sign occurs because of two valuedness of spin representation. The result for the multiplication between C. R. s is shown in Table III.

As was expressed in § 1, we take account of only 16 C. R. s explicitly and do not make usual enlargement of algebra by adding $R(2\pi)$. Therefore the representations occured in this section are essentially different from those in the previous section. The structure of $\mathfrak{A}(\boldsymbol{k})$ can be seen by combining Table II and III. The bases of each centrum of $\mathfrak{A}(\boldsymbol{k})$ are

$$\begin{aligned}
&\mathfrak{z}(\Gamma):\ \{\boldsymbol{E},\,(\boldsymbol{S}_4^{+}+\boldsymbol{S}_4^{-}),\,\boldsymbol{J},\,(\boldsymbol{JS}_4^{+}+\boldsymbol{JS}_4^{-})\}\,,\\
&\mathfrak{z}(H):\ \{\boldsymbol{E}\}\,,\\
&\mathfrak{z}(X):\ \{\boldsymbol{E},\,\boldsymbol{JU}_{xy}\}\,,\\
&\mathfrak{z}(W):\ \{\boldsymbol{E},\,\boldsymbol{C}_2,\,(\boldsymbol{S}_4^{+}+i\boldsymbol{S}_4^{-}),\,(\boldsymbol{JU}_{xy}+i\boldsymbol{JU}_{x\bar{y}})\,,\\
&\qquad\qquad(\boldsymbol{JM}_x+i\boldsymbol{JM}_y)\}\,,\\
&\mathfrak{z}(V):\ \{\boldsymbol{E},\,(\boldsymbol{JS}_4^{+}+\boldsymbol{JS}_4^{-})\}\,,\\
&\mathfrak{z}(B):\ \{\boldsymbol{E},\,(\boldsymbol{JS}_4^{+}+\boldsymbol{JS}_4^{-})\}\,,\\
&\mathfrak{z}(\Delta):\ \{\boldsymbol{E}\}\,,\\
&\mathfrak{z}(\Sigma):\ \{\boldsymbol{E}\}\,,\\
&\mathfrak{z}(Z):\ \{\boldsymbol{E},\,\boldsymbol{C}_2,\,\boldsymbol{JU}_{xy},\,\boldsymbol{JU}_{x\bar{y}}\}\equiv\mathfrak{A}(Z)\,, \qquad\qquad (17)\\
&\mathfrak{z}(Z'):\ \{\boldsymbol{E},\,\boldsymbol{U}_{x\bar{y}},\,\boldsymbol{JU}_{xy},\,\boldsymbol{JC}_2\}\equiv\mathfrak{A}(Z')\,,\\
&\mathfrak{z}(L):\ \{\boldsymbol{E},\,\boldsymbol{M}_x,\,\boldsymbol{J},\,\boldsymbol{JM}_x\}\equiv\mathfrak{A}(L)\,,\\
&\mathfrak{z}(Q):\ \{\boldsymbol{E},\,\boldsymbol{JM}_x\}\equiv\mathfrak{A}(Q)\,,\\
&\mathfrak{z}(P):\ \{\boldsymbol{E},\,\boldsymbol{M}_x\}\equiv\mathfrak{A}(P)\,,\\
&\mathfrak{z}(S):\ \{\boldsymbol{E},\,\boldsymbol{JC}_2\}\equiv\mathfrak{A}(S)\,,\\
&\mathfrak{z}(R):\ \{\boldsymbol{E},\,\boldsymbol{JU}_{x\bar{y}}\}\equiv\mathfrak{A}(R)\,,\\
&\mathfrak{z}(T):\ \{\boldsymbol{E},\,\boldsymbol{JU}_{xy}\}\equiv\mathfrak{A}(T)\,.
\end{aligned}$$

The bases of the representation modules of each $\mathfrak{A}(\boldsymbol{k})$ are given in Appendix C. When $\mathfrak{A}(\boldsymbol{k})$ and $\mathfrak{z}(\boldsymbol{k})$ are isomorphic, all representations are one dimensional. These one dimensional representations, however, are degenerated by time reversal symmetry because of the existence of inversion symmetry in white tin. For a convenience of the inspection and for the relation to Appendixes, we show characters χ in Table IV. The so-called single and double group representations are divided into two parts by a line. In the table the decomposition of the representations due to the addition of spin and the degeneracy due to time reversal symmetry (we abbreviate as T.R.S.) are also shown.

§ 5. Relation between White Tin and Grey Tin

As is well known, tin shows allotropic change in crystal structure. Grey tin is unstable at the temperatures above 18°C. This temperature of the transformation is excep-

$^1X_3$ and $^1X_4$ are degenerated by T.R.S.

tionally low in monoatomic metals. Since white tin is not so good conductor, while grey tin is a good semiconductor (the energy gap is the order of 0.08 ev), we may expect that the difference of both energy band structures is comparatively small. This clarification, however, need quantitative calculation, which is beyond the scope of present paper. Another interesting point is to see how the energy state changes with slight modification of grey tin to the D_{4h}^{19}-lattice due to pressure or any other effect.

Diamond crystal is obtained from white tin lattice by compressing in the directions of x-, y-axis and stretching in z-direction till the stage $a\rightarrow a'/\sqrt{2}$, $c\rightarrow a'$, $2a'$ being the lattice constant of grey tin. Following to usual description, we rotate x-, and y-axis in Fig. 1 by $-45°$ about z-axis and choose the axes as those in Fig. 3. Brillouin zone of grey tin lattice is shown in Fig. 4. C. R. s of $\mathfrak{G}$ are the following 48 elements:

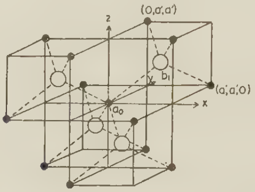

Fig. 3. Diamond lattice.

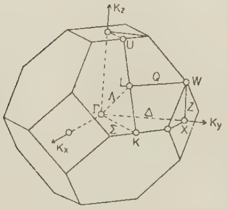

Fig. 4. First Brillouin zone for diamond lattice.

(i) $\boldsymbol{E}$ is the unit element,

(ii) $\boldsymbol{C}_2(x)$, $\boldsymbol{C}_2(y)$ and $\boldsymbol{C}_2(z)$ are the rotations by π about the axis shown in each parenthesis,

(iii) $\boldsymbol{S}_4^{\pm}(x)$, $\boldsymbol{S}_4^{\pm}(y)$ and $\boldsymbol{S}_4^{\pm}(z)$ are the rotations by $\pm(\pi/2)$ about the axis shown in each parenthesis followed by the reflection at the plane perpendicular to the rotation axis and through the origin,

(iv) $\boldsymbol{M}_{xy}$, $\boldsymbol{M}_{x\bar{y}}$, $\boldsymbol{M}_{yz}$, $\boldsymbol{M}_{y\bar{z}}$, $\boldsymbol{M}_{zx}$ and $\boldsymbol{M}_{z\bar{x}}$ are the reflections at the planes through [110] and z-axis, etc.,

(v) $\boldsymbol{D}^{\pm}_{xyz}$, $\boldsymbol{D}^{\pm}_{\bar{x}yz}$, $\boldsymbol{D}^{\pm}_{\bar{x}\bar{y}z}$ and $\boldsymbol{D}^{\pm}_{x\bar{y}z}$ are the rotations by $\pm(2/3)\pi$ about the body diagonals [111], etc.,

(vi) $\boldsymbol{J}$ is the inversion at the origin followed by the non-primitive translation $\boldsymbol{\tau}\equiv\overrightarrow{a_0b_1}$,

(vii) $\boldsymbol{J}\times$ (ii), (viii) $\boldsymbol{J}\times$ (iii), (ix) $\boldsymbol{J}\times$ (iv), (x) $\boldsymbol{J}\times$(v).

The symmetry elements of white tin and grey tin are corresponded as

$$\boldsymbol{E}\rightarrow\boldsymbol{E},\ \boldsymbol{C}_2\rightarrow\boldsymbol{C}_2(z),\ \boldsymbol{S}_4^{\pm}\rightarrow\boldsymbol{S}_4^{\pm}(z),\ \boldsymbol{U}_{xy}\rightarrow\boldsymbol{C}_2(y),$$

$$\boldsymbol{U}_{x\bar{y}}\rightarrow\boldsymbol{C}_2(x),\ \boldsymbol{M}_x\rightarrow\boldsymbol{M}_{xy},\ \boldsymbol{M}_y\rightarrow\boldsymbol{M}_{x\bar{y}},\ \boldsymbol{J}\rightarrow\boldsymbol{J}\ .$$

The shape of the Brillouin zone is classified into two types bordered by the case $a=c$, where Brillouin zone becomes that of body centred cubic. In the range $c/a>1$, the shape is much similar to that in Fig. 4, while in the range $c/a<1$, the shape is essentially the same as in Fig. 2.

The symmetry point W and symmetry lines V, Σ, Z and Q of white tin are isomorphic to the corresponding point and lines of grey tin*. These energy states should be qualitatively the same in both cases. The lines $\varDelta$ and $\varLambda$ with the inclusion of both ends are only symmetry lines to consider in detail. We do not, however, consider of one dimensional representations in O_h^7, since there is no further splitting by lowering of the symmetry from O_h^7 to D_{4h}^{19} because of the existence of the inversion symmetry in both cases. We show schematic diagrams of energy splittings:

O_h^7				D_{4h}^{19}

$\Gamma_7^{\pm}+{}^4\Gamma_8^{\pm}$	$\longleftarrow$	${}^3\Gamma_{25}^{\pm}$	$\longrightarrow$	$\Gamma_4^{\pm}+{}^2\Gamma_5^{\pm}$	$\longrightarrow$	$\Gamma_6^{\pm}+\Gamma_7^{\pm}+\Gamma_7^{\pm}$
$\varDelta_6+\varDelta_7$	$\longleftarrow$	${}^2\varDelta_5$	$\longrightarrow$	$\varDelta_2+\varDelta_3$	$\longrightarrow$	$\varDelta_5+\varDelta_5$
${}^4X_5$	$\longleftarrow$	${}^2X_1$, ${}^2X_2$	$\longrightarrow$	${}^2X_1$	$\longrightarrow$	X_3+X_4
${}^4X_5$	$\longleftarrow$	${}^2X_3$, ${}^2X_4$	$\longrightarrow$	${}^2X_2$	$\longrightarrow$	X_3+X_4
$({}^1L_4^{\pm}+{}^1L_5^{\pm})+L_6^{\pm}$	$\longleftarrow$	${}^2L_3^{\pm}$	$\longrightarrow$	$L_1^{\pm}+L_2^{\pm}$	$\longrightarrow$	$({}^1L_3^{\pm}+{}^1L_4^{\pm})+({}^1L_3^{\mp}+{}^1L_4^{\pm})$.

Since the change occurs directly from A′ to B′, there is no essential change at $\varDelta$ and L. But further splitting occurs at Γ and X. The magnitude of the splitting, of course, depends on the degree of the deviation from O_h^7. Herman[9)] suggested that the valence band edge is at the point Γ. Then we are particularly interesting for the splitting of ${}^4\Gamma_8{}^+$. In so small $\boldsymbol{k}$ as perturbational approximation is satisfied, warped surfaces at ${}^4\Gamma_8{}^+$ in grey tin become ellipsoidal after deformation to the D_{4h}^{19}-lattice.

---

* Table VIII by Elliott[4)] does not communicate Herring's corrected result faithfully.

The author wishes to express his gratitude to Dr. Conyers Herring for his support and some advice of present work.

Appendix A. Terminology

We write down briefly the terminology used in text for a convenience to some readers who are unfamiliar with algebra.

(a) Ring

The definition of ring $\mathfrak{R}$ is as follows:

(i) The product $\boldsymbol{\alpha\beta}$ of any elements $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ of $\mathfrak{R}$ is determined uniquely as the element of $\mathfrak{R}$.

(ii) The following combination law

$$\boldsymbol{\alpha\beta}\cdot\boldsymbol{\gamma}=\boldsymbol{\alpha}\cdot\boldsymbol{\beta\gamma}$$

is satisfied of the multiplication.

(iii) The assembly $\mathfrak{R}$ is a commutative group as to the addition (this additive Abel group is called a module), i.e. the addition and subtraction of any elements $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ of $\mathfrak{R}$ is contained in $\mathfrak{R}$

(iv) On the multiplication and addition, the following distribution laws

$$(\boldsymbol{\alpha}+\boldsymbol{\beta})\boldsymbol{\gamma}=\boldsymbol{\alpha\gamma}+\boldsymbol{\beta\gamma}\ ,\ \boldsymbol{\gamma}(\boldsymbol{\alpha}+\boldsymbol{\beta})=\boldsymbol{\gamma\alpha}+\boldsymbol{\gamma\beta}$$

are satisfied.

(b) Field

If all non-zero elements of a ring constitute a group as to the multiplication, we call such ring the field $\mathfrak{K}$. The assembly of usual complex numbers is a commutative field.

(c) Algebra

We assume $\mathfrak{K}$ to be a commutative field and that any element of $\mathfrak{K}$ is commutative to any element of ring $\mathfrak{A}$. If ring $\mathfrak{A}$ is a module of finite order c, $\mathfrak{A}$ is called algebra of order c over the field $\mathfrak{K}$. Then, with use of c bases $\boldsymbol{a}_i$ of $\mathfrak{A}$, $\mathfrak{A}$ is expressed as

$$\mathfrak{A}=\sum_{i=1}^{c}\boldsymbol{a}_i\mathfrak{K}\ .$$

The multiplication between the bases $\boldsymbol{a}_i$ and $\boldsymbol{a}_j$ is given by

$$\boldsymbol{a}_i\boldsymbol{a}_j=\sum_{k=1}^{c}c_{ij}^{k}\boldsymbol{a}_k\ ,\ c_{ij}^{k}\in\mathfrak{K}\ .$$

c_{ij}^{k} must be, however, determined to satisfy the combination law in (a)(ii).

(d) Ideal

Left ideal $\mathfrak{l}$ and right ideal $\mathfrak{r}$ of algebra $\mathfrak{A}$ are the submodules satisfing the following conditions respectively

$$\mathfrak{A}\mathfrak{l}=\mathfrak{l},\ \mathfrak{r}\mathfrak{A}=\mathfrak{r}\ .$$

The submodule satisfing two conditions at the same time is called ideal.

(e) Centrum

The commutative subalgebra composed of all elements commutative to all elements of algebra $\mathfrak{A}$ is called the centrum $\mathfrak{z}$ of $\mathfrak{A}$.

(f) Idempotent

The idempotent is defined as the element $\boldsymbol{a}$ satisfing the following formula

$$\boldsymbol{aa}=\boldsymbol{a}\neq 0\ .$$

(g) Representation Module

If the module $\mathfrak{M}$ expressed with use of the bases $\boldsymbol{a}_i$ of finite order as

$$\mathfrak{M}=\sum_{i=1}^{c}\boldsymbol{a}_i\mathfrak{K}$$

satisfies the following condition

$$\mathfrak{A}\mathfrak{M}\subseteq\mathfrak{M}\ ,$$

we call $\mathfrak{M}$ the representation module of $\mathfrak{A}$ over $\mathfrak{K}$.

Appendix B. Representation Modules. Case without Spin

a) Γ: $p=1$ for $X=\Gamma$, $p=-1$ for $X=\Gamma'$.

$$\boldsymbol{e}(\Gamma_l)=\frac{1}{16}\sum\chi_{\Gamma_l}^{*}(R)\boldsymbol{R}\ ,\ \Gamma_l=\Gamma_1\cdots\Gamma_4\,;\ \Gamma_1'\cdots\Gamma_4'$$

$$\left.\begin{array}{l}\boldsymbol{e}_{11}({}^2X_5)\\ \boldsymbol{e}_{22}({}^2X_5)\end{array}\right\}=\frac{1}{8}[\boldsymbol{E}-\boldsymbol{C}_2\pm(\boldsymbol{M}_x-\boldsymbol{M}_y)+p\{\boldsymbol{J}-\boldsymbol{JC}_2\pm(\boldsymbol{JM}_x-\boldsymbol{JM}_y)\}]\ ,$$

$$\left.\begin{array}{l}\boldsymbol{e}_{21}({}^2X_5)\\ \boldsymbol{e}_{12}({}^2X_5)\end{array}\right\}=\frac{1}{8}[\boldsymbol{U}_{xy}-\boldsymbol{U}_{x\bar{y}}\pm(\boldsymbol{S}_4{}^+-\boldsymbol{S}_4{}^-)+p\{\boldsymbol{JU}_{xy}-\boldsymbol{JU}_{x\bar{y}}\pm(\boldsymbol{JS}_4{}^+-\boldsymbol{JS}_4{}^-)\}]\ .$$

b) H: $p=1$ for H_1, $p=-1$ for H_2, and $q=1$ for H_3, $q=-1$ for H_4 .

$$\left\{\begin{array}{l}
\left.\begin{array}{l} \boldsymbol{e}_{11}({}^2H_l)\\ \boldsymbol{e}_{22}({}^2H_l)\end{array}\right\}=\frac{1}{8}[\boldsymbol{E}+\boldsymbol{C}_2+p(\boldsymbol{M}_x+\boldsymbol{M}_y)\pm\{\boldsymbol{S}_4^+ +\boldsymbol{S}_4^- +p(\boldsymbol{U}_{xy}+\boldsymbol{U}_{x\bar{y}})\}]\ ,\\
\left.\begin{array}{l} \boldsymbol{e}_{21}({}^2H_l)\\ \boldsymbol{e}_{12}({}^2H_l)\end{array}\right\}=\frac{1}{8}[\boldsymbol{J}+\boldsymbol{JC}_2+p(\boldsymbol{JM}_x+\boldsymbol{JM}_y)\pm\{\boldsymbol{JS}_4^+ +\boldsymbol{JS}_4^- +p(\boldsymbol{JU}_{xy}+\boldsymbol{JU}_{x\bar{y}})\}]\ ,
\end{array}\right.$$

$$\left\{\begin{array}{l}
\left.\begin{array}{l} \boldsymbol{e}_{11}({}^2H_l)\\ \boldsymbol{e}_{22}({}^2H_l)\end{array}\right\}=\frac{1}{8}[\boldsymbol{E}-\boldsymbol{C}_2+q(\boldsymbol{JM}_x-\boldsymbol{JM}_y)\pm\{\boldsymbol{M}_x-\boldsymbol{M}_y+q(\boldsymbol{J}-\boldsymbol{JC}_2)\}]\ ,\\
\left.\begin{array}{l} \boldsymbol{e}_{21}({}^2H_l)\\ \boldsymbol{e}_{12}({}^2H_l)\end{array}\right\}=\frac{1}{8}[\boldsymbol{U}_{xy}-\boldsymbol{U}_{x\bar{y}}-q(\boldsymbol{JS}_4^+-\boldsymbol{JS}_4^-)\pm\{\boldsymbol{S}_4^+-\boldsymbol{S}_4^- -q(\boldsymbol{JU}_{xy}-\boldsymbol{JU}_{x\bar{y}})\}]\ .
\end{array}\right.$$

c) X: $p=1$ for ${}^2X_1$ and $p=-1$ for ${}^2X_2$.

$$\left.\begin{array}{l} \boldsymbol{e}_{11}({}^2X_l)\\ \boldsymbol{e}_{22}({}^2X_l)\end{array}\right\}=\frac{1}{4}\{\boldsymbol{E}+p\boldsymbol{U}_{xy}\pm(\boldsymbol{J}+p\boldsymbol{JU}_{xy})\}\ ,$$

$$\left.\begin{array}{l} \boldsymbol{e}_{21}({}^2X_l)\\ \boldsymbol{e}_{12}({}^2X_l)\end{array}\right\}=\frac{1}{4}\{\boldsymbol{C}_2+p\boldsymbol{U}_{x\bar{y}}\mp(\boldsymbol{JC}_2+p\boldsymbol{JU}_{x\bar{y}})\}\ .$$

d) W: $p=1$ for ${}^2W_1$ and $p=-1$ for ${}^2W_2$.

$$\boldsymbol{e}_{11}({}^2W_l)=\frac{1}{4}\{\boldsymbol{E}+\boldsymbol{C}_2+p(\boldsymbol{S}_4^+ +\boldsymbol{S}_4^-)\}\ ,$$

$$\boldsymbol{e}_{22}({}^2W_l)=\frac{1}{4}\{\boldsymbol{E}-\boldsymbol{C}_2-ip(\boldsymbol{S}_4^+-\boldsymbol{S}_4^-)\}\ ,$$

$$\boldsymbol{e}_{21}({}^2W_l)=\frac{1}{4}\{\boldsymbol{JU}_{xy}+\boldsymbol{JU}_{x\bar{y}}+p(\boldsymbol{JM}_x+\boldsymbol{JM}_y)\}\ ,$$

$$\boldsymbol{e}_{12}({}^2W_l)=\frac{1}{4}\{i(\boldsymbol{JU}_{xy}-\boldsymbol{JU}_{x\bar{y}})+p(\boldsymbol{JM}_x-\boldsymbol{JM}_y)\}\ .$$

e) V, B: $p=\exp(\pi ik_zc)$ for $X=V$ and $p=i\cdot\exp(\pi ik_zc)$ for B.

Effect of External Illumination on Carrier Lifetime in Semiconductors

By Jun'ichi OKADA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co.,
Kawasaki, Japan

(Received July 29, 1959)

The lifetime of excess carriers in a nondegenerate semiconductor which is illuminated with a light in fundamental absorption band and a longer wavelength light is discussed. The recombination equations for many recombination-center levels in the presence of a steady external illumination are formulated. For steady-state case these equations can be solved exactly, but transient solutions are obtained only for specific cases. These results show that both steady-state and transient lifetimes are identical for small densities of recombination centers. This simple lifetime for single recombination-center level case is discussed.

§1. Introduction

Measurements of carrier lifetime in semiconductors are often made under a uniform and constant external illumination in the fundamental absorption band.

Ransom and Rose,[1] for example, have measured the temperature dependence of the lifetime in n-type germanium with various intensities of background illumination, and interpret the results in terms of both the activation energy and the densities of different recombination centers. Furthermore, when trapping effects are present, the measurements of lifetime as determined by the simple recombination centers can be made with the saturation of the traps by a steady illumination in fundamental absorption band.2) The dependence of lifetime on injection level can also be measured by varying the intensity of a steady external illumination.3)

However, no theoretical work has been reported that would explain in detail the effect of external illumination.

Moreover, it is also interesting to investigate the change of lifetime by illuminating with the long wavelength light which is absorbed only by a single recombination center.

In this paper we shall consider the effect of external illumination on carrier lifetime. The recombination equations in the presence of a steady external illumination will be formulated first. Then the steady-state and transient solutions of the equations will be discussed.

§ 2. Recombination Equations in the Presence of External Illumination

As shown in a previous paper,3) the behavior of excess carriers in a nondegenerate semiconductor where the recombination takes place via localized defect levels may be expressed by the equations of the form

$$\left.\begin{aligned}&\frac{d\Delta n}{dt}=L_n-\Sigma_j\Delta R_{nj}=L_n-\Delta R_n\,,\quad \frac{d\Delta p}{dt}L_p-\Sigma_j\Delta R_{pj}=L_p-\Delta R_p\,,\\&\frac{d\Delta N_j^+}{dt}=-\frac{d\Delta N_j^-}{dt}=\Delta R_{pj}-\Delta R_{nj}\pm L_j\qquad (j=1,2,\cdots)\,,\\&\Delta n=\Delta p+\Sigma_j\Delta N_j^+=\Delta p-\Sigma_j\Delta N_j^-,\quad \Delta N_j^+=-\Delta N_j^-\,,\end{aligned}\right\}\tag{2.1}$$

where

$$\left.\begin{aligned}&\Delta R_{nj}=\gamma_{nj}\{N_{j0}^+\Delta n-(n_0+n_j+\Delta n)\Delta N_j^-\}\,,\\&\Delta R_{pj}=\gamma_{pj}\{N_{j0}^-\Delta p-(p_0+p_j+\Delta p)\Delta N_j^+\}\,,\end{aligned}\right\}\tag{2.2}$$

and

$$N_{j0}^-=N_j\frac{n_0}{n_0+n_j}=N_j\frac{p_j}{p_0+p_j}\,,\qquad N_{j0}^+=N_j\frac{n_j}{n_0+n_j}=N_j\frac{p_0}{p_0+p_j}\,.\tag{2.3}$$

Here ΔR_{nj} and ΔR_{pj} are the net rates of capture of excess electrons and holes respectively by j-level, γ_{nj} and γ_{pj} are the rates of capturing an electron and a hole by a single j-center, ΔN_j^- and ΔN_j^+ are the changes of densities N_j^- and N_j^+ of filled and unfilled j-recombination centers respectively (from the electron point of view), N_j is the density of j-recombination centers, Δn and Δp are the changes in the thermal equilibrium densities n_0 and p_0 of free electrons and holes respectively, n_j and p_j are the densities of free electrons and holes when the Fermi level equals to the effective energy E_j of j-level, L_n and L_p are the rates of generation of electrons and holes by external means, and $\pm L_j$ is the rate of excitation of electrons or holes bound in j-level (+ sign for electrons and − sign for holes).

When external illumination is present, we can write

$$L_n=(L_n)^e+L(t)\,,\qquad L_p=(L_p)^e+L(t)\,,\tag{2.4}$$

where $(L_n)^e$ and $(L_p)^e$ are the generations of electrons and holes respectively by external illumination and $L(t)$ is the injection for measuring the carrier lifetime.

For a steady illumination, it is necessary to satisfy the steady-state conditions

$$(L_n)^e=(\Delta R_n)^e\,,\qquad (L_p)^e=(\Delta R_p)^e\,,\qquad \left(\frac{d\Delta N_j^+}{dt}\right)=0\qquad (j=1,2,\cdots)\tag{2.5}$$

where $(\quad)^e$ refers to external illumination.

Furthermore, we must consider following two cases.

Case A. Illumination in fundamental absorption band

In this case, we have

$$(L_n)^e=(L_p)^e=(L)^e \tag{2.6}$$

and

$$(\Delta R_{nj})^e=(\Delta R_{pj})^e \qquad (j=1,\ 2,\ \cdots). \tag{2.7}$$

Case B. Illumination with long wavelength Light

Here we assume that the long wavelength light excites electrons bound in recombination centers at t-level. In this case, we have

$$(L_n)^e=L_t=L_{nt}\,, \qquad (L_p)^e=0\,, \qquad L_j=0 \qquad (j\neq t) \tag{2.8}$$

and

$$\left.\begin{aligned}&(\Delta R_{nj})^e=(\Delta R_{pj})^e \qquad (j\neq t)\,,\\&(\Delta R_{nt})^e=(\Delta R_{pt})^e+L_{nt}\,.\end{aligned}\right\} \tag{2.9}$$

On the other hand, if the quantities such as δR_n, δn, δN_j^+, etc. denote the changes by $L(t)$, Eqs. (2.1) give

$$\left.\begin{aligned}&\frac{d\delta n}{dt}=L-\delta R_n\,, \quad \frac{d\delta p}{dt}=L-\delta R_p\,, \quad \frac{d\delta N_j^+}{dt}=\delta R_{pj}-\delta R_{nj}\,,\\&\delta n=\delta p+\Sigma_j\delta N_j^+\,, \qquad \delta N_j^+=-\delta N_j^-\,.\end{aligned}\right\} \tag{2.10}$$

Supposing that the disturbances by $L(t)$ are small enough that only first-order terms in δn, δp and δN_j^+ ($j=1,\ 2,\ \cdots$) need be considered, we get from Eqs. (2.2)

$$\left.\begin{aligned}&\delta R_{nj}=\gamma_{nj}[\{N_{j0}^{\ +}+(\Delta N_j^+)^e\}\delta n+\{n_0+n_j+(\Delta n)^e\}\delta N_j^+]\,,\\&\delta R_{pj}=\gamma_{pj}[\{N_{j0}^{\ -}-(\Delta N_j^+)^e\}\delta p-\{p_0+p_j+(\Delta p)^e\}\delta N_j^+]\,.\end{aligned}\right\} \tag{2.11}$$

Eqs. (2.10) and (2.11) constitute the fundamental equations which determine the behavior of excess carriers in the presence of a steady external illumination.

§ 3. Steady-State Lifetime

In this section we shall consider the case where the measurements of carrier lifetime is made under steady-state conditions

$$\frac{d\delta n}{dt}=\frac{d\delta p}{dt}=\frac{d\delta N_j^+}{dt}=0\,,$$

or

$$L=\delta R_n=\delta R_p\,, \qquad \delta R_{nj}=\delta R_{pj}\,. \tag{3.1}$$

For this case, the lifetimes of electrons and holes are defined by

$$\tau_n=\frac{\delta n}{\delta R_n}\,, \qquad \tau_p=\frac{\delta p}{\delta R_p}\,. \tag{3.2}$$

Using Eqs. (3.1) and (3.2), and the relations given in the case A or B in Appendix A, the dependence of the steady-state lifetimes on external illumination is given as

$$\left.\begin{aligned}\frac{1}{\tau_n}=&[\Sigma_j\{B_{pj}H_{pj}-\Delta n(\gamma_{nj}H_{pj}B_{pj}/B_j)+\Delta p(\gamma_{nj}H_{nj}B_{pj}/B_j)\}-(\gamma_{nt}B_{pt}L_{nt}/B_t^2)]\\&+\lambda[\Sigma_j\{B_{nj}H_{nj}+\Delta n(\gamma_{pj}H_{pj}B_{nj}/B_j)\\&\quad-\Delta p(\gamma_{pj}H_{nj}B_{nj}/B_j)\}-(\gamma_{pt}B_{nt}L_{nt}/B_t^2)]\,,\\\frac{1}{\tau_p}=&[\Sigma_j\{B_{nj}H_{nj}+\Delta n(\gamma_{pj}H_{pj}B_{pj}/B_j)-\Delta p(\gamma_{pj}H_{nj}B_{nj}/B_j)\}-(\gamma_{pt}B_{nt}L_{nt}/B_t^2)]\\&+\frac{1}{\lambda}[\Sigma_j\{B_{pj}H_{pj}-\Delta n(\gamma_{nj}H_{pj}B_{pj}/B_j)\\&\quad+\Delta p(\gamma_{nj}H_{nj}B_{pj}/B_j)\}+(\gamma_{nt}B_{pt}L_{nt}/B_t^2)]\,,\end{aligned}\right\} \tag{3.3}$$

where

$$\lambda=\frac{(1+H_p)-\Delta n\Sigma_j(\gamma_{nj}H_{pj}/B_j)+\Delta p\Sigma_j(\gamma_{nj}H_{nj}/B_j)+(\gamma_{nt}L_{nt}/B_t^2)}{(1+H_n)+\Delta n\Sigma_j(\gamma_{pj}H_{pj}/B_j)-\Delta p\Sigma_j(\gamma_{pj}H_{nj}/B_j)-(\gamma_{pt}L_{nt}/B_t^2)}\,, \tag{3.4}$$

and

$$\Delta p=\frac{1+H_p}{1+H_n}\Delta n-\frac{1}{1+H_n}\,\frac{L_{nt}}{B_t}\,. \tag{3.5}$$

Here

$$H_n=\Sigma_jH_{nj}=\Sigma_j\frac{\gamma_{pj}N_{j0}^-}{B_j}\,,\qquad H_p=\Sigma_jH_{pj}=\Sigma_j\frac{\gamma_{nj}N_{j0}^+}{B_j}\,, \tag{3.6}$$

and

$$B_j=B_{nj}+B_{pj}=\gamma_{nj}(n_0+n_j+\Delta n)+\gamma_{pj}(p_0+p_j+\Delta p)\,. \tag{3.7}$$

Since there is no fear of confusion, $(\ )^e$ is omitted here and hereafter Δn, Δp, ΔN_j^+, etc. refer only to the changes by steady external illumination. In these expressions the lifetimes for the case A are obtained by setting $L_{nt}=0$ and for the case of the excitation of the holes in t-level by long wavelength light, L_{nt} must be replaced by $-L_{pt}$.

If we make the assumption that all N_j's are small enough compared to any one of the quantities n_0, p_0, n_j, p_j, Eqs. (3.4) and (3.5) reduce

$$\lambda=\frac{1+(\gamma_{nt}L_{nt}/B_t^2)}{1-(\gamma_{pt}L_{pt}/B_t^2)}\,,\qquad \Delta p=\Delta n-\frac{L_{nt}}{B_t}\,. \tag{3.8}$$

(i) *Case A*

Since $L_{nt}=0$, we obtain from Eqs. (3.8)

$$\lambda=1\,,\qquad \Delta p=\Delta n\,. \tag{3.9}$$

Substituting Eqs. (3.9) into Eqs. (3.3), single lifetime is given by

$$\frac{1}{\tau}=\frac{1}{\tau_n}=\frac{1}{\tau_p}=\Sigma_j\frac{\tau_{j0}(1+2\Delta\varphi)+\tau_{j\infty}(\Delta\varphi)^2}{(\tau_{j0}+\tau_{j\infty}\Delta\varphi)^2}\,, \tag{3.10}$$

where

$$\left.\begin{aligned}&\Delta\varphi=\frac{\Delta n}{n_0+p_0}=\frac{\Delta p}{n_0+p_0}\,,\qquad \tau_{j0}=\tau_{nj}\frac{p_0+p_j}{n_0+p_0}+\tau_{pj}\frac{n_0+n_j}{n_0+p_0}\,,\\ &\tau_{j\infty}=\tau_{nj}+\tau_{pj}\,,\qquad \tau_{nj}=\frac{1}{\gamma_{nj}N_j}\,,\qquad \tau_{pj}=\frac{1}{\gamma_{pj}N_j}\,.\end{aligned}\right\} \tag{3.11}$$

(ii) *Case B*

From Eq. (2.9), L_{nt} can be written as

$$\frac{L_{nt}}{B_t}=\frac{\Sigma_jB_{pj}H_{pj}}{B_{nt}}\Delta n+\frac{\Sigma_jB_{nj}H_{nj}}{B_{nt}}\Delta p\,. \tag{3.12}$$

Thus, as long as $\gamma_{nj}N_j$ and $\gamma_{pj}N_j$ are smaller than $\gamma_{nt}(n_0+n_t+\Delta n)$ for all N_j's, $L_{nt}/B_t\ll\Delta n$ or Δp and $L_{nt}/B_t^2\ll1$. In this case we obtain from Eqs. (3.8)

$$\lambda\simeq1\,,\qquad \Delta p\simeq\Delta n\,, \tag{3.13}$$

and Eqs. (3.3) reduce to a single lifetime given by

$$\frac{1}{\tau}=\frac{1}{\tau_n}=\frac{1}{\tau_p}=\Sigma_j\frac{\tau_{j0}(1+2\Delta\varphi)+\tau_{j\infty}(\Delta\varphi)^2}{(\tau_{j0}+\tau_{j\infty}\Delta\varphi)^2}+\frac{\tau_{t0}-\nu_{nt}\tau_{t\infty}}{\tau_{t0}+\tau_{t\infty}\Delta\varphi}\cdot\frac{1+\Delta\varphi}{\nu_{nt}+\Delta\varphi}\cdot\Sigma_j\frac{1}{\tau_{j0}+\tau_{j\infty}\Delta\varphi}\,, \tag{3.14}$$

where

$$\nu_{nt}=\frac{n_0+n_t}{n_0+p_0}\ . \tag{3.15a}$$

For the case where the holes in t-level are excited, ν_{nt} is replaced by

$$\nu_{pt}=\frac{p_0+p_t}{n_0+p_0}\ . \tag{3.15b}$$

§ 4. Transient Lifetime

In this section we shall consider the decay of δn and δp following a sudden interruption of excitation L. However, it is impossible to obtain general analytical solutions of Eqs. (2.10) for many recombination level case. Thus, we shall limit ourselves here to some elementary cases where the solutions can easily be obtained.

4.1. *Single recombination-center level*

Solutions of Eqs. (2.10) for this case have been given by Sandiford[5)] and Wertheim,[6)] and are of the form

$$\delta n=C_n^- \exp(-t/\tau_-)+C_n^+ \exp(-t/\tau_+) \tag{4.1}$$

(see Appendix B)

If the density of recombination centers is sufficiently small, we can neglect shorter time constant since measurements of lifetime yield longer one. For this case, with $\Delta n=\Delta p$, we obtain from Eqs. (B.3) and (B.4) in Appendix B

$$\tau=\frac{(\tau_0+\tau_\infty\Delta\varphi)^2}{\tau_0(1+2\Delta\varphi)+\tau_\infty(\Delta\tau)^2} \qquad \text{for case A,} \tag{4.2}$$

and

$$\tau=\frac{(\tau_0+\tau_\infty\Delta\varphi)^2}{\tau_0(1+2\Delta\varphi)+\tau_\infty(\Delta\varphi)^2+(\tau_0-\nu\tau_\infty)((1+\Delta\varphi)/(\nu+\Delta\varphi))\Delta\varphi} \qquad \text{for case B,} \tag{4.3}$$

where ν is $(n_0+n_1)/(n_0+p_0)$ or $(p_0+p_1)/(n_0+p_0)$ corresponding to the excitation of electrons or holes.

4.2. *Two recombination-center levels*

In this case it is easy to show that the solution of Eqs. (2.10) is of the form

$$\delta n=C_{n1}\exp(-t/\tau_1)+C_{n2}\exp(-t/\tau_2)+C_{n3}\exp(-t/\tau_3)\ , \tag{4.4}$$

and three time constants are given by a equation of the form

$$\left(\frac{1}{\tau}\right)^3-p\left(\frac{1}{\tau}\right)^2+q\left(\frac{1}{\tau}\right)-r=0\ , \tag{4.5}$$

where the expressions for the quantities p, q and r are given in Appendix C.

If the densities N_1 and N_2 of both recombination centers are small enough, the largest time constant is approximately

$$\frac{1}{\tau}=\frac{r}{q}\ . \tag{4.6}$$

With $\Delta n=\Delta p$ the lifetime under external illumination are given from Eq. (4.6) as follows.

(i) *Case A*

$$\frac{1}{\tau}=\frac{\tau_{10}(1+2\Delta\varphi)+\tau_{1\infty}(\Delta\varphi)^2}{(\tau_{10}+\tau_{1\infty}\Delta\varphi)^2}+\frac{\tau_{20}(1+2\Delta\varphi)+\tau_{2\infty}(\Delta\varphi)^2}{(\tau_{20}+\tau_{2\infty}\Delta\varphi)^2}\ . \tag{4.7}$$

(ii) *Case B where electrons or holes in 2-level are excited*

$$\frac{1}{\tau}=\frac{\tau_{10}(1+2\Delta\varphi)+\tau_{1\infty}(\Delta\varphi)^2}{(\tau_{10}+\tau_{1\infty}\Delta\varphi)^2}+\frac{\tau_{20}(1+2\Delta\varphi)+\tau_{2\infty}(\Delta\varphi)^2}{(\tau_{20}+\tau_{2\infty}\Delta\varphi)^2}$$
$$+\frac{\tau_{20}-\nu_2\tau_{2\infty}}{\tau_{20}+\tau_{2\infty}\Delta\varphi}\left[\frac{1}{\tau_{10}+\tau_{1\infty}\Delta\varphi}+\frac{1}{\tau_{20}+\tau_{2\infty}\Delta\varphi}\right]\frac{1+\Delta\varphi}{\nu_2+\Delta\varphi}\Delta\varphi\,. \tag{4.8}$$

where ν_2 is $(n_0+n_2)/(n_0+p_0)$ or $(p_0+p_2)/(n_0+p_0)$ corresponding to the excitation of electrons or holes in 2-level.

Moreover, since other two time constants are of the order of $(1/B_1)+(1/B_2)$ and $1/(B_1+B_2)$, and are associated with smaller amplitudes, it is possible to neglect them in measurements of lifetime.

4.3. *A recombination-center level and A trap level*

We consider here the case of a hole trap level in conjunction with a recombination level.

Let subscripts r and t refer to recombination center and hole trap respectively. We obtain

$$\frac{d\delta n}{dt}=-\delta R_{nr}\,,\qquad \frac{d\delta p}{dt}=-\delta R_{pr}-\delta R_{pt}\,, \tag{4.9a}$$

$$\frac{d\delta N_r^+}{dt}=\delta R_{pr}-\delta R_{nr}\,,\qquad \frac{d\delta N_t^+}{dt}=\delta R_{pt}\,, \tag{4.9b}$$

$$\delta n=\delta p+\delta N_r^+ +\delta N_t^+\,, \tag{4.9c}$$

and the equation determining the time constants has the same form as Eq. (4.5).

In order to investigate the effect of external illumination on carrier lifetime, it is necessary to consider two larger time constants. This is complicated and it is difficult to obtain analytical solutions. Thus we shall be concerned only with the case where the carrier lifetime is measured with the saturation of the trap by constant external illumination in fundamental absorption band. In this case, Eq. (4.9b) gives

$$N_t^-\simeq\Delta N_t^+\,. \tag{4.10}$$

Since ΔN_t^+ is given, from Eq. (A.2) in Appendix A, as

$$\Delta N_t^+=\frac{N_t^-\Delta p}{p_0+p_t+\Delta p}\,, \tag{4.11}$$

Eq. (4.10) is satisfied only when

$$\Delta p\gg p_0+p_t\,. \tag{4.12}$$

Under these conditions, $\delta N_t^+\simeq 0$ and Eqs. (4.9) reduce to the equations for a single recombination center level with external illumination. Thus, if the density of recombination center is small, the lifetime is given by Eq. (4.2) and we have

$$\tau=\frac{(\tau_{r0}+\tau_{r\infty}\Delta\varphi)^2}{\tau_{r0}(1+2\Delta\varphi)+\tau_{r\infty}(\Delta\varphi)^2} \qquad (\Delta\varphi\gg\nu_{pt}), \tag{4.13}$$

where $\nu_{pt}=(p_0+p_t)/(n_0+p_0)$ and for an electron trap ν_{pt} is replaced by $\nu_{nt}=(n_0+n_t)$ (n_0+p_0).

§ 5. Discussion

The results presented above show that both steady-state and transient lifetime are identical for small densities of recombination centers. This identification may be proved more generally by assuming that the change in electron (or hole) occupation of the recombination centers is negligible compared with the free excess carrier concentrations.

For simplicity, we shall discuss here this simple lifetime for single level case.

5.1. *Illumination in fundamental absorption band*

In this case we have the lifetime of the form

$$\tau=\frac{(\tau_0+\tau_\infty\Delta\varphi)^2}{\tau_0(1+2\Delta\varphi)+\tau_\infty(\Delta\varphi)^2}\,, \tag{5.1}$$

and the variation of τ with $\Delta\varphi$ is monotonous between $\tau=\tau_0$ (for $\Delta\varphi=0$) and $\tau=\tau_\infty$ (for $\Delta\varphi\to\infty$). This is also observed experimentally and an example is shown in Fig. 1 for p-type germanium specimen.

In our experiments, carrier lifetimes were measured by photoconductivity decay method described in the previous paper.[3] For external illumination a 24-watt tungsten lamp fed from a d.c. supply was used and $\Delta\varphi$ was changed by varing the intensity of this light. The value of $\Delta\varphi$ was calculated by using the relation

$$\Delta\varphi = M\cdot\frac{V_0 - V_L}{V_L}\,, \tag{5.2}$$

where V_L and V_0 are the voltage across the specimens with and without external illumination, M is given by $b/(1+b)$ for n-type or $1/(1+b)$ for p-type and b is the ratio of the mobilities (μ_n/μ_p). As shown in Fig. 1, if we use proper values of τ_0 and τ_∞, the agreement between the calculated curve and the experimental data is fairly good.

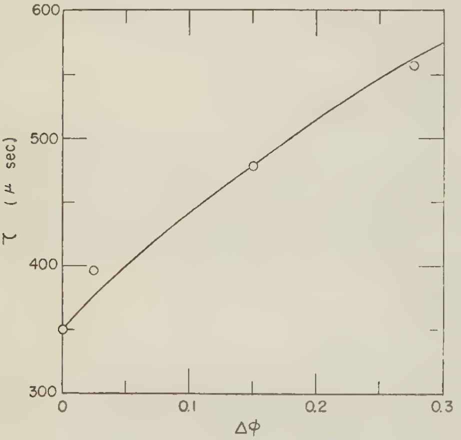

Fig. 1. Lifetime in a p-type germanium sample as a function of excess carrier concentrations injected by the illumination in fundamental absorption band. The open circles represent experimental results. The solid line was calculated from Eq. (5.1) with $\tau_0 = 350\,\mu$ sec and $\tau_\infty = 850\,\mu$ sec.

On the other hand, several authors[3),6),7)] have shown that the lifetime in darkness or without external illumination depends on injection level $\Delta\varphi$ as

$$\tau = \frac{\tau_0 + \tau_\infty \Delta\varphi}{1 + \Delta\varphi}\,. \tag{5.3}$$

Apparently, this expression is simpler than that of Eq. (5.1). Thus, in the case where τ_0 and τ_∞ are determined from the measurements of the dependence of τ on $\Delta\varphi$, it is unfavourable to use the method of varing the intensity of external illumination, even though the injection level $\Delta\varphi$ can be measured exactly.

Furthermore, in Eq. (5.1) τ_0 is a function of temperature and $\Delta\varphi$ may also vary with temperature $(\Delta\varphi \propto (L)^e \cdot \tau(T))$. This implies that the temperature dependence of the lifetime under external illumination is not simple. In other words, even in a single recombination level case, the behavior of the variation of lifetime with temperature can be changed by the application of external illumination. This is contradictory to the interpretation of Ransom and Rose[1)]. Therefore, in order to arrive at the correct interpretation of the process, it is necessary to investigate the variation of lifetime with injection level at various temperatures.

5.2. *Illumination with long wavelength light*

The lifetime for this case is of the form

$$\frac{(\tau_0 + \tau_\infty \Delta\varphi)^2}{\tau_0(1+2\Delta\varphi) + \tau_\infty(\Delta\varphi)^2 + (\tau_0 - \nu\tau_\infty)((1+\Delta\varphi)/(\nu+\Delta\varphi))\Delta\varphi}\,, \tag{5.4}$$

and the variation of τ with $\Delta\varphi$ depends strongly on ν. Especially, if ν is sufficiently small so that $\tau_0 \gg \nu\tau_\infty$, for $\Delta\varphi \ll 1$ we obtain from Eq. (5,4)

$$\tau = \tau_0 \frac{1 + (\Delta\varphi/\nu)}{1 + 2(\Delta\varphi/\nu)}\,, \tag{5.5}$$

and, in contrast with the case discussed in sub-section 5.1, τ decreases with increasing $\Delta\varphi$ even when τ_∞ is larger than τ_0. The dependence of τ on $\Delta\varphi$ is plotted in a qualitative fashion in Fig. 2 for arbitrary values of

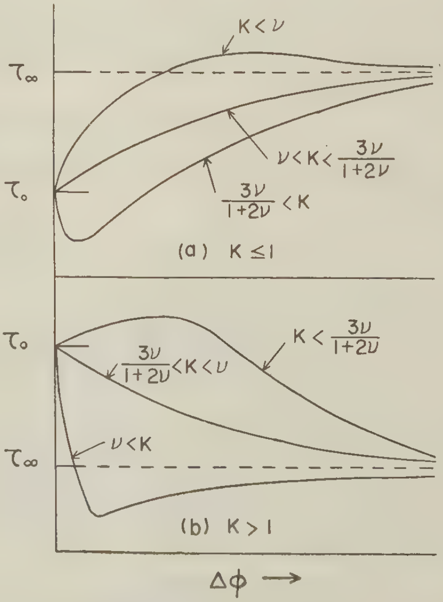

Fig. 2. Dependence of lifetime on excess carrier concentrations injected by the long wavelength light. K is the ratio τ_0/τ_∞.

the parameters τ_0, τ_∞ and ν.

Experimentally, however, in this case it is difficult to obtain a measurable value of $\Delta\varphi$, because the optical absorption due to recombination centers is very small. Thus, in most cases, the effect of the illumination with a long wavelength light may be undetected.

On the other hand, in order to observe this effect, it is necessary to introduce a large amount of recombination centers. In this case, the lifetime decreases considerably and the experimental results must be analyzed by using more general equations such as Eqs. (3.3).

Acknowledgement

The author would like to thank Mr. Katsuhisa Suzuki for making lifetime measurements.

Appendix A

As shown in previous papers,[3),4)] we have from Eqs. from (2.6) to (2.8) the relations between the quantities changed by steady external illumination as follows.

Case A. Illumination in fundamental absorption band

$$\frac{\Delta p}{\Delta n}=\frac{1+H_p}{1+H_n}\,, \tag{A.1}$$

$$\Delta N_j^+=H_{nj}\Delta p-H_{pj}\Delta n\,. \tag{A.2}$$

Case B. Illumination with long wavelength light

$$(1+H_p)\Delta n=(1+H_n)\Delta p+\frac{L_{nt}}{B_{nt}}\,, \tag{A.3}$$

$$\Sigma_j(B_{pj}H_{pj}\Delta n+B_{nj}H_{nj}\Delta p)=\frac{B_{nt}}{B_t}L_{nt}\,, \tag{A.4}$$

and

$$\left.\begin{aligned}\Delta N_j^+&=H_{nj}\Delta p-H_{pj}\Delta n\,,\\ \Delta N_t^+&=H_{nt}\Delta p-H_{pt}\Delta n+\frac{L_{nt}}{B_t}\,.\end{aligned}\right\} \tag{A.5}$$

For the case where the holes in t-level are excited, L_{nt} and $B_{nt}L_{nt}$ must be replaced by $-L_{pt}$ and $B_{pt}L_{pt}$ respectively. Here H_n, H_p and B_j are given by Eqs. (3.6) and (3.7).

Appendix B

As shown by Wertheim,[6)] τ_+ and τ_- in Eq. (4.1) are given by

$$\tau_\pm=\frac{2}{(\alpha_n+\alpha_p)[1\pm(1-y)^{1/2}]}\,, \tag{B.1}$$

where

$$y=4(\alpha_n\alpha_p-\beta_n\beta_p)(\alpha_n-\alpha_p)^{-2}\,, \tag{B.2}$$

and

$$\left.\begin{aligned}\alpha_n&=\gamma_n[(N_0^++\Delta N^+)+(n_0+n_1+\Delta n)]\,,\\ \beta_n&=\gamma_n(n_0+n_1+\Delta n)\,,\\ \alpha_p&=\gamma_p[(N_0^--\Delta N^+)+(p_0+p_1+\Delta p)]\,,\\ \beta_p&=\gamma_p(p_0+p_1+\Delta p)\,.\end{aligned}\right\} \tag{B.3}$$

If the density of recombination centers is sufficiently small so that $N_0^+<(n_0+n_1)$ and $N_0^-<(p_0+p_1)$, these two time constants are expressed as

$$\tau_-=\frac{\alpha_n+\alpha_p}{\alpha_n\alpha_p-\beta_n\beta_p}\,,\qquad \tau_+=\frac{1}{\alpha_n+\alpha_p}\,. \tag{B.4}$$

Appendix C

The coefficients in Eq. (4.5) are given by

$$\left.\begin{aligned}p&=a_{11}+a_{22}+a_{33}\,,\\ q&=a_{11}a_{22}+a_{22}a_{33}+a_{33}a_{11}-a_{12}a_{21}\\ &\quad-a_{23}a_{32}-a_{31}a_{13}\,,\\ r&=a_{11}a_{22}a_{33}+a_{12}a_{23}a_{31}+a_{21}a_{32}a_{13}\\ &\quad-a_{11}a_{23}a_{32}-a_{22}a_{31}a_{13}-a_{33}a_{12}a_{21}\,,\end{aligned}\right\} \tag{C.1}$$

where

$$\left.\begin{aligned}a_{11}&=\gamma_{n1}(N_1^++\Delta N_1^+)+\gamma_{n2}(N_2^++\Delta N_2^+)\\ &\quad+\gamma_{n2}(n_0+n_2+\Delta n)\,,\\ a_{12}&=-\gamma_{n2}(n_0+n_2+\Delta n)\,,\\ a_{13}&=\gamma_{n1}(n_0+n_1+\Delta n)-\gamma_{n2}(n_0+n_2+\Delta n)\,,\\ a_{21}&=-\gamma_{p2}(p_0+p_2+\Delta p)\,,\\ a_{22}&=\gamma_{p1}(N_1^--\Delta N_1^+)+\gamma_{p2}(N_2^--\Delta N_2^+)\\ &\quad+\gamma_{p2}(p_0+p_2+\Delta p)\,,\\ a_{23}&=-\gamma_{p1}(p_0+p_1+\Delta p)\\ &\quad+\gamma_{p2}(p_0+p_2+\Delta p)\,,\\ a_{31}&=\gamma_{n1}(N_1^++\Delta N_1^+)\,,\\ a_{32}&=-\gamma_{p1}(N_1^-+\Delta N_1^+)\,,\\ a_{33}&=\gamma_{n1}(n_0+n_1+\Delta n)+\gamma_{p1}(p_0+p_1+\Delta p)\,.\end{aligned}\right\}$$

Dynamical Theory of Electron Diffraction in Laue-case*, I. General Theory

By Fuminori FUJIMOTO

Institute of Physics, College of General Education,
University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received July 2, 1959)

A new formulation of the theory of electron diffraction for the Laue-case, based upon the matrix representation of Niehrs and Wagner, is presented by introducing the scattering matrix for an electron elastically scattered by a plate-like crystal. The intensity and also the integrated intensity of reflections for thin crystals are computed. The results obtained here indicate that the intensity does not approach to that of the pseudo-kinematical theory, but to that of the kinematical theory. The theory predicts also the failure of Friedel's law in the case of non centro-symmetric crystals. The formula for the scattered amplitude can be transformed into the form which coincides with the result given by Cowley and Moodie derived on the basis of the Huygens' principle.

§ 1. Introduction

In the dynamical theory of electron diffraction, initiated by Bethe,1) the Schrödinger equation for an electron in the periodic potential of a crystal is solved under appropriate boundary conditions, by assuming the wave function to be the superposition of plane waves. The problem is reduced, in this case, to solve the secular equation of infinite order.2) For the practical calculation, the number of waves is reduced by neglecting all waves other than the incident and a few reflected waves. Such a treatment, however, becomes rapidly difficult with increasing number of waves, and in the usual treatment of the "*two-wave approximation*", only two waves, the incident and a diffracted, are considered. However, the other diffracted waves which are neglected in the two-wave approximation may sometimes take an important role, e.g. in the forbidden reflection such as the 222-reflection from diamond type crystals3),4) and in the failure or Friedel's law.5),6)

In order to take into account the effect of other reflection waves, Bethe1) introduced the so called "*dynamic potential*" instead of v_h, the Fourier component of the periodic potential in crystal. However, this procedure does not only give the exact solution, but it sometimes leads to serious paradox as to the diffracted intensity in the Laue-case for a thin crystal, as pointed out by Miyake.7)

For the sake of more extensive treatment of many reflections, Niehrs and Wagner8) used the matrix representation and derived some useful relations among the waves in the crystal. In the present paper, the scattering matrix,9) which connects the amplitudes of the incident and the diffracted waves, for an infinite, parallel-sided crystal plate in the Laue-case, is obtained by extending their theory. The intensity of diffracted waves and also the integrated intensity of reflection are obtained, without solving the secular equation, by expanding the component of the scattering matrix in the power series of $D/2k$, where D is the thickness of the crystal and k, the wave number of electron in crystal. The intensity obtained by the present method is in accordance with the result of the recent theory of Cowley and Moodie10) which was derived by appling Huygens' principle for the electron diffraction, and Fujiwara's theory11) which was derived by the interation of the Born approximation for the scattered waves within the crystal.

§ 2. Scattering Matrix

The Schrödinger equation for an electron of energy E in a field of the crystal potential $V(\boldsymbol{r})$ has the form:

$$\Delta\Psi+\frac{8\pi^2m}{h^2}\{E-V(\boldsymbol{r})\}\Psi=0\,. \qquad (1)$$

---

* During the preparation of this manuscript, the author was told that H. Niehrs had independently developed a similar theory.

The potential $V(\boldsymbol{r})$ and the wave function can be expanded as

$$\left.\begin{aligned} &-\frac{8\pi^2 m}{h^2}V(\boldsymbol{r})=\sum_h v_h \exp(i\boldsymbol{b}_h\cdot\boldsymbol{r}) ,\\ &\text{and}\\ &\Psi=\sum_h \psi_h \exp(i\boldsymbol{k}_h\cdot\boldsymbol{r}) \quad (\boldsymbol{k}_h=\boldsymbol{k}_0+\boldsymbol{b}_h), \end{aligned}\right\} \qquad (2)$$

where $\boldsymbol{b}_h$ is 2π-times the reciprocal lattice vector and $\boldsymbol{k}_h$ is the wave vector of the $\boldsymbol{h}$-reflection wave. Substituting (2) into (1), we obtain

$$(k^2-k_h^2)\psi_h+\sum_{g\neq h} v_{h-g}\psi_g=0 , \qquad (3)$$

where

$$k^2=\frac{8\pi^2 m}{h^2}(E+v_0) .$$

If we express (3) in matrix representation, we obtain

$$\begin{pmatrix} \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots k^2-k_0^2 \cdots v_{0h} \cdots v_{0g} \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots v_{h0} \cdots k^2-k_h^2 \cdots v_{hg} \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots v_{g0} \cdots v_{gh} \cdots k^2-k_g^2 \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \end{pmatrix} \begin{pmatrix} \vdots \\ \psi_0 \\ \vdots \\ \psi_h \\ \vdots \\ \psi_g \\ \vdots \end{pmatrix} =0, \qquad (4)$$

where

$$v_{lm}=v_{l-m}=v_{ml}^* . \qquad (5)$$

Introducing the "Ampassung" ζ and the "Anregungsfelher" ρ_h (Fig. 1), we have

$$k_h=k-\rho_h-\zeta\cos\theta_h . \qquad (6)$$

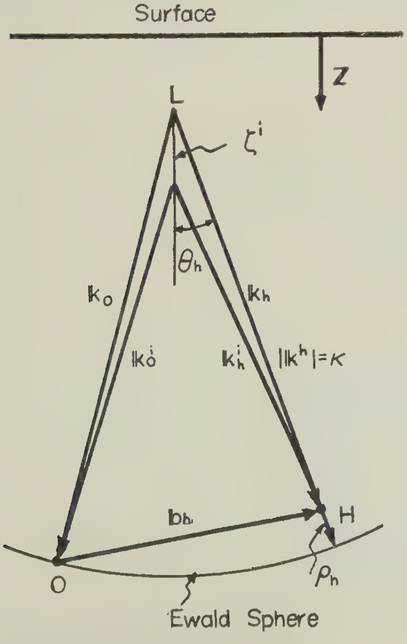

Fig. 1. Construction I.

In the Laue-case, ζ is so small in comparison with k that we may neglect ζ^2 and $\rho\zeta$, and further we can assume $\cos\theta_h=1$. Hence, $(k^2-k_h^2)$ may be written as

$$k^2-k_h^2=2k\zeta+2k\rho_h+\rho_h^2=-x+p_h , \qquad (6)$$

where

$$2k\zeta=-x , \quad \text{and} \quad 2k\rho_h+\rho_h^2=p_h . \qquad (8)$$

If only the reciprocal lattice points are considered which lie on a plane passing through the origin and being nearly perpendicular to the incident direction, p_h depends only on the component of k along that plane but not on the magnitude of k.

Substituting (7) into (4), we obtain

$$\mathrm{M}\phi=x\phi , \qquad (9)$$

where M is an hermitian matrix given by

$$\mathrm{M}=\begin{pmatrix} \cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots p_0 \cdots v_{0h} \cdots v_{0g} \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots v_{h0} \cdots p_h \cdots v_{hg} \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots v_{g0} \cdots v_{gh} \cdots p_g \cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots \end{pmatrix} . \qquad (10)$$

Matrix M is independent of k, so that, the eigen value x^i and the eigen vector ϕ^i whose components are $\cdots\psi_0^i, \cdots\psi_h^i, \cdots\psi_g^i, \cdots$ are also independent of k.

Assuming that the incident wave is of unit amplitude and ϕ^i is normalized, we can put the amplitude of the $\boldsymbol{h}$-wave belonging to the i-th wave field as

$$u_h^i=\alpha_i\psi_h^i ,$$

where α_i is the coefficient which is determined by the boundary condition at the entrance surface given by

$$\sum_i u_h^i=\sum_i \alpha_i\psi_h^i=\delta_{h0} . \qquad (11)$$

Multiplying the both sides of (11) by ψ_h^{j*} and summing up with the index h, we obtain α_j from the orthogonality of the eigen vector ϕ^i:

$$\alpha_j=\psi_0^{j*} .$$

Then we have

$$u_h^i=\psi_0^{i*}\psi_h^i . \qquad (12)$$

This result was previously given by Niehrs and Wagner.[8)]

The wave function for the $\boldsymbol{h}$-reflection is given by

$$\Psi_h=\sum_i u_h^i \exp(i\boldsymbol{k}_h^i\cdot\boldsymbol{r}) , \qquad (13)$$

where $\boldsymbol{k}_h^i$ is the wave vector of the $\boldsymbol{h}$-reflection of the i-th wave field and may be written in terms of of ζ^i and wave vector $\boldsymbol{k}_h$ corresponding to the wave point L for which $\zeta=0$ (Fig. 1), namely

$$\boldsymbol{k}_h{}^i=\boldsymbol{k}_h-\zeta^i\boldsymbol{z}\ , \tag{14}$$

where $\boldsymbol{z}$ is the unit vector normal to the crystal surface directing inwardly. Substituting (8), (12) and (14) into (13), we get

$$\begin{aligned}\Psi_h&=\sum_i \psi_0{}^{i*}\psi_h{}^i \exp(-i\zeta^i z)\exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})\\&=\sum_i \psi_0{}^{i*}\psi_h{}^i \exp\left(i\frac{z}{2k}x^i\right)\exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})\ .\end{aligned} \tag{15}$$

On the other hand, we obtain the following equation from (9) for one of the eigen values:

$$\mathrm{M}^n\boldsymbol{\psi}^i=(x^i)^n\boldsymbol{\psi}^i\ ,$$

and for the h-component:

$$(x^i)^n\psi_h{}^i=\sum_g \psi_g{}^i(\mathrm{M}^n)_{hg}\ , \tag{16}$$

where $(\mathrm{M}^n)_{hg}$ is the h, g component of the matrix M^n. Multiplying the both sides of (16) by $\psi_0{}^{i*}$ and summing up with i, we get

$$\begin{aligned}\sum_i (x^i)^n\psi_0{}^{i*}\psi_h{}^i&=\sum_i\sum_g \psi_0{}^{i*}\psi_g{}^i(\mathrm{M}^n)_{hg}\\&=\sum_g\Big(\sum_i \psi_0{}^{i*}\psi_g{}^i\Big)(\mathrm{M}^n)_{hg}=(\mathrm{M}^n)_{h0}\ ,\end{aligned} \tag{17}$$

since we have

$$\sum_i \psi_0{}^{i*}\psi_g{}^i=\delta_{g0}$$

by the boundary condition. Using (17), we can rewrite equation (15) as follows:

$$\begin{aligned}\Psi_h&=\sum_i\left[\psi_0{}^{i*}\psi_h{}^i\sum_n\frac{1}{n!}\left(i\frac{z}{2k}x^i\right)^n\right]\exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})\\&=\left[\exp\left(i\frac{z}{2k}\mathrm{M}\right)\right]_{h0}\exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})\ .\end{aligned} \tag{18}$$

This represents that the amplitude of the $\boldsymbol{h}$-reflection wave in the crystal is given by

$$\left[\exp\left(i\frac{z}{2k}\mathrm{M}\right)\right]_{h0}.$$

When we apply (18) for the plate-like crystal with thickness D and assume the amplitude of incident wave is Φ_0, the amplitude φ_h of the diffracted waves at the exit surface is given by

$$\begin{pmatrix}\varphi_0\\ \varphi_1\\ \varphi_2\\ \vdots\end{pmatrix}=\exp\left(i\frac{D}{2k}\mathrm{M}\right)\begin{pmatrix}\Phi_0\\ 0\\ 0\\ \vdots\end{pmatrix},$$

where S is the scattering matrix given by

$$\mathrm{S}=\exp\left(i\frac{D}{2k}\mathrm{M}\right). \tag{19}$$

The wave function of the scattered wave transmitted from the exit surface of the crystal is written as

$$\Psi=\sum_h \Phi_0\mathrm{S}_{h0}\exp[i(\gamma_h-\Gamma_h)D]\exp(i\boldsymbol{K}_h\cdot\boldsymbol{r})\ ,$$

where $\boldsymbol{K}_h$ is the wave vector of the $\boldsymbol{h}$-reflection in vacuum and γ_h and Γ_h are the normal components of $\boldsymbol{k}_h$ and $\boldsymbol{K}_h$ respectively.

In the case where we cannot put $\cos\theta_h=1$, we can also obtain the scattering matrix in a similar way as above. The results are given in Appendix.

§ 3. Intensity

According to (18), the intensity of the $\boldsymbol{h}$-reflection wave is given by

$$I_h=\left|\left[\exp\left(i\frac{D}{2k}\mathrm{M}\right)\right]_{h0}\right|^2,$$

which may be expanded as follows:

$$\begin{aligned}I_h=&\left(\frac{D}{2k}\right)^2|\mathrm{M}_{h0}|^2+\frac{i}{2}\left(\frac{D}{2k}\right)^3[(\mathrm{M}^2)_{h0}\mathrm{M}_{h0}{}^*-\mathrm{M}_{h0}(\mathrm{M}^{*2})_{h0}]\\&-\left(\frac{D}{2k}\right)^4\left[\frac{1}{6}(\mathrm{M}^3)_{h0}\mathrm{M}_{h0}{}^*-\frac{1}{4}(\mathrm{M}^2)_{h0}(\mathrm{M}^{*2})_{h0}+\frac{1}{6}\mathrm{M}_{h0}(\mathrm{M}^{*3})_{h0}\right]+\cdots\ ,\end{aligned} \tag{20}$$

where M* is the conjugate matrix of M. The first term of (20) is

$$\left(\frac{D}{2k}\right)^2|\mathrm{M}_{h0}|^2=\left(\frac{D}{2k}\right)^2|v_h|^2\ . \tag{21}$$

The 2nd term is

$$\begin{aligned}
&\frac{i}{2}\left(\frac{D}{2k}\right)^3[(\mathrm{M}^2)_{h0}\mathrm{M}_{h0}{}^*-\mathrm{M}_{h0}(\mathrm{M}^{*2})_{h0}]\\
&=\frac{i}{2}\left(\frac{D}{2k}\right)^3[\{\sum_g{}'v_{h-g}v_g+v_h(p_0+p_h)\}v_h{}^*-v_h\{\sum_g{}'v_{h-g}{}^*v_g{}^*+v_h{}^*(p_0+p_h)\}]\\
&=\frac{i}{2}\left(\frac{D}{2k}\right)^3[v_h{}^*\sum_g{}'v_{h-g}v_g-v_h\sum_g{}'v_{h-g}{}^*v_h{}^*]\\
&=\left(\frac{D}{2k}\right)^3\mathfrak{I}(v_h\sum_g{}'v_{-g}v_{g-h})\ ,
\end{aligned}\tag{22}$$

where the symbol $\mathfrak{I}$ indicates the imaginary part and the prime after the symbol $\sum$ indicates the absence of zero and h terms. The 3rd term is

$$\begin{aligned}
&\left(\frac{D}{2k}\right)^4\left[\frac{1}{4}|(\mathrm{M}^2)_{h0}|^2-\frac{1}{3}\mathfrak{R}\{(\mathrm{M}^3)_{h0}\mathrm{M}_{h0}{}^*\}\right]\\
&=\left(\frac{D}{2k}\right)^4\Bigg[\frac{1}{4}|\sum_g{}'v_{h-g}v_g|^2+\frac{1}{2}(p_0+p_h)\mathfrak{R}\{v_{-h}\sum_g{}'v_{h-g}v_g\}+\frac{1}{4}|v_h|^2(p_0+p_h)^2\\
&\quad-\frac{1}{3}\mathfrak{R}\Bigg\{v_{-h}\{v_h{}^3+v_h(p_0{}^2+p_0p_h+p_h{}^2)+v_h\sum_g{}'|v_g|^2+v_h\sum_g{}'|v_{h-g}|^2\\
&\quad+(p_0+p_h)\sum_g{}'v_{h-g}v_g+\sum_{\substack{g,l\\ g\neq l}}{}'v_{h-g}v_{g-l}v_l+\sum_g{}'p_gv_{h-g}v_g\}\Bigg\}\Bigg]\,.
\end{aligned}\tag{23}$$

where the symbol $\mathfrak{R}$ indicates the real part.

The higher order terms are much more complicated. If the crystal is sufficiently thin and the accerelating voltage sufficiently high, the higher terms can be neglected.

§ 4. Comparison of the Present Theory with the Kinematical Theory

When D is small or k is large we may neglect higher order terms in (20), and obtain

$$I_h=\left(\frac{D}{2k}\right)^2|v_h|^2\,. \tag{24}$$

This indicates that for thin crystals, (i) the intensity given by the dynamical theory coincides with that of kinematical theory, even if we take into account many reflections, and (ii) the intensity is independent of the incident direction, since (24) does not include any factor dependent upon the incident direction. This means, in terms of the Ewald construction, that the reciprocal lattice points are elongated in the direction normal to the crystal surface, just as in the kinematical theory for very thin crystals, and this circumstance may explain the appearance of the cross grating pattern. It must be noted here, however, that the critical thickness of the crystal within which (24) holds varies with the incident direction. As we shall see in the next paper, (24) is applicable up to a certain value of the thickness of crystal. This thickness is largest at the Bragg position and decreases as the direction of the incident beam deviates from the Bragg position. A rough estimation shows that this critical thickness at the Bragg position is about 15A for the 111-reflection from Au.

When $D/2k$ is large, the value of the third term including p_h, which depends on the incident beam, becomes appreciable, and by this contribution the intensity falls rapidly for increasing value of p_h. Thus the characteristic of the two-dimensional pattern becomes gradually lost with increasing $D/2k$.

§ 5. Relation between the Scattering Matrix and the Two-wave Approximation

It is of interest to study the relation between the treatments by the scattering matrix and that by the two-wave approximation. Select the terms related only with the indices 0 and h from each of the terms in the expansion series of the matrix component S_{h0}. Then we can see that the sum of these terms coincides with the h, 0 component of the scattering matrix S_B for two-wave approximation, which is expressed by

$$S_B=\exp\left(i\frac{D}{2k}M_B\right),$$

where

$$M_B=\begin{pmatrix} p_0 & v_{-h} \\ v_h & p_h \end{pmatrix}.$$

The amplitude of **h**-reflection, φ_h, can be written as

$$\varphi_h=\varphi_h{}^B+\varphi_h{}',$$

where $\varphi_h{}^B$ is the amplitude calculated exactly by the two-wave approximation as

$$\varphi_h{}^B=\frac{2v_h i}{\sqrt{(p_0-p_h)^2+4v_h{}^2}}\cdot\sin\left(\frac{1}{2}\sqrt{(p_0-p_h)^2+4v_h{}^2}\,\frac{z}{2k}\right)\cdot\exp\left(i\frac{z}{2k}\,\frac{p_0+p_h}{2}\right),$$

and $\varphi_h{}'$ is the sum of terms which involve 0, h and other indices and represents the contribution due to the interaction of 0-and h-waves with other waves.

§ 6. Failure of Friedel's Law

The experimental observation of the failure of Friedel's law was reported on zincblend by Miyake and Uyeda[5] and the theoretical explanation by Kohra,[6] who considered the simultanious reflection of 331 and 33$\bar{1}$ in the Bragg case.

The second term in (20) vanishes for centro-symmetric crystals, but not for non-centro-symmetric crystals. In the latter case, the intensity of **h**- and $\bar{\boldsymbol{h}}$-reflection becomes

$$\left.\begin{aligned} I_h&=\left(\frac{D}{2k}\right)^2|v_h|^2+\left(\frac{D}{2k}\right)^3\Im\Big(v_h{\sum_g}'v_{-g}v_{g-h}\Big)+\cdots \\ &\text{and} \\ I_{-h}&=\left(\frac{D}{2k}\right)^2|v_h|^2-\left(\frac{D}{2k}\right)^3\Im\Big(v_h{\sum_g}'v_{-g}v_{g-h}\Big)+\cdots, \end{aligned}\right\} \qquad (25)$$

This indicates the failure of Friedel's law in the Laue-case. The difference between I_h and I_{-h} appears in the third power of $D/2k$ and this term is independent of the incident direction. In general, this difference appears in each odd power term which vanishes for centro-symmetric crystals.

As we see from (25), the asymmetry of the intensity arises from the interaction of weak waves, without any strong simultanious reflection. This may also be valid in the Bragg-case.

§ 7. Integrated Intensity

For experimental verification of the theory, it is necessary to calculate the intengrated intensity of the reflection. The integrated intensity for the Laue-case was given by Blackman[12] on the basis of the two-wave approximation. But his result may not be applicable when the interaction with other waves are strong. Let us now consider the integrated intensity of the **h**-reflection by the present formulation. When the crystal is slightly out of the Bragg position, the intensity of reflection becomes weak and the influence of the interactions due to weak waves becomes relatively important. In particular, the so called "*systematic interactions*", the interactions between the reflections corresponding to the reciprocal lattice points lying on the lattice row passing through the origin and the reciprocal lattice point H is important[4]. In the following we consider only the "systematic interactions", and further assume that $\overline{OH}$ is parallel to the surface and that every Fourier coefficient of the potential is real.

When $D/2k$ is small, (24) is valid at the Bragg position. Outside the Bragg position, however, we should take into account the higher order terms, and we have

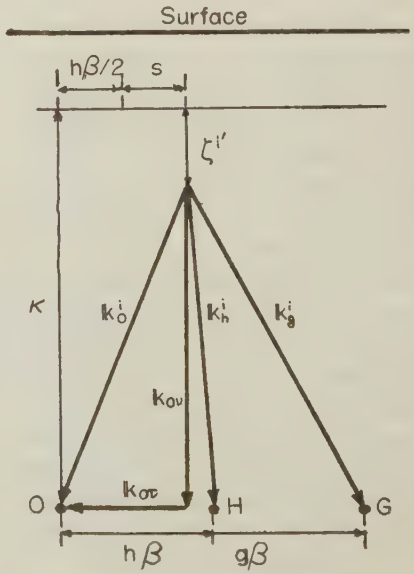

Fig. 2. Construction II.

$$I_h=\left(\frac{D}{2k}\right)^2 v_h{}^2-\frac{1}{12}\left(\frac{D}{2k}\right)^4[v_h{}^2\{4(v_h{}^2+2\sum_g{}' v_g{}^2)+(p_0-p_h)^2\}$$
$$-3(\sum_g{}' v_{h-g}v_g)^2-2(p_0+p_h)v_h\sum_g{}' v_{h-g}v_g+4v_h\sum_{\substack{g,l\\ g\neq l}}{}' v_{h-g}v_{g-l}v_l+4v_h\sum_g{}' p_g v_{h-g}v_g]+\cdots. \tag{26}$$

Introducing the new parameters ζ' for ζ, and s as are shown in Fig. 2, we have

$$k_{0\nu}+\zeta'=k\,, \qquad k_{0\tau}=\frac{h}{2}\beta+s\,,$$

where τ and ν indicate the tangential and normal components with respect to the surface, respectively, and $\beta=2\pi/d$. Thus, we have

$$p_0=-\left(\frac{h}{2}\beta+s\right)^2, \qquad p_h=-\left(\frac{h}{2}\beta-s\right)^2, \qquad \text{and} \qquad p_g=-\left(g\beta-\frac{h}{2}\beta-s\right)^2. \tag{27}$$

Substituting (27) into (26) and neglecting the higher order terms, we have

$$I_h=\left(\frac{D}{2k}\right)^2 v_h{}^2-\frac{1}{12}\left(\frac{D}{2k}\right)^4[4v_h{}^2(v_h{}^2+2\sum_g{}' v_g{}^2)-3(\sum_g{}' v_{h-g}v_g)^2$$
$$+4v_h\sum_{\substack{g,l\\ g\neq l}}{}' v_{h-g}v_{g-l}v_l-4v_h\sum_g{}' v_{h-g}v_g(g^2-hg)\beta^2]-\frac{1}{3}\left(\frac{D}{4k}\right)^4 v_h{}^2(h\beta s)^2\,. \tag{28}$$

The integrated intensity can be expressed as

$$J_h=\int_{-\infty}^{+\infty} I_h d\alpha=\frac{1}{k}\int_{-\infty}^{+\infty} I_h ds\,.$$

If we take into account all the terms in I_h, I_h is positive for any value of s. But if we take only the first two terms in (26), I_h becomes negative for the value of s beyond the certain value s_0, for which I_h given by (28) is zero. As the value of I_h near the Bragg position is important in the integration, we approximately get

$$J_h=\frac{1}{k}\int_{-s_0}^{s_0} I_h ds=\frac{4}{3k}\Bigg[\left(\frac{D^2}{2k}\right)v_h{}^2-\frac{1}{12}\left(\frac{D}{2k}\right)^4\{4v_h{}^2(v_h{}^2+2\sum_g{}' v_g{}^2)-3(\sum_g{}' v_{h-g}v_g)^2+4v_h\sum_{\substack{g,l\\ g\neq l}}{}' v_{h-g}v_{g-l}v_l$$
$$-4v_h\sum_g{}' v_{h-g}v_g(g^2-hg)\beta^2\}\Bigg]^{3/2}\left\{\frac{1}{3}\left(\frac{D}{2k}\right)^2 v_h{}^2(h\beta)^2\right\}^{-1/2}.$$

When v_h is neither zero nor very small, J_h can be rewritten as

$$J_h=\frac{2\sqrt{3}}{3}\frac{D}{2k^3}\frac{v_h{}^2}{\theta_0}\Bigg[1-\frac{1}{2}\left(\frac{D}{2k}\right)^2\Bigg\{v_h{}^2+2\sum_g{}' v_g{}^2-\frac{3}{4}\left(\sum_g{}'\frac{v_{h-g}v_g}{v_h}\right)^2$$
$$+\frac{1}{v_h}(\sum_{\substack{g,l\\ g\neq l}}{}' v_{h-g}v_{g-l}v_l-\sum_g{}' v_{h-g}v_g(g^2-hg)\beta^2)\Bigg\}\Bigg], \tag{29}$$

where $\theta_0=h\beta/2k$ is the Bragg angle. For small value of $D/2k$, the second terms in the bracket of (29) can be neglected and we have

$$J_h=1.15\frac{D}{2k^3}\frac{v_h{}^2}{\theta_0}\,. \tag{30}$$

The integrated intensity is proportional to the square of v_h in accordance with the characteristic of the kinematical theory, and (30) coincide with the corresponding formula of Blackman except for the numerical factor 1.15. The appearance of this factor may be due to the neglect of higher terms, for if we make a similar approximation in Blackman's formulation, we have the same factor.

When v_h is zero, the integrated intensity can be calculated by taking into account the higher order terms. This will be discussed, in the next paper, for the case of the 222-reflection for the crystal of diamond type for which $v_{222}=0$.

§ 8. Another Method of Calculation of the Scattering Matrix

In the preceding sections we studied the power expansion of the amplitude of diffracted waves with respect to $D/2k$. In this section, we consider the expansion with respect to the Fourier coefficient v's.

The matrix element $(\mathrm{M}^n)_{h0}$ is given by the sum of terms of the n-th order product of v's and p's. Select from the sum the terms including the m-th order product of v's, say v_{h-g_1}, $v_{g_1-g_2}$, $\cdots$, $v_{g_{m-1}}$, then the sum of these terms makes the $n-m$-th order homogeneous and symmetric polynomial with respect to p's. This polynominal can be written in the form

$$v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}\left[\frac{p_0^n}{(p_0-p_h)(p_0-p_{g_1})\cdots(p_0-p_{g_{m-1}})}+\frac{p_h^n}{(p_h-p_0)(p_h-p_{g_1})\cdots(p_h-p_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{p_{g_i}^n}{(p_{g_i}-p_0)(p_{g_i}-p_h)(p_{g_i}-p_{g_1})\cdots(p_{g_i}-p_{g_{i-1}})(p_{g_i}-p_{g_{i+1}})\cdots(p_{g_i}-p_{g_{m-1}})}\right]. \tag{31}$$

The term (31) is not contained in $(\mathrm{M}^n)_{h0}$ for which $n<m$. Since, however, the braket in (31) vanishes for $0\leqq n<m$, we can add these zero terms to the terms including m-th order product of v in the expansion of S_{h0}. We have thus

$$\sum_{n=0}^{\infty}\sum_{g_1g_2\cdots g_{m-1}}\frac{1}{n!}\left(i\frac{z}{2k}\right)^n v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}$$
$$\times\left[\frac{p_0^n}{(p_0-p_h)(p_0-p_{g_1})\cdots(p_0-p_{g_{m-1}})}+\frac{p_h^n}{(p_h-p_0)(p_h-p_{g_1})\cdots(p_h-p_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{p_{g_i}^n}{(p_{g_i}-p_0)(p_{g_i}-p_h)(p_{g_i}-p_{g_1})\cdots(p_{g_i}-p_{g_{i-1}})(p_{g_i}-p_{g_{i+1}})\cdots(p_{g_i}-p_{g_{m-1}})}\right]$$
$$=\sum_{g_1g_2\cdots g_{m-1}}v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}$$
$$\times\left[\frac{\exp(i\cdot z/2k\cdot p_0)}{(p_0-p_h)(p_0-p_{g_1})\cdots(p_0-p_{g_{m-1}})}+\frac{\exp(i\cdot z/2k\cdot p_h)}{(p_h-p_0)(p_h-p_{g_1})\cdots(p_h-p_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{\exp(i\cdot z/2k\cdot p_{g_i})}{(p_{g_i}-p_0)(p_{g_i}-p_h)(p_{g_i}-p_{g_1})\cdots(p_{g_i}-p_{g_{i-1}})(p_{g_i}-p_{g_{i+1}})\cdots(p_{g_i}-p_{g_{m-1}})}\right], \tag{32}$$

where the symbol $\sum\limits_{g_1g_2\cdots g_{m-1}}$ indicates the sum for all the possible permutations of $m-1$ values of g under the condition $h-g_1$, g_1-g_2, $\cdots$, $g_{m-1}\neq 0$. If we put $p_0=0$, and $p_g=2k\rho_g$ neglecting ρ_g^2 in (8), we have for (31)

$$\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{(2k)^{m-1}}\left[\frac{(2k\rho_h)^{n-1}}{(\rho_h-\rho_{g_1})(\rho_h-\rho_{g_2})\cdots(\rho_h-\rho_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{(2k\rho_{g_i})^{n-1}}{(\rho_{g_i}-\rho_h)(\rho_{g_i}-\rho_{g_1})\cdots(\rho_{g_i}-\rho_{g_{i-1}})(\rho_{g_i}-\rho_{g_{i+1}})\cdots(\rho_{g_i}-\rho_{g_{m-1}})}\right]. \tag{31$'$}$$

Therefore, we have for (32)

$$\sum_{g_1g_2\cdots g_{m-1}}\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{(2k)^m}\left[\frac{\exp(iz\rho_h)-1}{\rho_h(\rho_h-\rho_{g_1})(\rho_h-\rho_{g_2})\cdots(\rho_h-\rho_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{\exp(iz\rho_{g_i})-1}{\rho_{g_i}(\rho_{g_i}-\rho_h)(\rho_{g_i}-\rho_{g_1})\cdots(\rho_{g_i}-\rho_{g_{i-1}})(\rho_{g_i}-\rho_{g_{i+1}})\cdots(\rho_{g_i}-\rho_{g_{m-1}})}\right]. \tag{32$'$}$$

And (18) can be written as follows:

$$\Psi_h=\sum_{m=1}^{\infty}\sum_{g_1g_2\cdots g_{m-1}}\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{(2k)^m}\left[\frac{\exp(iz\rho_h)-1}{\rho_h(\rho_h-\rho_{g_1})\cdots(\rho_h-\rho_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{\exp(iz\rho_{g_i})-1}{\rho_{g_i}(\rho_{g_i}-\rho_h)(\rho_{g_i}-\rho_{g_1})\cdots(\rho_{g_i}-\rho_{g_{i-1}})(\rho_{g_i}-\rho_{g_{i+1}})\cdots(\rho_{g_i}-\rho_{g_{m-1}})}\right]$$
$$\times\exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})$$
$$=\sum_{m=1}^{\infty}\sum_{g_1g_2\cdots g_{m-1}}\exp(-i\rho_hz)\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{(2k)^m}\left[\frac{\exp(iz\rho_h)-1}{\rho_h(\rho_h-\rho_{g_1})\cdots(\rho_h-\rho_{g_{m-1}})}\right.$$
$$\left.+\sum_{i=1}^{m-1}\frac{\exp(iz\rho_{g_i})}{\rho_{g_i}(\rho_{g_i}-\rho_h)(\rho_{g_i}-\rho_{g_1})\cdots(\rho_{g_i}-\rho_{g_{i-1}})(\rho_{g_i}-\rho_{g_{i+1}})\cdots(\rho_{g_i}-\rho_{g_{m-1}})}\right]$$
$$\times\exp(i\boldsymbol{k}^h\cdot\boldsymbol{r})\,, \tag{33}$$

since $k_h=k^h-\rho_h$, where $\boldsymbol{k}^h$ is the vector in the direction of $\boldsymbol{k}_h$ and $|\boldsymbol{k}^h|=k$ (see Fig. 1). (33) coincides with the result given by Cowley and Moodie,10) which was obtained by the iteration of Huygens' principle.

If we take into account the direction cosine of the wave vector of each wave with respect to the surface normal, which we have assumed to the equal to unity, we get the result coinciding with that of Fujiwara's theory11) which was deduced by the iteration of Born approximation (see Appendix).

§ 9. Discussions

i) Bethe's second approximation

It is usually believed that the intensity of reflection at the Bragg position in the Laue-case for small D or large k, approaches to that due to the kinematical theory. This conclusion was derived from the two-wave approximation of Bethe. However, as Miyake7) has recently pointed out, Bethe's result for the small limit of $D/2k$ does not coincide with that of the kinematical theory if we use, instead of v_h, the dynamic potential V_{12} given by

$$V_{12}=v_h-\sum_g{}'\frac{v_{h-g}v_h}{k^2-k_g^2}\,.$$

Let us use g and g' for the upper index i in $u_h{}^i$ corresponding to the couple of branches of dispersion surface passing through the vicinity of the section of the two spheres of radius k, having the reciprocal lattice points G and H–G as centres (see Fig. 3). Then, we can say that the dynamic potential was introduced by taking into account only the weak waves $u_g{}^h$ and $u_g{}^{h'}$ ($g\neq 0$, h), whose amplitudes are approximately given by

$$u_g{}^{h,h'}=-\frac{u_0{}^{h,h'}v_g+u_h{}^{h,h'}v_{g-h}}{k^2-k_g{}^2}\,.$$

Since this relation may be accurate except for small $k^2-k_g{}^2$, the geometry of dispersion surface (h and h') may be corrected fairly well by taking into account the effect of the weak waves $u_g{}^h$ etc.

On the other hand, in the present theory, by which formally the same intensity limit is obtained as that of the two-wave approximation, namely, that of the kinematical theory, for small D and λ, the weaks $\boldsymbol{h}$-

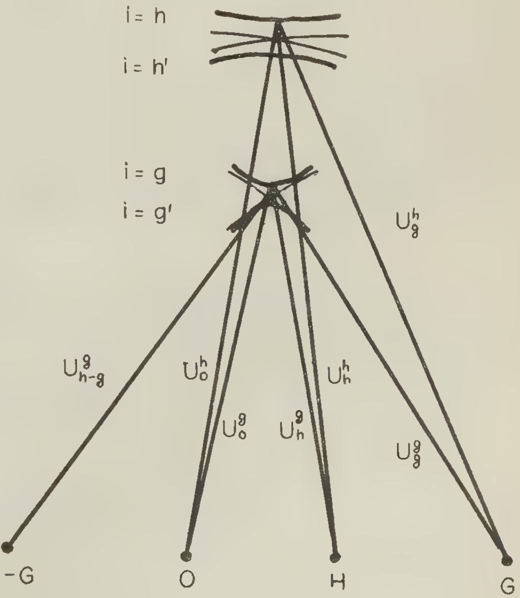

Fig. 3. The relation between amplitude and wave field.

waves u_h^g, $u_h^{g'}$ etc. are taken into account besides the u_g^h etc. The effect of the waves u_h^g, $u_h^{g'}$ etc. may be important especially for the limit of small $D/2k$. The failure of the use of the dynamic potential in calculating the intensity of reflection in thin limit is due to the neglect of the waves u_h^g, $u_h^{g'}$ etc.

ii) Pseudo-kinematical theory

When the molecule is composed of heavy and light atoms, the diffraction intensity is affected by the phase shift, as was studied by Glauber and Schomaker,$^{13)}$ and Hoerni and Ibers.$^{14)}$ Horni extended this study to the crystal by simply replacing the ordinary atomic structure factor in the kinematical formula of reflected intensity by the complex atomic structure factor. He graphycally showed that in the limit of small D and λ the intensity due to the dynamical theory taking account of the multiple scattering approaches to that of the pseudo-kinematical theory. However, it is actually difficult to confirm the agreement between the former two theory by his graph, especially for small D and λ.

On the other hand, our theory, which starts from the dynamical theory taking account of many reflections, indicates the fact that the intensity of reflection by the dynamical theory approaches to that of the kinematical theory rather than that of the pseudo-kinematical theory. This result is in a sharp contradiction to the result of Hoerni.

Hoerni calculated the intensity of 111- and $\bar{1}\bar{1}\bar{1}$-reflections at the Bragg position from cadmium sulphide, which has the polar axis [111], by the pseudo-kinematical and also by the dynamical theories, and showed the failure of Friedel's law. The intensities given by the pseudo-kinematical theory are

$$\left.\begin{aligned} &I_{111}=1.22\times10^{-4}\,D^2 \\ \text{and}\qquad &I_{\bar{1}\bar{1}\bar{1}}=0.925\times10^{-4}\,D^2\,. \end{aligned}\right\} \tag{34}$$

This result differs again from the conclusion of the present theory. The intensity given by (34), which shows the failure of Friedel's law, is proportional to D^2, whereas in our result (25) the difference between I_{111} and $I_{\bar{1}\bar{1}\bar{1}}$ appears first in the $(D/2k)^3$ term.

In the dynamical theory, the effect of multiple scattering, and so the effect of phase shift, are automatically taken into account. The difference between the results of these theories may arise from the fact that, in the dynamical theory, only the discrete set of waves whose wave vectors are related by the reciprocal lattice vectors are considered in the crystal, whereas in the pseudo-kinematical theory, continuous set of waves are considered in an atom, as was emphasised by Miyake.$^{7)}$

iii) The intensity formula (20) expressed by the power series in $D/2k$ is practically applicable for small D or λ. When D or λ is large, we cannot simply apply the present method, since in this case it is appropriate to consider the intensity averaged over D which is given by

$$\overline{I_h}=\sum_i |u_h^i|^2=\sum_i |\psi_0^{i*}\psi_h^i|^2\,.$$

In order to obtain ψ_0^i and ψ_h^i, it is necessary to solve the secular equation.

The author would like to thank Prof. S. Takagi for his guidance throughout this work, and Prof. K. Kohra for his helpful discussions. This work was partly supported by a research grant of the Ministry of Education.

Appendix

If we consider the direction cosine of each beam with respect to the surface normal which is almost equal to 1 in the Laue-case, we get the following equation instead of (7)

$$k^2-k_h^2=2k\zeta\cos\theta_h+p_h=-x\cos\theta_h+p_h\,,$$

and (9) becomes

$$\mathrm{M}\phi=x\mathrm{Q}^2\phi\,, \tag{35}$$

as was shown by Niehrs and Wagner. Here the matrix Q is the diagonal matrix whose elements are

$$\mathrm{Q}_{hg}=\delta_{hg}\sqrt{\cos\theta_h}\,.$$

We can rewrite (35) as follows:

$$Q^{-1}MQ^{-1}\cdot Q\phi = xQ\phi\ . \tag{36}$$

$Q^{-1}MQ^{-1}$ is an hermitian, whose eigen vector is $Q\phi$. If $Q\phi$ is normalized, the amplitude $u_h{}^i$ is given by

$$\begin{aligned} u_h{}^i &= \psi_0{}^{i*}\psi_h{}^i \cos\theta_0 \\ &= \sqrt{\cos\theta_0}\,\psi_0{}^{i*}\sqrt{\cos\theta_h}\,\psi_{hi}\sqrt{\frac{\cos\theta_0}{\cos\theta_h}}\ . \end{aligned} \tag{37}$$

We can derive the wave function of the **h**-reflection wave by the same way as we get (18), namely

$$\Psi_h = \left[\exp\left(i\frac{z}{2k}Q^{-1}MQ^{-1}\right)\right]_{h0}\sqrt{\frac{\cos\theta_0}{\cos\theta_h}} \times \exp(i\boldsymbol{k}_h\cdot\boldsymbol{r})\ . \tag{38}$$

Then, the scattering matrix is given by

$$\begin{aligned} S &= Q^{-1}\exp\left(i\frac{z}{2k}Q^{-1}MQ^{-1}\right)Q \\ &= \exp\left(i\frac{z}{2k}Q^{-2}M\right), \end{aligned}$$

and we have

$$[(Q^{-2}M)^n]_{h0} = \sum_{g_1g_2\cdots g_{n-1}} \frac{v_{hg_1}v_{g_1g_2}\cdots v_{g_{n-1}0}}{\cos\theta_h\cos\theta_{g_1}\cdots\cos\theta_{g_{n-1}}}\ ,$$

since

$$(Q^{-2}M)_{hg} = \frac{v_{hg}}{\cos\theta_h}\ , \qquad (v_{hh}=p_h)$$

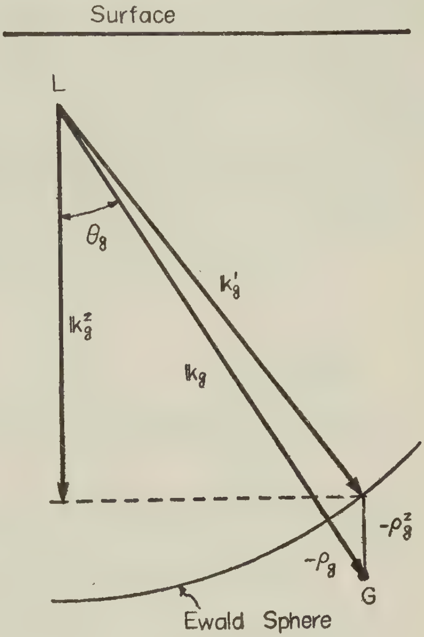

Fig. 4.

If we use the symbol $\rho_h{}^z$, $\boldsymbol{k}_h{}^z$, $\boldsymbol{k}_h{}'$ defined in Fig. 4, (38) is rewritten as follows:

$$\begin{aligned} \Psi_h = &\sum_{m=1}^{\infty}\sum_{g_1g_2\cdots g_{m-1}} \exp(-i\rho_h{}^z z)\,\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{(2k)^m\cos\theta_h\cos\theta_{g_1}\cdots\cos\theta_{g_{m-1}}} \\ &\times\left[\frac{\exp(iz\rho_h{}^z)-1}{\rho_h{}^z(\rho_h{}^z-\rho_{g_1}{}^z)\cdots(\rho_h{}^z-\rho^z_{g_{m-1}})}\right. \\ &\left.+\sum_{i=1}^{m-1}\frac{\exp(iz\rho_{g_i}{}^z)-1}{\rho_{g_i}{}^z(\rho_{g_i}{}^z-\rho_h{}^z)(\rho_{g_i}{}^z-\rho_{g_1}{}^z)\cdots(\rho_{g_i}{}^z-\rho^z_{g_{i-1}})(\rho_{g_i}{}^z-\rho^z_{g_{i+1}})\cdots(\rho_{g_i}{}^z-\rho^z_{g_{m-1}})}\right] \\ &\times\exp(i\boldsymbol{k}_h{}'\cdot\boldsymbol{r}) \\ = &\sum_{m=1}^{\infty}\sum_{g_1g_2\cdots g_{m-1}} \exp(-i\rho_h{}^z z)\,\frac{v_{h-g_1}v_{g_1-g_2}\cdots v_{g_{m-1}}}{2^m k_h{}^z k_{g_1}{}^z\cdots k^z_{g_{m-1}}}\left[\frac{\exp(iz\rho_h{}^z)-1}{\rho_h{}^z(\rho_h{}^z-\rho_{g_1}{}^z)\cdots(\rho_h{}^z-\rho^z_{g_{m-1}})}\right. \\ &\left.+\sum_{i=1}^{m-1}\frac{\exp(iz\rho_{g_i}{}^z)-1}{\rho_{g_i}{}^z(\rho_{g_i}{}^z-\rho_h{}^z)(\rho_{g_i}{}^z-\rho_{g_1}{}^z)\cdots(\rho_{g_i}{}^z-\rho^z_{g_{i-1}})(\rho_{g_i}{}^z-\rho^z_{g_{i+1}})\cdots(\rho_{g_i}{}^z-\rho^z_{g_{m-1}})}\right] \\ &\times\exp(i\boldsymbol{k}_h{}'\cdot\boldsymbol{r})\ . \end{aligned} \tag{39}$$

(39) agrees with the result given by Fujiwara.11) The first term in (39) is

$$\Psi_h{}^1 = \frac{v_h}{2k_h{}^z}\,\frac{1-\exp(-i\rho_h{}^z z)}{\rho_h{}^z}\exp(i\boldsymbol{k}_h{}'\cdot\boldsymbol{r})\ .$$

This formula was obtained by Raether.15)

(Received November 12, 1958, Revised manuscript received August 10, 1959)

Measurement of the magnetic anisotropy energy of a single crystal of natural pyrrhotite in c-plane was made by means of the torque method at room temperature up to a magnetic field of 20000 oe and at low temperature in a constant field. It was found that the easy axis lay along $[2\bar{1}0]$ direction above -80°C which, however, changed to [100] direction below that temperature. The torque curves in c-plane were composed of two- and six-fold symmetric parts. It was also found that in the range of strong magnetic fields the six-fold symmetric part at room temperature decreased with the inverse square of the applied field; such a field dependence is explained assuming a triad structure for the single crystal of pyrrhotite. A remark is also given on the origin of the two-fold symmetric torque.

§ 1. Introduction

The experiment by Weiss and others[1)2)] on a single crystal of natural pyrrhotite revealed that this crystal was paramagnetic along [001] direction while it was ferromagnetic in (001) plane. In (001) plane they found a magnetic anisotropy of two-fold symmetry superposed on that of six-fold. They regarded the two-fold part as essential. On the other hand Kaya and Miyahara[3)] obtained a result which showed a complete six-fold symmetry and concluded that the six-fold symmetric part was essential. However, the magnetic field used by these authors was not so strong that sufficient knowledge on the magnetic anisotropy of this crystal was not obtained. The present authors have measured the magnetic anisotropy of a single crystal of natural pyrrhotite from the same source as those used by Kaya and Miyahara up to a field of about 20000 oe. In this paper the results of the measurement are shown together with some remarks on the origin of the field dependence of the torque curve.

---

* A part of this investigation is based upon the dissertation (Master Course (1956), Tohoku University) presented by Itsuo Mikami, now at the Hitachi Central Research Laboratory, Tokyo.

** Now at the Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai.

§ 2. The Method of Measurement and the Specimen

For the measurement of the magnetic anisotropy constant a vacuum torque-meter was used. The temperature was measured by a copper-constantan thermo-junction attached to the specimen and the induced thermo-e.m.f. was led to a potentiometer by means of fine spiral wires of the same material which did not introduce any detectable mechanical influence in the performance of the torque-meter.

A circular disk of about 8.5 mm in diameter and 0.5 mm in thickness was cut from a crystal of natural pyrrhotite. The deviation in diameter was about 0.5 mm. The torque due to the anisotropy of the demagnetizing energy expected from such deviation is less than 1% of the torque due to the crystalline anisotropy energy, so that the effect of the shape is negligible in our case. It was also shown from the Laue spots taken at the center of the disk that the normal of the basal plane of the disk deviated 5° from [001] direction and its projection on (001) basal plane lay along [100] direction. It was also found that mosaic spread was about 1°.

§ 3. The Experimental Results

(1) Torque measurements at room temperature

First the magnetic field was applied in the basal plane and the resulting torque is shown in Figs. 1 and 2, in which the ordinate represents the torque per unit volume and φ_0 indicates the angle from [$2\bar{1}0$] axis. In Fig. 1 the torque curves at several field strengths from 800 up to 7500 oe are shown and in Fig. 2. those from 9800 to 19150 oe. Each curve can be understood by the superposition of those with six-fold and two-fold symmetry. The six-fold symmetric parts are shown in Fig. 3. These six-fold symmetric torque curves pass through zero at $\varphi_0=0$. It should be noted that throughout the measurement the stable position of the specimen was not found in the vicinity of $\varphi_0=\pm 30°$ or [100] direction, showing that [$2\bar{1}0$] axis is the direction of easy magnetization at room temperature. The field dependence of the six-fold symmetric torque at $\varphi_0=15°$ is shown in Fig. 4. As is shown, the magnitude of torque increases at first, reaches its maximum at about 6000 oe, and then decreases to zero as

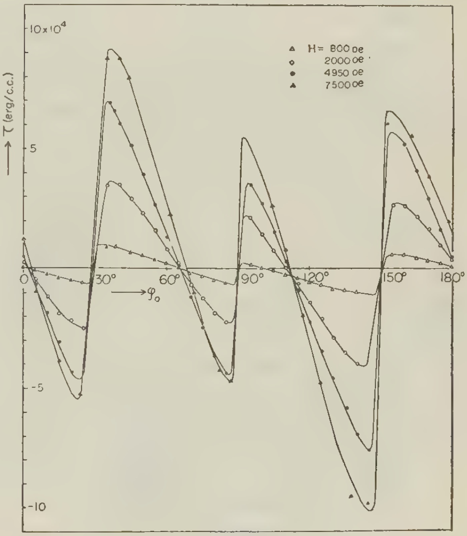

Fig. 1. Torque curves in c-plane at room temperature, field strength (H) from 800 to 7500 oe.

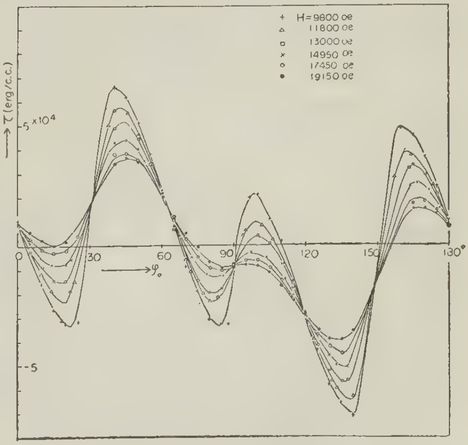

Fig. 2. Torque curves in c-plane at room temperature, field strength from 9800 to 19150 oe.

H increases further. The shape of the torque curve becomes sinusoidal at strong field.

When the six-fold symmetric part is substracted from the observed torque values there remains a two-fold symmetric torque, as shown in Fig. 5.1. In the high field range the curves are smooth and nearly sinusoidal but in the low field range they show steps at $\varphi_0=90°$ and $180°$. The relation between the amplitude of the two-fold symmetric torque and field strength is shown in Fig. 5.2. The amplitude seems to reach a saturated value of about 3×10^4 ergs per unit volume at about 10000 oe.

(2) Torque measurements at low temperatures

The temperature variation of the torque was measured below the room temperature by keeping the field strength constant at 12900 oe. In Fig. 6 the measured torque values at different temperatures are shown. The torque amplitude decreases at first with lowering temperatures. It seemes at $-80°C$ the direction of the easy magnetization changes from [2$\bar{1}$0] to [100].

§ 4. Interpretation of the Experimental Results

As has been analyzed above, it is convenient for the following discussion to separate the experimental results into two, namely the six-fold symmetric anisotropy and the two-

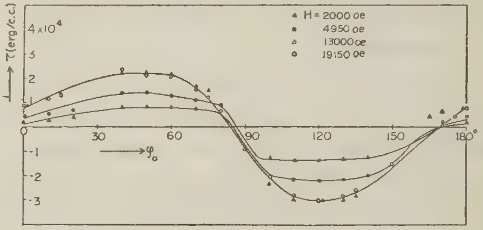

Fig. 5.1. Two-fold symmetric torque curves in c-plane which are separated numerically from observed torque curves (cf. Fig. 1 and Fig. 2).

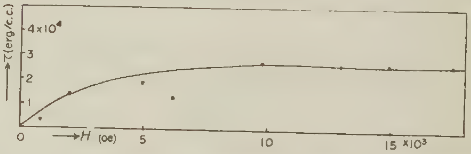

Fig. 5.2. Relation between two-fold symmetric torque amplitude and magnetic field strength.

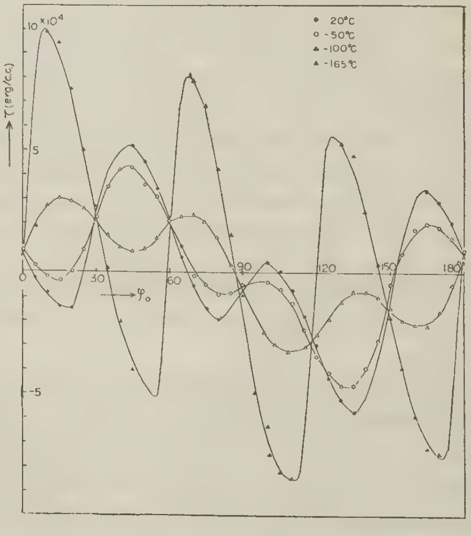

Fig. 6. Variation of torque curve with lowering temperature. A constant field, $H=12900$ oe is applied in measurements and φ_0 is the angle from [2$\bar{1}$0] direction.

fold one. At first the six-fold part is discussed. In a normal ferromagnetic crystal the torque amplitude increases monotonously with the strength of the applied magnetic field until saturation is reached. However, in the present case the torque amplitude with the six-fold symmetry decreased in high fields. Such an unusual magnetic behavior of the pyrrhotite crystal can be explained by assuming a twin-like structure in this crystal.

According to Bertant[4] the crystal lattice of pyrrhotite belongs to the pseudo-orthorhombic (monoclinic) system. An actual crystal of pyrrhotite is thought to be an aggreagate of three kinds of small crystal domains with such orthorhombic symmetry; each domain has common c-axis but the orientations of *a*- and *b*- axis distribute among the three directions which make an angle of $2\pi/3$ with one another respectively. Such an assembly of crystallites or domains behaves, as a whole, like a pseudo-hexagonal crystal. Since the c-axis of each crystal domain is the axis of the two-fold symmetry, the magnetic anisotropy in c-plane of the whole crystal is to be produced by the superposition of those of the individual crystal domains with two-fold symmetry. Based on the model here proposed, it is shown that the field dependence of the apparent six-fold anisotropy can be reproduced theoretically together with its change with the magnetic field.

When K_1, I_s, and H denote the postulated two-fold symmetric magnetic anisotropy constant within c-plane, the saturation magenetization of each domain, and intensity of the external magnetic field respectively, the energy of each domain per unit volume, E_k $(k=1, 2, 3)$, is given by

$$E_k=-K_1\cos^2\left(\alpha_k-\frac{2}{3}k\pi\right)-HI_s\cos(\alpha_k-\varphi_0)\,, \tag{1}$$

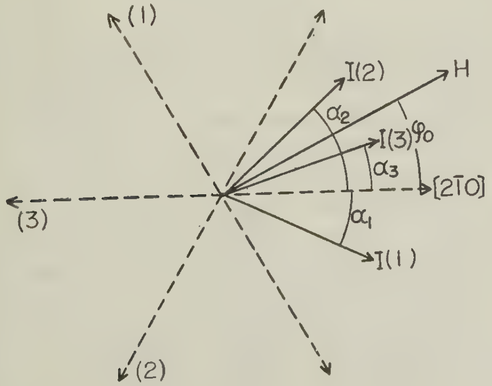

Fig. 7. Schematic diagram of three domains in c-plane.
(K) ←-→; anisotropy axis of domain k.
$I(K)$ ⟵; magnetization vector of domain k.

where α_k and φ_0 are, as shown in Fig. 7, the orientation of the magnetization of domain k and the direction of the external field. By assuming that the total volume of each kind of domain is equal, following results can be obtained.

(1) When the magnetic field is sufficiently small, then the torque per unit volume τ is given by

$$\tau(\varphi_0)=\frac{2}{3}HI_s\sin\varphi_0\left(-\frac{\pi}{6}\leq\varphi^0\leq\frac{\pi}{6}\right).$$

The torque amplitude will be proportional to the field H. Torque curves at 800 oe and also probably at 2000 oe presented in Fig. 3 are described qualitatively by this equation.

(2) In a strong field the directions of magnetizations in each crystal domains fall in the field direction $(\alpha=\varphi_0)$, then the total energy of the system is shown to be independent of φ_0, resulting the negligibly small torque.

(3) In the intermediate field range $HI_s>K_1$, the torque is shown to be expressed by the following type of equation.

$$\tau(\varphi_0)=-\frac{3}{2}K_1\eta^2(1-2\eta^2)\sin 6\varphi_0 +10K_1\eta^5\sin 12\varphi_0 \tag{2}$$

with

$$\eta=K_1/HI_s\,.$$

As seen from it the torque changes as $\sin 6\varphi_0$ and with the increase of the field strength the torque amplitude approaches zero in proportion to H^{-2}. When H approaches a value K_1/I_s, the term proportional to $\sin 12\varphi_0$ in Eq. (3) becomes effective, and the departure from simple sinusoidal curve of $\sin 6\varphi_0$ becomes appreciable. The theoretical curve shown in Figs. 3 and 4 were obtained by choosing the best value of K_1 and by putting 80 gauss for the saturation magnetization I_s after Lotgering[5]. The value of K_1 thus determined is 2.83×10^5 ergs per c.c. at room temperature.

Now for the two-fold symmetric part of the torque in c-plane three possible origins could be enumerated:

(1) The total volume of each kind of

micro-crystal domain ($k=1, 2, 3$) mentioned above is slightly different from one another. In this case a small uniaxial anisotropy remains in c-plane.

(2) Basal plane of the specimen used in our experiment slightly inclines to the crystallographic c-plane.

(3) Some imperfections such as ferromagnetic precipitates exist in this natural single crystal.

As the normal of the basal plane of our specimen deviated by 5° from [001] direction and its projection on (001) plane lay along [100] direction, the case (2) will be probable*.

§ 5. Origin of the magnetic anisotropy

It was previously shown by Bertaut that the crystal lattice of pyrrhotite is built by alternate stacking of the net planes of iron ions with and without vacant sites. Considering the measured value of the saturation magnetization, it is more probable that ferric ions are in the planes which contain vacant sites[7]. In order to get the two-fold symmetric anisotropy in c-plane, it might be possible to consider some type of ordering of vacant sites and iron ions in these net planes. An atomic arrangenent is proposed in Fig. 8. In the c-planes including vacancies, there appear linear arrays of iron atoms with and without vacancies in alternate succession. It is assumed here that the ions in the arrays including vacancy are trivalent. The anisotropy energy in c-plane which is caused mainly from Fe^{2+} ions is estimated to be the order of 10^6 ergs per unit volume[8]. This is somewhat greater than that obtained by the present experiment, namely, 2.83×10^5 ergs per unit volume. This difference in the value of K_1, however, will be lowered by assuming that both the ferrous and ferric ions are not arranged perfectly in order. Of course it should be assumed that the direction of such parallel linear array in each crystal domain is in either of the three equivalent directions $[2\bar{1}0]$, [120] and $[2\bar{1}0]$. Reversal of the sign K_1 (the change of apparent six-fold symmetric anisotropy axis from the $[2\bar{1}0]$ to [100] direction) at −80°C may be due to the change of the energy levels of ferrous ion induced by the temperature change of the axial ratio c/a.

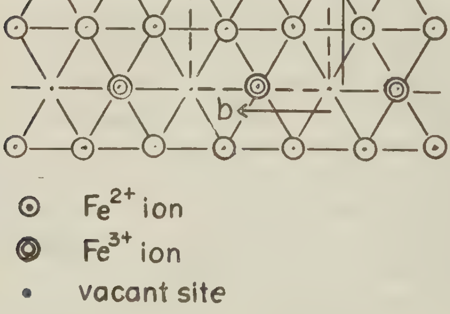

Fig. 8. Proposed ionic ordering in the vacancy including c-plane. Dotted line shows basal plane of the unit cell.

The present authors wish to express their hearty thanks to Prof. N. Tsuya, who kindly arranged for them the specimen of pyrrhotite and gave valuable suggestion for the present investigation. They also wish to express their sincere thanks to Prof. S. Chikazumi of Gakushuin Univ. and Prof. M. Yamamoto of Tohoku Univ. for their kind and valuable suggestions to the interpretation of torque curves. The present work was supported in part by the Grand-in-Aid of Scientific Researches of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 11, NOVEMBER, 1959

Effects of Ionizing Radiations on Synthetic Polymer Solutions

By Shintaro SUGAI

Physics Department, Faculty of Science, Hokkaido University
Sapporo, Hokkaido

(Received May 6, 1959)

Aqueous solutions, containing disolved oxygen, of sodium salt of carboxy-methyl cellulose and of polyacrylic acid and so on were irradiated with γ-rays from Co^{60} or with 90 KV X-rays, and the degeneration of molecules in the solutions brought about under various conditions was studied by viscometric, ultracentrifugal, and electrical measurements.

Ideal indirect kinetics of main chain fractures through activated water has been recognized in all the cases from highly concentrated solutions to fairly diluted ones. In the case of extremely diluted solutions, however, free-radical recombination seems to make the reaction inefficient.

From a simple consideration of these fact, a certain information as to the molecular extension and form in the solution has been derived.

Inclusion of salts and alcohols in the solution protects effectively the degeneration due to irradiation, which can be explained satisfactorily likewise on the assumption of "*indirect effect*".

The molecular contraction and change of molecular form caused by the inclusion of salts have been estimated.

The irradiation effect on dilute solutions of non-electrolyte polymers was also investigated. The efficiency of chain fractures comes out not much smaller than in the case of polyelectrolyte molecules in the same concentration range. Here the rate of fracture seems to indicate again the "*indirect effect*".

It may therefore be concluded that electrical charges on polyelectrolyte molecules, in a certain range, are not essential for degradation and their extension is not much different from that of non-electrolyte molecules.

It has been observed that, in the case of concentrated polyelectrolyte solutions containing oxygen, irradiation does not give rise to formation of gel, although micro-gel may be formed.

§ 1. Introduction

Recently, many investigators observed the the effect of irradiation on various solid polymers, and it has been concluded that polymers can be divided into two groups from view-point of radiation chemistry: in one of them degradation of molecules is the main reaction, and in the other crosslinking between molecules is the most important effect²⁾.

However, in the case of copolymers or in more complicated cases, where some low molecular substances are included in the solid polymers, circumstances turn out considerably complex²⁾.

In the case of polymer solution, which is one of the typical many-component systems, similar complications may well be expected to arise.

It is probably for this reason that there have hitherto been comparatively few researches concerning the effect of ionizing radiation on polymer solutions, especially on synthetic ones, notwithstanding that such researches have acquired importance in the branch of radiation biology³⁾ as well as of polymer science.

Some authors have found that synthetic polymer solutions are very sensitive to ionizing radiations compared with solid polymers, especially in the case of dilute aqueous solution containing oxygen⁴⁾.

Explanation which have been given to such a tendency is based on the idea of the so-called "*indirect effect of radiation on solution*⁵⁾."

If the reaction occurring in the solution due to irradiation be indirect, the total dose R necessary to producea certain amount of degeneration should be related, under simple circumstance, to the concentration c of the solution by

$$R/c = constant \quad (\equiv k). \qquad (1)$$

Alexander and Fox confirmed the validity of this relation by measuring the viscosity change of dilute aqueous solution of polymethacrylic acid partly neutralized with sodium hydroxide[6]. For verifying Eq. (1), poly-electrolyte aqueous solutions of polymer prove most useful, since the physical and chemical properties can be measured over an extended range of concentration than in the case of non-electrolyte polymer solutions.

Alexander and Charlesby observed, on the other hand, that the main reaction due to irradiation occuring in dilute aqueous solutions of polymer is always a chain scission[7], and that, while in a number of cases of concentrated non-electrolyte aqueous solutions gel formation takes place[8], no gel formation ensures in concentrated polyelectrolyte aqueous solutions.

Further, according to many authors, the rate of reaction in the irradiated dilute aqueous solution of polymer depends not only on the concentration of the polymer and quantity of oxygen but also largely on the molecular extension[9] The dependency upon the molecular extension serves as an indication of the indirect effect of radiation on the solution.

As for the irradiation effect on non-aqueous polymer solutions, there have been but few researches. One of the authors[10] has noted the direct effect of γ-rays upon polystyrene (*PS*)-carbon tetrachloride (CCl_4) solution, while another has called attention to the indirect effect for the same system[11].

In this case it is, as pointed out above, not easy to check the validity of Eq. (1) exactly. Therefore use cannot be made of Eq. (1) for determining whether the effect is direct or indirect. According to the existing data, the effect in non-electrolyte solutions is comparatively small, which is likely to be considered as indicating the direct effect.

However, in consideration of the circumstances that the range of concentration where the measurement can be made is comparatively high and that the molecular extension in non-electrolyte solution may be small compared with that in polyelectrolyte one, small yield of reaction will not necessarily lead to the conclusion of direct effect.

Also it must be noted that when polyelectrolyte aqueous solution completely free from oxygen is irradiated, scission yield is comparatively small.

In the present work, the irradiation effects of γ- and *X*-rays on polyelectrolyte aqueous solutions were studied over a concentration range from extreme dilution to high concentration, by making use of viscometric, ultracentrifugal, and electrical measurements. Special attension was paid to the relation between reaction rate and molecular extension.

The difference in irradiation effect between polyelectrolyte and non-electrolyte solutions was also examined.

§ 2. Experimental Procedures

Polyelectrolytes used in this study were sodium salts of carboxy-methyl cellulose (*Na-CMC*), and of polyacrylic acid (*Na-PA*), and copolymer (*CP*) of poly-(potassium methacrylate) and polymethyl methacrylate (ratio 3 : 1).

Average degree of polymerization (*DP*) and that of etherification of *Na-CMC* were respectively 560 (calculated from the intrinsic viscocity[12]) and 0.685. However, according to the ultracentrifugal patterns of highly concentrated aqueous solutions, *Na-CMC* was found to consist of two groups, characteristics of which are indicated in Table I.

Table I. Characteristics of *Na-CMC* used in this study.

1 Degree of Etherification 0.685
Degree of Polymerization 560
Max. Value of η_{sp}/c of Aqueous Solution 1.0×10^4 *cc/gr* ($c = 4.5 \times 10^{-5}$ *gr/cc*)
2 Ultracentrifugal Coefficient (Aqueous Solution including 1 *Mol NaCl*)

c	s_1	s_2	f_1
gr/cc	*sved*	*sved*	%
2.4×10^{-3}	2.0	7.9	66.7
6.7×10^{-4}	2.5		100

s_1, s_2 : ultracentrifugal coefficients of two groups
f_1 : fraction of the first group

DP of *Na-PA* (calculated from the intrinsic viscosity[13]) was about 1.0×10^4.

The data concerning the properties of *CP* is very meager, only its behaviour in aqueout solution including 1 *Mol* of potassium chloride is known to resemble that of non-electrolyte.

The samples were purified by the ordinary method, the specific conductivity of the water used being $1.0\times10^{-6}\,\Omega^{-1}cm^{-1}$.

The viscosity was measured with Ostwald-type viscometer at 25°*C* and the electric conductivity was determined by supplying 1000 *c/s A.C.* with impedance bridge and cathode-ray oscilloscope.

Ultracentrifugal patterns were obtained by the use of Spinco *E* Centrifugal *M*achine at 56000 *r/m*.

As γ-ray source, 42 *Curies* of Co^{60} in charge of Department of Radiology and 20 *milli-Curies* of Co^{60} (needle type) were used. The latter was intended for the irradiation at extremely low dose-rate.

As X-ray source served a 90 *KV* X-ray tube with no filter.

The solution containing oxygen was sealed in a glass vessel, the volume ralio between the solution and air in the vessel being kept constant throughout the experiment. It is to be noted that no stabilizers were introduced in the solutions, because even a small quantity of foreign substance in the solution may effectively protects the solution from degeneration. Exact measurement of degeneration due to irradiation was achieved by comparison with the natural degeneration of non-irradiated solution, which had been stocked under the same condition.

Non-electrolyte polymers subjected to irradiation were polyvinyl alcohol (*PVA*), polyvinyl chloride (*PVC*) and polystyrene (*PS*). *DP* of these polymers determined by measuring the intrinsic viscosity came out respectively 2260, 750 and 2400. Aqueous or non-aqueous solutions of these samples containing oxygen were irradiated under the same conditions as described above.

§ 3. Experimental Results

A) *Degradation of molecule in dilute aqueous solution of polyelectrolyte.*

Relative changes in specific viscosity η_{sp} of the dilute aqueous solution of various polyelectrolytes caused by γ-ray and *X*-ray irradiations are shown in Table II, which shows that viscosity of all dilute solutions studied in this case decreases markedly under any dose-rate of irradiation and that the higher the concentration of solution, the smaller is the effect of irradiation.

These results are qualitatively in accord with those hitherto reported and seem to suggest the indirect effect of the ionizing radiation on polyelectrolyte aqueous solutions.

Table II. Relative decrease in specific viscosity $-\Delta\eta_{sp}$ of dilute aqueous solutions of various polyelectrolytes (γ-rays).

In order to examine quantitatively the indirect effect through the activated water, inquiry must be made as to whether relation (1) holds good or not. Theoretically speaking, relation (1) for viscosity change holds strictly only within a narrow range of concentration, since free radical recombination may be not strictly taken into consideration[14].

Actually however, as shown in Table III, which gives the degeneration of three polyelectrolytes at various concentrations, Eq. (1) is satisfied over a considerably wide range of concentration. Thus from Table III the following conclusions may be drawn:

1) The ideal type of indirect effect on viscosity change is realized in polyelectrolyte solution, notwithstanding the complicated circumstances described above, except at extremely dilute concentration.
2) Degeneration does not depend on dose-rate over a wide range. Therefore a dosemeter can be made by the use of these solutions, especially for low dose.
3) There appears a marked inefficiency of radiation in causing degeneration in extremely dilute solutions. (Probably, it arises from recombination of free radicals.)

* NaCl was introduced in the solutions after irradiation.

Now, to ascertain the main-chain fractures of polymer molecules and to calculate the rate of reaction, the intrinsic viscosity changes must be examined. In Table IV are given the intrinsic viscosity of irradiated *Na-CMC* queous solution and the efficiency of main-chain fractures *G*-values were calculated on the assumption of random fracture[15], which is justified by the observation on the change of ultracentrifugal patterns, as shown in Table V. One sees that the greater the molecular weight, the faster is the reaction, that is, that the fracture of main-chain takes place at random.

G-values in Table IV are considerably smaller than those reported in the case of degradation of polymethacrylic acid. This may

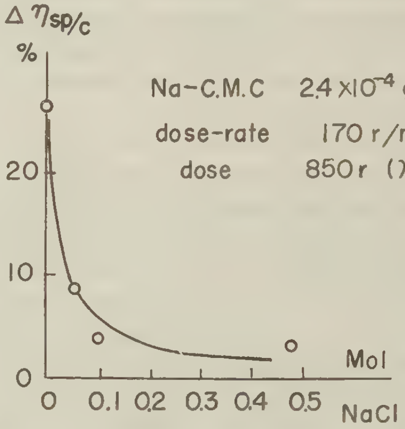

Fig. 1. Change of degeneration of irradiated *Na-CMC* aqueous solutions due to salt inclusion.

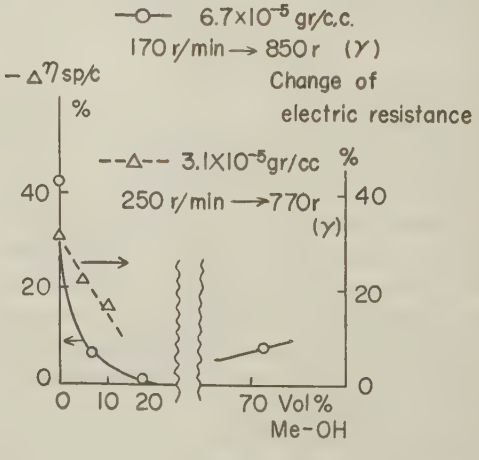

Fig. 2. Protection effects of methyl alcohol in irradiated *Na–CMC* aqueous solutions.

probably be accounted for by assuming that *Na-CMC* molecules are much smaller than those of polymethacrylic acid.

Table IV indicates another interesting fact that G is not constant but gradually increases as the concentration of the solution decreases, while Eq. (1) is satisfied in the same range of concentration. Discussion will be given later.

The general dependency of molecular degradation due to irradiation on molecular extension can be seen from Fig. 1, which shows data on the change in viscosity of *Na-CMC* aqueous solutions including various quantities of sodium chloride, and also from Table VI, which gives G-values for these solutions. Evidently, the salt acts as effective protector against degradation of molecules in polyelectrolyte aqueous solution.

Fig. 2 indicates another type of protection, which arises from the existence of alcohol in the solution. The protective power is here considerably great. It is true, the inclusion of alcohol in aqueous solutions of polyelectrolytes is very likely to change the molecular extension[16], but it will be noted later that protection in this case cannot completely be explained only be molecular contraction.

Finally, it is to be remarked that there exists an after effect of degeneration in *Na-CMC* aqueous solution subjected to irradiation of high dose, whereas aqueous solutions of the other two polyelectrolytes did not show any indication of after effect. Alexander and Charlesby also did not observe any after effect in the irradiated synthetic polymer solutions.

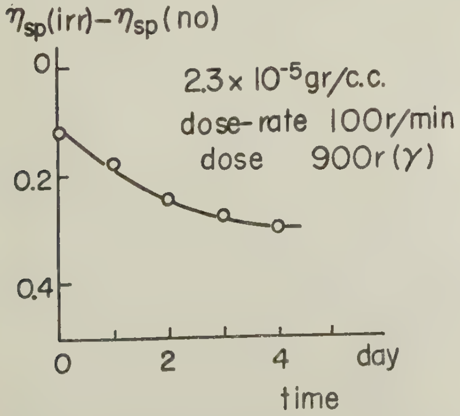

Fig. 3. After-effect of *Na–CMC* aqueous solution.

In view of the fact that solid cellulose exhibits a larger after-effect[17], the tendency as seen in Fig. 3 may probably be regarded as characteristic of *Na-CMC* molecules.

B) Effect of γ-rays on the electric conductivity of dilute aqueout solution of polyelectrolyte.

Various results mentioned in *A*) indicate the molecular degradation in the irradiated dilute aqueous solutions of polyelectrolyte. Now comes up the question: what kind of effect is brought about by the ionizing radiaon the electric properties of polyelectrolytes?

There have been few investigations with reference to this point, although some workers seem to have confirmed the effect of irradiation upon the electrical properties of low molecular solutions[18].

It is known that the electric conductivity of polyelectrolyte aqueous solution has no definite dependency on molecular weight[19]. Some authors, however, have shown that, if between the two solutions, in which the same sort of molecules are disolved with the same concentration, there is a great difference in molecular weight of the disolved molecules, they will have different conductivities[20].

Now, from Fig. 4 which shows the change

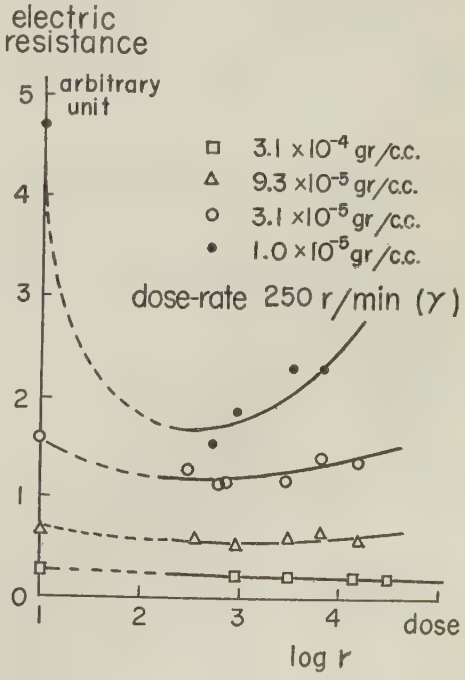

Fig. 4. Change of electric-resistance of *Na–CMC* aqueous solution due to irradiation.

in electric conductivity of irradiated solutions for 1000 *c/s A.C.*, it is mainfest that, while at higher concentrations the change in conductivity is much smaller than that in viscosity, it increases as the concentration is lowered. This suggest that in dilute solution the marked degradation of molecules is brought about so far as to cauge an appreciable change in conductivity.

If the dependency of the change in conductivity on the concentration of solution be such that it satisfies Eq. (1), it would definitely indicate the indirect effect. Actually, however, the dependency proved to be so complex that Eq. (1) could not be checked in this case.

What is interesting to be noticed in Fig. 4 is the fact that the change in conductivity of irradiated solution versus radiation dose has a maximum.

That this does not mean gel-formation in strongly irradiated solution is evident, since the curve of viscosity change turns out monotonous, as shown in Fig. 5. In order to make further inquiry into this phenomenon, the temperature dependency of the conductivity of irradiated solution was investigated. The results are illustrated in Fig. 6, which shows that the conductivity of irradiated solution is certainly greater than that of non-irradiated one at low temperatures, while the situation is revesed at higher temperatures. The reverse temperature is 30°*C* in this case.

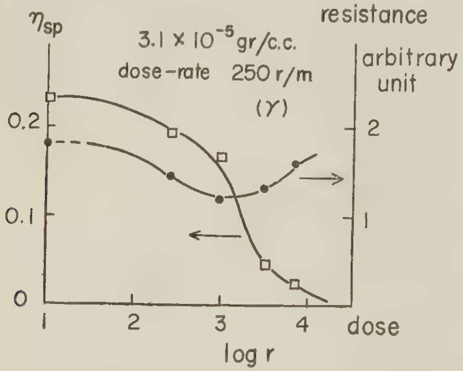

Fig. 5. Comparison of electric-resistance change of *Na-CMC* solution with viscosity change.

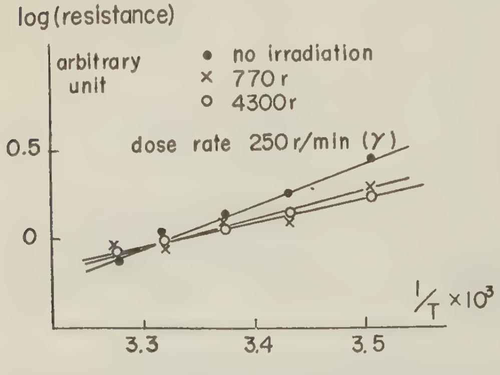

Fig. 6. Temperature dependency of electric resistance of irradiated *Na-CMC* aqueous solutions.

Thus, it must be remembered that the change in conductivity of the irradiated polyelectrolyte solution depends on temperature, that is, that if temperature, at which measurement was carried out, were different, the curve in Fig. 4 have come out entirely different.

In this connection it is to be noticed that methyl alconol acts as protecting agency against the change in conductivity and that, the after effect mainfests itself in some cases, as in the case of viscosity change.*

C) *Concentrated aqueous solutions of polyelectrolyte.*

As shown in Table V, ultracentrifugal measurement indicated the molecular degradation in highly concentrated *Na-CMC* aqueous solutions.

Table VII gives the change in viscosity of some concentrated solutions of *Na-CMC* and *CP*. Even in the case where the concentration is so high that all the molecules may be considered to be in contact with each other, the viscosity of the solution shows a decrease but no increase, at least when oxygen is present in the solutions, the fact which implies that no gel formation takes place.

But, what is to be noticed, it was observed that in some cases the ultracentrifugal velocity of the irradiated concentrated aqueous solutions of *CP* increased appreciably at the initial stage of irradiation, as shown also in Table VII.

Thus the possibility of intermolecular linkage can not completely be neglected. Be that as it may, macro-gel as revealed in the irradiated concentrated aqueous solutions of *PVA* was not observed in this case.

The question remains for solution whether the electric charges on polymers stand in any causal relation to this difference.

The fact that *Na-CMC* in solid state is far more insensitive to irradiation that in solution implies that the degradation in the solution must be caused by a reaction through the activated solvent molecules.

---

D) Non-electrolyte polymer solutions

It may be of interest to examine the mechanism of degeneration in polyelectrolyte aqueous solutions by comparison with that in non-electrolyte polymer solutions, aqueous or non-aqueous, in which molecular extension may be widely different from that in electrolyte solutions[21].

The effect on non-electrolyte solutions of various polymers is shown in Table VIII, where R/c is calculated for dose R necessary to produce 10% relative change in specific viscosity.

The degeneration in dilute aqueous solution of *PVA* is probably due to the action of activated waters as in the case of polyelectrolyte aqueous solutions, efficiency of degeneration being, as can be seen from Table VIII, comparable to that in the case of electrolyte. The value of about 0.5 recently reported[22] for the *G*-value of chain scission in *PVA* aqueous solution is not less than that in the case of *Na-CMC* aqueous solution in the present study.

For non-aqueous solutions, concentration dependency of the change in viscosity or the relation between the sort of the solvent and the degeneration seems to indicate likewise the indirect reaction of radiation.

That degeneration in *PS*-benzene solution is relatively small harmonizes with the known fact that benzene is a very stable solvent against irradiation.

Table VIII. Degeneration of non-electrolyte polymer solution due to γ-ray irradiation.

1. Change of specific viscosity and relation between R ($-\Delta\eta_{sp}=10\%$) and c.

polymer-solvent	c	*dose-rate*	*dose*	$-\Delta\eta_{sp}/c$	R	R/c
	gr/cc	*r/min*	*r*		*r*	*r·cc/gr*
PVA—water	4.0×10^{-3}	210	1500	0		
〃	1.0×10^{-3}	〃	1500	6.0	4.0×10^{3}	4.0×10^{6}\*

PS—benzene	2.7×10^{-3}	〃	4800	2.5	2.4×10^{4}	8.0×10^{6}
PS—CCl₄	3.4×10^{-3}	50	11000	13.7	4.8×10^{3}	1.0×10^{6}

* Viscometer type II.
Other data were obtained by using viscometer type I.

2. Scission yields *G* for non-electrolyte polymers containing oxygen.

polymer	*solvent*	*G*	*reference*
PVA	*water*	0.3～0.5	22
PS	CH_3Cl	1.6	11
〃	CCl_4	0.75	〃
〃	*benzene*	0.18	*present study*

And also, it is to be remarked that scission yields in the non-electrolyte solutions are not always smaller than those in polyelectrolyte solutions, which indicates that electric charges are not essential for degradation of polyelectrolyte molecules *at least in the concentration range above* $1.0\times10^{-3}\,gr/cc$. In other words, the effective molecular extension of polyelectrolyte molecule may not be very different from that of non-electrolyte molecule in above described range. However, in the case of diluted solutions ($<1.0\times10^{-3}\,gr/cc$), to which measurement is not yet accessible, considerable difference of molecular extension and G-value of chain scission might be expected.

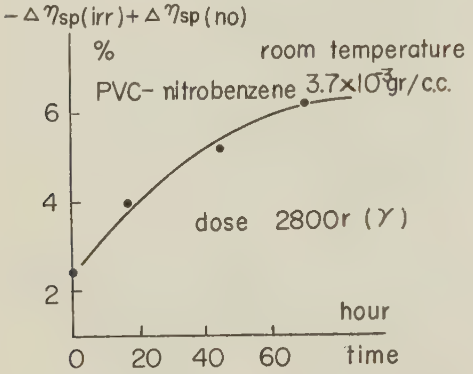

Fig. 7. After-effect in the case of non-electrolyte polymer solution.

It should be noted that, as shown in Fig. VII, marked after effect of irradiation is recognized in non-aqueous solutions. Durup obtained similar results for PS-CCl_4 solutions. If this after effect is taken into account in the calculation of scission yields, their values will come out considerably great; therefore except in the case where the solvent is extremely stable, it is not at all correct to say that the non-electrolyte and non-aqueous solutions of polymers are insensitive to radiation.

§ 4. Qualitative Discussions

The general scheme of the reaction induced by irradiation in the solution may be represented by[23])

$$\text{solvent} \xrightarrow{\gamma} \text{free radical } r \qquad (2)$$

$$r+S \longrightarrow S_i \qquad (3)$$

$$r+S_i \longrightarrow S_i \qquad (4)$$

$$r+P \longrightarrow \text{inactive radical} \qquad (5$$

$$r+r \longrightarrow \text{stable product} \qquad (6$$

where S means a solute molecule, S_i any reaction product, and P a protector such as alcohol. It being possible to know the rate constant of reaction in each case and S and P in the solution, the production rate of S_i can be calculated.

Now, free radicals produced in aqueous solutions are H· and ·OH, and therefore stable products in the reaction (6) may be considered to be H_2 and H_2O. However, if oxygen in the solution, comparatively stable radical HO_2· and recombination product H_2O_2 are produced.

These oxidative agents are more effective in causing the polymer molecule in the solution to degenerate than H· or ·OH radical because of their longer life. Mean free path of H· or ·OH radical may be considerably smaller than molecular extension[24]).

A) Molecular extension and degeneration efficiency.

Reaction (6) makes the degeneration less probable; the more so, if the space including no polymer molecule becomes larger. Therefore, by determining the dependency of fracture efficiency on concentration of the solution, some information concerning the molecular extension may be obtained.

Strictly speaking, estimation of the molecular extension would require a close study on the mean free path of degradative agent. But it may not be unreasonable to assume that in the case of *Na-CMC* aqueous solution the free space begins to appear at the concentration of $5.0\times10^{-5}\,gr/cc$, since the inefficiency of viscosity change becomes remarkable below this critical concentration, as shown in Table III. Moreover, from the fact that the curve of η_{sp}/c versus c of *Na-CMC* solution has a large maximum approximately at this critical concentration, it may be inferred that the molecules attain considerably large extension, free space becoming remarkable, as the concentration is further lowered.

Simple calculation based on the assumption of spherical molecule, which will be justified later, gives the value of about 1500 A for the molecular diameter at this critical region.

The insensitivity of *Na-PA* solutions becomes appreciable at the concentration as low as $1.0\times10^{-5}\,gr/cc$. This is probably due to the larger molecular weight of *Na-PA* than of *Na-CMC*.

B) Molecular form of polyelectrolyte molecules in the solution.

As is well known, the molecular form of high polymer in the solution is implicated in the constant α given by the equation

$$\eta_{sp}/c = AM^{\alpha}\ , \qquad (7)$$

where A is a constant and M is the molecular weight of the polymer. α takes the value 2 in the case of rod-like polymer, while 1 and 1/2 respectively for random coil and rigid sphere25).

Now, applying the results of irradiation fractures shown in Table III and IV, one can obtain the values of α. As the relative viscosity change of the irradiated solution depends on the irradiation dose r, it follows from Eq. (7) that

$$\begin{aligned} -1/(\eta_{sp}/c)\cdot d(\eta_{sp}/c)/dr &= -\alpha/M\cdot dM/dr \\ &= -\alpha/M_0\cdot dM/dr\ , \qquad (8) \end{aligned}$$

which holds for the initial stage of reaction, M_0 being the initial molecular weight.

On the other hand, viscosity change of the irradiated solution is proportional to the dose r at the initial stage of reaction, so that dose R necessary for producing 10% relative change in viscosity is given by

$$1/10R = 1/(\eta_{sp}/c)\cdot d(\eta_{sp}/c)/dr\ . \qquad (9)$$

Eqs. (8), (9) and (1) yield

$$1/10kc = \alpha/M_0\cdot dM/dr = 1/10R\ . \qquad (10)$$

The value of k in Eq. (10) depends on the average shear rate used in viscosity measurements. Thus Eq. (10) may be used for the securing at least qualitative information concerning α-values.

From Table IX, where variations of α-values are given, it may well be inferred that *Na-CMC* molecule takes a rod-like shape at higher concentrations, while as the concentration is lowered it gradually increases in size, developing into a shape of random-coil type, and as a consequence the scission yield increases owing to the dimension of free radical recombination.

Table IX. Values of α concerning Na-CMC molecules in dilute aqueous solutions.

c	k (*average*)	R	dN/dr	α^*	α^{**}
gr/cc	$r\cdot cc/gr$	r	r		
6.7×10^{-5}	1.0×10^{7}	150	8.0×10^{-4}	1.8	1.3
2.4×10^{-4}	〃	320	2.1×10^{-4}	2.0	1.8
6.7×10^{-4}	〃	610	6.4×10^{-5}	2.3	2.5
2.0×10^{-3}	〃		1.4×10^{-5}	3.5	

* calculation by aid of k and dN/dr

** 〃 of R and dM/dr

R and N are given in Tables III and IV.

Variation of α-values due to inclusion of salt in the solution can also be calculated by using Eq. (10), in which k is not constant any more.

Table X. Variation of α-values due to inclusion of sodium chloride in *Na-CMC* aqueous solutions ($c = 2.4\times10^{-4} gr/cc$).

Salt	R	$-1/P_0\cdot dP/dr$	α
Mol	r	$/r$	
0	320	1.8×10^{-4}	1.8
0.05	990	1.2×10^{-4}	0.84
0.48	1510	8.8×10^{-5}	0.75

P: degree of polymerization.

The results are shown in Table X, which indicates that a small quantity of salt changes the molecular form effectively and leads to the formation of rigid sphere. These consequences are consistent with the results obtained by other method26).

B) Protection effect of alcohols

According to some authors, the end-to-end distance h of a polyelectrolyte molecule in the solution, of which the solvent has dielectric constant ε, is given by[27]

$$h^2 = (Z^2e^2h_0^2/3\varepsilon kT)D\ , \qquad (11)$$

where h_0 is the end-to-end distance of the same molecule having no charge, and D is a constant. From this equation it follows that

$$-1/h^2\cdot dh^2/d\varepsilon = 1/\varepsilon\ . \qquad (12)$$

Therefore the relative change of h is at most 10% under the condition described in Fig. 2, and so the effective protection of alcohols seems not to be wholly due to the change in molecular extension.

Protective powers calculated by the ordinary method for *Na-CMC* aqueous solutions are as listed in Table XI, in which the values are compared with other data obtained in the case of irradiated protein solution28).

D) Electric conductivity and irradiation.

It was already shown in § **3** *B*) that an interesting electrical degeneration is brought about by the irradiation in an extremely diluted *Na-CMC* aqueous solution. But, inasmuch as there is no satisfactory theory

Table XI. Protective powers of alcohols in *Na-CMC* aqueous solutions.

polymer	*c*	*protector*	*concentration*	*protective power*
	gr/cc		*vol%*	
Na-CMC	6.7×10^{-5}	*Me-OH*	6.5	0.0087
〃	〃	〃	17.0	0.047
〃	1.0×10^{-4}	*Et-OH*	0.2	0.13
〃	〃	〃	4.0	0.032
〃	〃	〃	10.0	0.079
carboxy-peptidase		*thiourea*		4.7
〃		*glucase*		0.79
〃		*urea*		0.00075

available with respect to the electrical phenomena of polyelectrolyte solutions, the introduction of any assumption will be too bold to explain the observed facts. Therefore only a brief note shall be added here.

The electric conductivity of a polyelectrolyte aqueous solution in low frequency *A.C.* can be expressed by[29]

$$\kappa = ne(u_1+u_2)\,, \tag{13}$$

where n is the number density of free ions having charge e, u_1 their mobility, and u_2 the mobility of a single ion on polymer chain.

n and u_2 depend on temperature, concentration of solution and molecular weight, but u_1 seems to be independent of the molecular weight of the polymer.

If the effect of irradiation be simply to cause depolymerization of molecule, change in conductivity $\Delta\kappa$ comes out, by Eq. (13), to be

$$\Delta\kappa/\kappa = \Delta n/n + \Delta u_2/(u_1+u_2)\,. \tag{14}$$

Thus, at least in the case of dilute aqueous solution of *Na-CMC* at *ca.* 30°*C*, the following important relation can be obtained:

$$\Delta n \cdot \Delta u_2 < 0\,. \tag{15}$$

Acknowledgements

The author expresses his thank to Prof. J. Furuichi for continuous guidance and valuable discussions, and also to Mr. M. Ishikawa for helpful assistances.

Ferromagnetic Crystalline Anisotropy of Fe-Mn-Ferrite System

By Zenya FUNATOGAWA, Nahonori MIYATA and Seiji USAMI
Department of Physics, Yokohama National University, Yokohama

(Received May 9, 1959)

Ferromagnetic resonance absorption of microwave (9300 Mc/s) in synthetic single crystals of $Mn_xFe_{3-x}O_4$ $(0.2 \leqq x \leqq 1.15)$ has been investigated to study their magnetic crystalline anisotropy, g-factor and line width. The pronounced valley in the curve, magnetic crystalline anisotropy $(-K_1/M)$ *vs.* composition (x), was observed in the temperature region between 90°K and 300°K. $-K_1/M$ was a minimum in the region $0.6 < x < 0.7$ and changed its sign. g-value and line width decreased with x more rapidly in the region $x < 0.6$ than $x > 0.6$. It seems difficult to explain these experimental results on the view point of one-ion-model which proved successful in many other ferrites.

§ 1. Introduction

Both experimental[1] and theoretical[2] investigations have been reported recently on the magnetic crystalline anisotropy of ferrites, which is one of the most fundamental properties of ferromagnetic substances. It is now expected that the study may be systematically extended to wider dimension, the solid solution of simple ferrites, because the research previously obtained seems to be limited to simple ferrites prepared from the different raw materials and by the different methods of crystallization.

The research on Fe_3O_4-$MnFe_2O_4$ system is reported here. There are two things interesting in this system; (1) the research on the magnetite side connected with the pronounced variation of the anisotropy constant with temperature[3] just above the electronic order-disorder transformation, the relation between them being not clear today, (2) the dependence of anisotropy on the composition of the solid solution of simple ferrites, neglecting the phenomenon mentioned in (1). The content of this paper is limited to the problem of (2). The study on (1) will be reported later. The data of magnetite used here are quoted from Bickford's paper[3].

§ 2. Specimens

The Bridgman method was used to get large crystals, which was not necessary for the microwave absorption experiment but useful to study the magnetostriction or the electric resistance etc. of the same materials.

Fe_2O_3 and $MnCO_3$ were used for the raw materials, the impurity content of which was analysed spectroscopically and given in Table I. According to the colorimetric and gravimetric analysis, cobalt, which exerted a harmful influence upon the study of the anisotropy, was less than 0.04 wt.% in both compounds. The ferrite powder was made by the usual ceramic technique; perfect mixing, prefiring at 1200°C and dry crushing with the steel ball mill. Large crystals, 1 cm in diameter and 5 cm in length, were grown in the air by the same way as J. Smiltens[4] with a higher speed, 2.8 cm/h, and cooled slowly in CO_2 gas atmosphere.

According to M. W. Shafer's paper[5] it was concluded that specimens prepared by the process mentioned above were excess or deficient in oxygen compared with the stoichiometric composition in the region of magnetite side or Mn-ferrite side, respectively. In our case, the shift of the transition temperature[6] indicated that magnetite obtained had the composition $Fe_{2.99}V_{0.01}O_4$ where V was vacancy. On the other hand, by the chemical analysis of a specimen, $Mn_{1.15}Fe_{1.85}O_{4+\varepsilon}$, ε was ±0.1 and it was not clear whether it was deficient in oxygen or not. Besides, the same analysis of three different parts of the crystal along the direction of the crystal growth (bottom, middle and top) showed no segregation of Fe and Mn within ±2%.

Specimens, cut from the bottom of the crystals, were completed in the shape of sphere, about 0.5 mm in diameter, by polishing by the method evolved by W. L. Bond[7] and etching in HCl solution to take away the surface layer. The X-ray analysis showed that they had the single spinel structure over the whole region as expected and their lattice constants depended linearly on the Mn concentration within the experimental error, ±0.07% (Fig. 1). Their compositions are:

(1) x=0.2, 0.4, 0.6, 0.75, 0.85, 0.97, 1.03, 1.15, for the measurement at room temperature.

(2) x=0.6, 0.85, for the measurement of the temperature dependency between 90°K and 300°K and x=0.4, 1.15, for that between 90°K and 500°K.

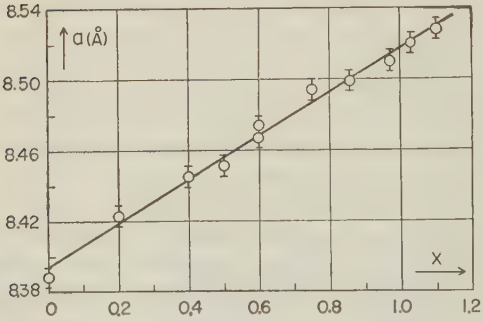

Fig. 1. Lattice constant a *vs.* composition x of $Mn_xFe_{3-x}O_4$.

§ 3. Experimental Procedures

(a) *Microwave techniques*

The apparatus was constructed according to the general scheme of the ferromagnetic resonance experiment. As specimens of Mn-rich side showed the large absorption and the narrow line width, the direct method of observing the minimum point of Q of the cavity was available. But for those of Fe-rich (magnetite) side the field modulation system was needed because the line width was broad and absorption intensities became smaller. ΔH was measured by the field modulation method: it was the distance from peak to peak in the differential curve of the absorption line shape. The microwave frequency was about 9300 Mc/s and its precise value was determined each time by the heterodyne frequency meter. For the measurement of the applied magnetic field we used the proton resonance apparatus[8] and also referred to the D. P. P. H. paramagnetic resonance.

(b) *Method of analysis*

Spherical specimens were set by the X-ray diffraction photographic method so as to rotate about a [110]-axis within ±1°. They were mounted with the dental cement to hold them rigidly at a high temperature. Magnetic anisotropy constant, g-value and line width were analysed by the usual way from the measurement of the static magnetic field where the ferromagnetic resonance absorption was observed in the specimen at the various crystallographic orientations in a (110)-plane. The 2nd term in the expression of the magnetic crystalline anisotropy energy, K_2, was neglected here. This abbreviation scarcely affected an error on the results, as indicated by the analysis.

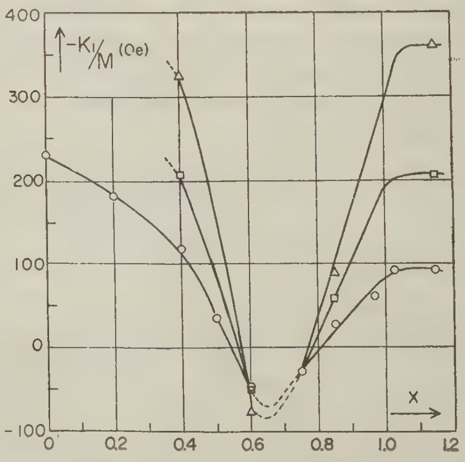

Fig. 2. Magnetic crystalline anisotropy $-K_1/M$ *vs.* composition x with a parameter of temperature; ○: 290°K, □: 190°K, △: 90°K.

§ 4. Experimental Results

Ferromagnetic crystalline anisotropy ($-K_1/M$) is plotted against composition (x) in Fig. 2 with the parameter of temperature and Fig. 3 shows its temperature dependency of each specimen. The pronounced valley is observed in the curve in Fig. 2. $-K_1/M$ is a minimum in the region $0.6<x<0.7$ and changes its sign.

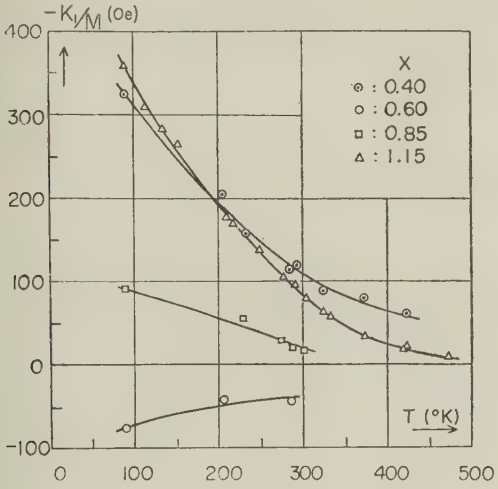

Fig. 3. Magnetic crystalline anisotropy $-K_1/M$ *vs.* temperature T of each specimen.

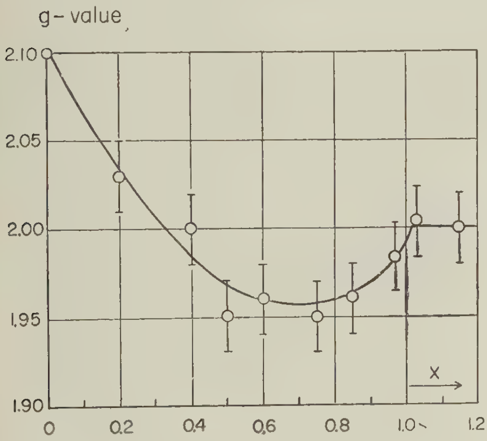

Fig. 4. g-value *vs.* composition x at room temperature.

g-value *vs.* composition at room temperature is shown in Fig. 4. g-value is 2.00 ± 0.02 in Mn excess Mn-ferrite and slightly less than 2.00 in the region $0.5\leq x\leq0.97$ independent of temperature. For $x=0.2$ and 0.4, though special, the g-value is appreciablly large, about 2.2, at liquid oxygen temperature and followed by the considerably narrow line width.

The tendency of the line width variation with the content x is gradual in the region $0.6\leq x\leq1.15$. But after passing through $x=0.6$ to the magnetite, it shows a considerable change and ΔH becomes broad rapidly (Fig. 5). Here the line width ΔH means the average value of them for three principal directions, ⟨100⟩, ⟨110⟩, ⟨111⟩.

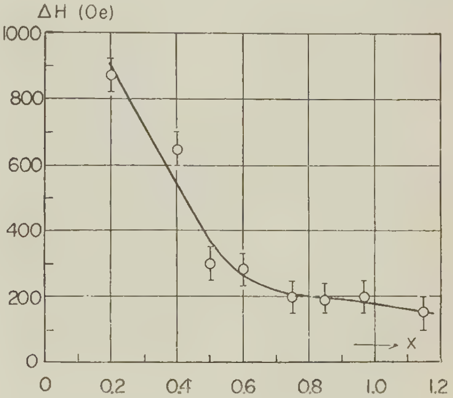

Fig. 5. Line width ΔH *vs.* composition x at room temperature.

§ 5. Discussions

(a) *Comparison with the results previously obtained*

The anisotropy constant of Mn-ferrite and its dependence on temperature have been reported by many authors[9]. Results described in § 4 are in good agreement with these.

Recently R. F. Penoyer and M. W. Shafer reported on the anisotropy of the same ferrite system as ours at the 4th Conference of Magnetism and Magnetic Materials (Nov. 1958). The details are still unknown to us. But so far as we have heard, they used the torque method, static one, contrary to our microwave, dynamic, method, and obtained the consistent results with ours, in spite of the difference of the experimental technique. g-value of Mn-ferrite is in good agreement with other authors' but ΔH is rather large.

(b) *Consideration of experimental results*

(1) Ferromagnetic anisotropy constant, $-K_1/M$

The dependence on temperature of each specimen seems to be in good agreement with the theory of Yoshida and Tachiki[2].

The curve $-K_1/M$ *vs.* x is very curious. As mentioned in § 2, this ferrite system has the simple spinel phase. Then, from the view point of the one-ion-model, K_1/M is expected to depend linearly on the composition x, as in the case of Mg-ferrite[10], if Mn^{2+} is substituted linearly for Fe^{2+}, through the medium of Fe^{3+} at the A-site, from magnetite, inverse spinel[11], to Mn-ferrite, nearly normal spinel[12].

But according to the analysis of the electric resistance of this ferrite system, it was concluded by authors[13] that by the substitution for Fe^{2+} in magnetite by Mn^{2+} the latter occupied B-sites until the concentration where the normal type spinel was stable. Now if we assume that the boundary of the inverse and partly normal type distribution of Mn-ions takes place at $x \approx 0.6$, the relation of $-K_1$ *vs.* x at 0°K, neglecting the transformation of magnetite at a low temperature, is expected to be the solid line shown in Fig. 6. The reason is as follows.

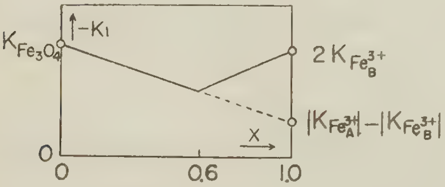

Fig. 6. Schematic expression of $-K_1$ *vs.* x.

$K_{Fe^{3+}_A}>0$, $K_{Fe^{3+}_B}<0$ by Folen and Rado's experiment on Mg-ferrite[14] (each term represents the contribution of Fe^{3+} ion at A and B-site, respectively, to the anisotropy constant) and

$K_{Ni^{2+}_B}\sim 0$, $K_{Mn^{2+}}\sim 0$ by the theoretical consideration by Yoshida and Tachiki[2].

When Mn^{2+} ions are substituted at B-sites for Fe^{2+} over all concentration, the anisotropy constant K_1 goes linearly from the value of magnetite to that of Ni-ferrite. As the latter is inverse type spinel, its anisotropy is given by $|K_{Fe^{3+}_A}|-|K_{Fe^{3+}_B}|$. Mn-ferrite of the perfect normal type has the anisotropy of $2K_{Fe^{3+}_B}$. Then, if the assumption about the distribution of Mn-ions, mentioned above, is correct, a minimum should appear in the curve $-K_1$ *vs.* x at $x \approx 0.6$.

But these considerations do not explain the experimental fact of the positive value of K_1, because the anisotropy constant of Ni-ferrite is negative,[15],[16] K_1/M being -400 Oe at 4°K. Also it should be mentioned that the experimental values of K_1/M of Mn-ferrite at 4°K, previously obtained by many authors[8], are dispersed in the range from -433 Oe to -1250 Oe. The reason is not clear today but may be attributed to the difference of the source of the specimens.

A. H. Eschenfelder[17] showed that the higher valency of Mn-ion than +2 should be considered in the region $x \gtrsim 0.7$ to explain the magnetization of this ferrite system. But the positive value of K_1 is not attributed to this fact.

(2) *g*-value

The observed g-value is expressed theoretically by the equation[18]

$$g=\sum_i g_i<S_{zi}>_{av}/\sum_i<S_{zi}>_{av} ,$$

where g_i is the g-value and $<S_{zi}>_{av}$ is the quantum statistical average value of z-component of the spin, respectively, of i-th ion. Now both Fe^{3+} and Mn^{2+} are in ^6S state and only Fe^{2+} ions, which are always at the B-sites, help to make g different from 2.00. Then g should vary nearly linearly with x in the region $0 \leqq x \leqq 1$, independent of Mn-ion distribution. The experiment shows that the situation is not like this.

According to T. Okamura[19] and D. W. Healy et al[16], the internal field, the physical meaning of which is not clear now, should be considered for the explanation of the frequency dependency of g-value of ferrites. One should

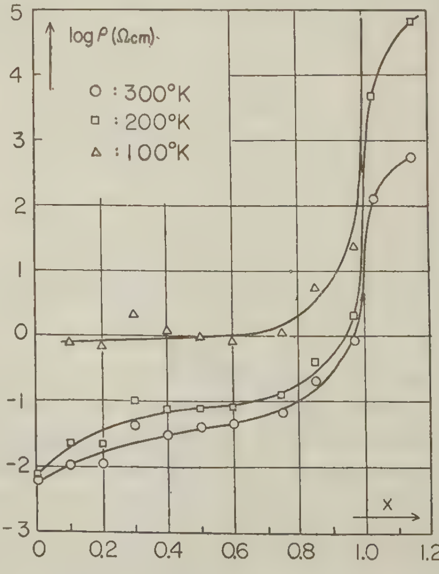

Fig. 7. Specific electric resistance *vs.* composition x at various temperature.

take care of this fact for the analysis of *g*-value.

Low electric resistance of specimens should also be taken into account, because the skin effect may affect the absolute value of *g*-factor. But Figs. 4 and 7 show no intimate relation between them.

(3) Resonance line width, ΔH

The origin of ΔH is not clearly understood today. Values of it in Fig. 5 should be treated with the caution to the skin effect which changes the absorption line shape and the absolute value of ΔH.

(c) *Conclusion*

As we have seen above, it seems that the experimental results are too complicated to be explained from the stand point of the one-ion model. Also, it should be noticed that the quantitative knowledge about the ion distribution on lattice points, for instance by the neutron diffraction experiment, is expected to give us the important information to analyse the physical properties of Fe-Mn ferrite system.

The research on other ferrite systems, now proceeded in our laboratory, will make clear the origin of phenomena described here.

Acknowledgement

The authors are indebted to Dr. H. Kitagawa of the Hitachi Central Laboratory and to Mr. T. Karasawa and other members of Tokyo Denki Kagaku Kogyo Co.. They also wish to thank Mr. Y. Gondo in our laboratory for his valuable discussions. This work was partly supported by the Scientific Research Expenditure of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 11, NOVEMBER, 1959

Temperature Dependence of the Magnetostriction Constants in Iron and Silicon Iron

By Eiji TATSUMOTO and Tetsuhiko OKAMOTO

Department of Physics, Faculty of Science, Hiroshima University, Hiroshima

(Received June 15, 1959)

The magnetostriction constants λ_{100} and λ_{111} of Fe, 1.08 and 3.83% Si-Fe have been measured by using single crystals at temperatures below Curie point down to liquid air temperature with two newly designed apparatuses.

In iron, λ_{100} has a minimum around 400°K, while λ_{111} monotonously decreases in numeral with increasing temperature. Addition of silicon to iron has a tendency to make the minimum in λ_{100} disappear and to decrease λ_{111} numerically at any temperature, retaining the similar monotonous variation with temperature.

Several existing theories have been applied to account for the experimental results, but no theory appears to be successful in interpreting them.

§ 1. Introduction

Practically, the anisotropic magnetostriction phenomena are characterized by the two magnetostriction constants λ_{100} and λ_{111}.

From a theoretical standpoint, it would be of much importance to observe the influence of temperature and alloying element on the magnetostriction constants, since temperature and composition of alloy are the most important factors affecting the interaction responsible for the magnetostriction. No satisfactory observation of magnetostriction constants has been done except for that of iron done by Takaki[1)] and that of 3.5% Si-Fe by Shturkin[2)], because of great experimental difficulties. The purpose of the present work is to perform such observation on iron, 1.08% Si-Fe and 3.83% Si-Fe, by using a new technique which has the same performance as the strain gauge technique.

Since Goldman[3)] successfully utilized the strain gauge technique for measuring the magnetostriction constants λ_{100} and λ_{111}, the technique has been widely used, but mostly at room temperature. This technique is especially excellent in the respect that small samples can be used. However, we can use paper strain gauges neither at temperatures much higher than room temperature, because of their burning, nor at much lower temperatures on account of uncertainty of the gauge factors which are defined as the ratio of the resistance change to the strain. In the present experiment, instead of the paper strain gauge a straight gauge wire that composes the main part of the paper strain gauges has been used, in order to make the observation possible at any temperature. The principle of this new technique is very simple as follows. A specimen maintained at any temperature is connected with a thin and long quartz rod and a straight strain gauge wire kept at room temperature in order and in series. Thus, the distortion of the specimen can be directly converted to that of the gauge wire, so that the strain of the specimen at the temperature can be computed from the strain of the gauge wire, provided the gauge factor is known at room temperature. The gauge factor can easily be obtained by measuring the known strain of the specimen.

As to the observation of λ_{100} and λ_{111}, it is, in general, experimentally difficult to obtain the reliable λ_{100}, because of the uncertainty of the domain configuration at a reference state. The difficulty has already been overcome by the authors by making use of the (001)−[100] single crystal strips[*)] and by producing technically a simple and definite domain structure in the specimen at the reference state[4)]. On the other hand, λ_{111} can be measured without any experimental dif-

---

[*] For example, the notation (001)−[100] signifies that the crystal plane (001) and the crystal axis [100] coincide with the surface plane and the longitudinal direction of the specimen, respectively.

ficulty with the [111] single crystal rods or strips on account of the symmetrical orientations of the domains referred to the [111] direction at the ordirary demagnetized state. In the present experiment the $(1\bar{1}0)-[111]$ single crystal strips have been used.

§ 2. Specimens

The specimens are the $(001)-[100]$ and $(1\bar{1}0)-[111]$ single crystal strips of iron, 1.08% Si-Fe and 3.83% Si-Fe, the sizes of which are 0.3∼0.5 mm in thickness, 3∼5 mm in width and 50 mm in length. They are all produced by Fujiwara's method[5]. Before making use of them for the measurement, all the specimens are annealed at the temperatures, 850°C 1000°C, lower than the allotropic transformation temperature for 3∼5 hours in a vacuum furnace.

§ 3. Measurement of λ_{100} and λ_{111}

As is well known, in the ferromagnetic metals and alloys of the cubic structure, the magnetostriction of a single magnetic domain occurring from an imaginary nonferromagnetic state is represented practically by the phenomenological equation[6]

$$\begin{aligned}\frac{dl}{l_0}=\lambda_0+\frac{3}{2}\lambda_{100}(\alpha_1^2\beta_1^2+\alpha_2^2\beta_2^2+\alpha_3^2\beta_3^2)\\+3\lambda_{111}(\alpha_1\alpha_2\beta_1\beta_2+\alpha_2\alpha_3\beta_2\beta_3\\+\alpha_3\alpha_1\beta_3\beta_1)+\cdots ,\end{aligned} \tag{1}$$

where λ_{100} and λ_{111} are the magnetostriction constants which are characteristic of the material and which vary with temperature; l_0 is the length along the measuring direction and λ_0 the isotropic strain occurring from the imaginary nonferromagnetic state; α's and β's are the direction cosines of the intrinsic magnetization vector and measuring orientation, respectively, referred to the cubic axes. The magnetostriction constants λ_{100} and λ_{111}, as long as the domain configuration is known completely at a definite reference state, are successfully obtained by measuring the so-called saturation magnetostriction from a reference state demagnetized adequately.

In the first place, the $(001)-[100]$ specimens are used for measuring λ_{100}. As the reference state, we use the one having the simple and definite domain structure shown schematically in Fig. 1[7]. This domain structure is easily produced by utilizing the circular field induced by a comparatively weak direct current through the specimen, since the field in the specimen is nearly parallel to the easy magnetization axis $\langle 100\rangle$ as is illustrated in the same figure. In this reference state, we have λ_0 from Eq. (1) as the magnetostriction in the [100] direction, $(dl/l_0)_{\perp[100]}$. In the state where the magnetization is saturated in the [100] direction, we also have $\lambda_0+(3/2)\lambda_{100}$ as the magnetostriction in the same direction, $(dl/l_0)_{//[100]}$. Then, we get $(3/2)\lambda_{100}$ as the difference between two states. Now, we may consider that the difference is almost equal to the so-called saturation magnetostriction in the [100] direction observed in this case, $(dl/l)_{[100]\mathrm{sat.}}$, because of negligibly small differences among the dimensions of the three states (the imaginary nonferromagnetic, the reference and the saturation magnetization state); that is,

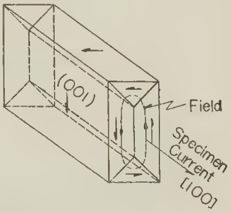

Fig. 1. Domain structure of the (001)−[100] single crystal strip in the presence of a sufficiently large direct current.

$$\left(\frac{dl}{l}\right)_{[100]\mathrm{sat.}}\simeq\frac{3}{2}\lambda_{100}\ . \tag{2}$$

The current sufficient to produce the domain structure as shown in Fig. 1 is obtained by measuring the saturation magnetostriction as a function of the current. As an example, a run of the measurements made on the iron specimen at room temperature is given in Fig. 2, where the circles show the saturation magnetostriction measured when demagnetized by a gradually decreasing alternating field in the presence of a current (method (a)); the crosses show those measured when the reverse process was operated (method (b)). The necessary and sufficient current is taken obviously above the current which begins to have the constant saturation magnetostriction. In the present experiment, the method (a) has always been adopted, since smaller current can be used than with the method (b).

In the next place, the $(1\bar{1}0)-[111]$ specimens are used for measuring λ_{111}. In this case we may take the ordinary demagnetized state as the reference state. In this reference state we have $\lambda_0+(1/2)\lambda_{100}$ as the magnetostriction in [111] direction, $(dl/l_0)_{<100>[111]}$, since all domains are symmetrical about the [111] direction. In the state where the magnetization is saturated in the [111] direction, we have $\lambda_0+(1/2)\lambda_{00}+\lambda_{111}$ as the magnetostriction in the same direction, $(dl/l_0)_{//[111]}$. Then, the difference between the two states is λ_{111}. Thus, for the same reason as in the case of λ_{100}, we obtain

$$\left(\frac{dl}{l}\right)_{[111]\text{sat.}} \simeq \lambda_{111} \ . \tag{3}$$

where $(dl/l)_{//[111]}$ is the so-called saturation magnetostriction in the [111] direction observable in this case. It is noted, however, that the [111] single crystal rods or strips can be employed as well.

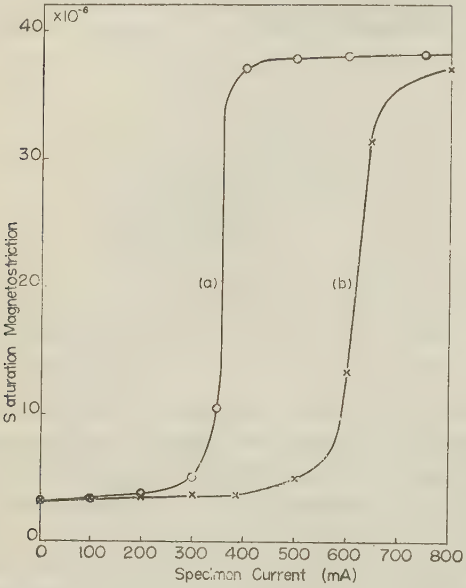

Fig. 2. Difference in longitudinal saturation magnetostriction *vs.* specimen current for the (001)–[100] iron specimen at room temperature; the circles correspond to measurements made on the specimen demagnetized in the presence of a specimen current; the crosses correspond to measurements made on the specimen in the presence of a specimen current after the demagnetization with no specimen current.

§ 4. Apparatus for Low Temperatures

For the measurement at temperatures below room temperature, the apparatus is diagrammatically shown in Fig. 3. The magnetizing coil is inclined by about 10° referred to the vertical line, so that the specimen and the quartz pipe may contact well with the top surface of the specimen base made by micata. The magnetizing coil constant $(4\pi n)$ is 450 and the field is uniform within 2% in a region 100 mm long around the central part. To each end of the specimen, a small copper plate is soldered. Its bottom is fixed with a small screw to the sample base, and its top is sharpened and inserted tightly into the bottom of the quartz pipe, which is 1.5 mm in inner-diameter, 2.5 mm in outer-diameter and 260 mm in length. To the top of the quartz pipe, the bottom end of the straight gauge wire of 0.025 mm in diameter and 60 mm in length is fixed by wax and the other top end is connected with a silk thread, the other free end of which is weighted with a load of 10 gr, through a pulley so as to stretch the gauge wire elastically.

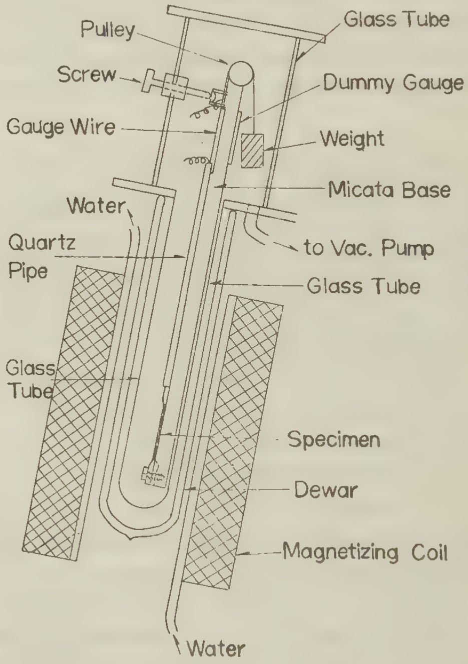

Fig. 3. Apparatus for measuring magnetostriction at low temperatures.

Such a combination is set in a container which is constructed with two glass tubes which are different in size. Inside of the container vacuum can be maintained. The top end of the gauge wire can be fixed with a small screw out of the container, when the specimen is settled down to a certain temperature. Then, the linear distortion of the specimen is directly converted, via the quartz pipe, to that of the gauge wire as the reverse linear distortion, and this is observed as the corresponding strain by measuring the resistance change with D. C. Wheatstone bridge circuit, the dummy gauges of which are made by the same kind of the wires. Accordingly, we can calculate the strain of specimen from the strain of gauge wire thus measured. In this case, we obviously need to know the gauge factor of the gauge wire. This method will be described in the following section.

§ 5. Temperature Dependence of the Gauge Factor of Paper Strain Gauges

At present, it seems that there is no measurement on the gauge factor of paper strain gauges at low temperatures, except that by Day and Sevand[8] who used the ordinary technique measuring the constant bending of a beam on which the gauges are cemented. In the present work, the measurement was made as an auxiliary project as follows.

As mentioned previously, in order to accomplish the measurement of λ_{100} or λ_{111}, we need to know the gauge factor of the strain gauge wire set in the apparatus at room temperature. The gauge factor can be computed by comparing a certain strain of the specimen, which is measured by the paper strain gauges cemented on its both surface planes, with the same strain which is measured by the strain gauge wire. In practice, it is convenient to measure $(3/2)\lambda_{100}$ of the $(001)-[100]$ specimens or λ_{111} of the $(1\bar{1}0)-[111]$ specimens as a standard strain. Thus, we can measure contrariwise the gauge factor of the paper strain gauges at any temperature by the same method, as long as the paper strain gauges stick tightly on the specimen. As glues, Duco cement and the similar kind of cements have been tried, and they were all ascertained to be available for any temperature down to the liquid air temperature. However, no confirmation has been made whether they are still available even when immersed directly in such as liquid air.

In the present experiment, the paper strain gauges, type S_{121}, made by Shinkoh communication Industry Co., Ltd. were used and their gauge factor was measured at temperatures below room temperature down to liquid air temperature. In Fig. 4 this is plotted with one of the results obtained by Day and Sevand[8]. The gauge factor of type S_{121} decreases slightly and the decreasing rate increases with decreasing temperature. This temperature dependence is distinctly different from that due to Day and Sevand. Therefore, we may conclusively say that the temperature variation depends on materials of the wire.

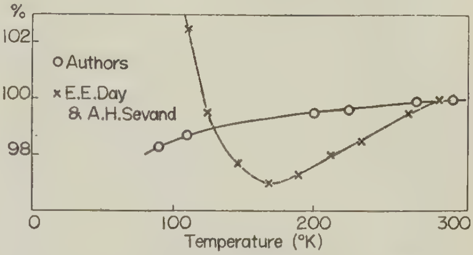

Fig. 4. Temperature dependence of the gauge factor below room temperature. The ordinate shows the gauge factor in percentage referred to that at room temperature.

Now, we can use the paper strain gauges for measurements of such strain as magnetostriction at various low temperatures, at least down to liquid air. In the measurement of magnetostriction, however, we should not disregard their own magnetoresistance, since it is, in general, fairly large in high fields as well as at low temperatures. In the present experiment, it was scarcely observed even in liquid air temperature, because the measurement was made in a comparatively weak field less than 900 oersteds in every case.

§ 5. Apparatus for High Temperatures

For the measurement at temperatures above room temperature, the apparatus for low temperatures was somewhat reformed as is diagrammatically shown in Fig. 5. The same magnetizing coil is horizontally set, inside which a noninductive electric furnace is

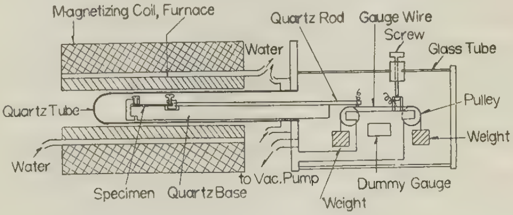

Fig. 5. Apparatus for measuring magnetostriction at high temperatures.

inserted. The sample base and the vacuum container are changed to the ones of quartz. The left end of the specimen is fastened by a small molybdenum fixer having a screw to the quartz base, and the specimen and the quartz rod of 2 mm in diameter and 380 mm in length are connected in series with a small molybdenum joint having two screws. The straight strain gauge wire of 40 mm long is fixed with wax to the quartz rod and stretched elastically from both sides by weighting two equal loads of 10 gr each as shown in the figure, so that no tension acts on the specimen. All the other parts are not reformed further.

In this equipment at elevated temperatures the molybdenum joint comes often loose as its thermal expansion is larger than that of quartz. To fix tightly together, therefore, a small copper wedge is inserted between them, as its thermal expansion is larger than that of molybdenum. Thus, all fixing goes well in the ascending process in temperature, but in the reverse process they become often slack. We may suppose then that the slackness results from the plastic deformation either of the specimen, or of the molybdenum fixer or of the copper wedge happening at elevated temperatures. However, this fact can be disregarded because we can safely operate the equipment in the ascending process in temperature. Furthermore, the pressure of the molybdenum fixers acting on the specimen would presumably change the domain structure around there, but even if it happens, it also matters little for the measurements of the magnetostriction constants, because in the case of λ_{111} it has no relation with the measurement and in the case of λ_{100} the domain structure at the reference state is newly produced, as was described previously, by using the current.

§ 6. Influences of Temperature and Addition of Silicon on λ_{100} and λ_{111}

Figs. 6 and 7 show the magnetostriction constants λ_{100} and λ_{111} which have been measured at temperatures above liquid air temperature up to the Curie point.

In iron, an essential feature of the temperature dependences of λ_{100} and λ_{111} may be regarded as the minimum appearing around 400°K in λ_{100}, since the minimum has a tendency to disappear with the increase of amount of silicon as is seen in Fig. 6 and was not found in 3.5% Si-Fe on which Shturkin made the measurement at higher temperatures than 0°C[2]. This minimum was found for the first time by Takaki who made the measurement on iron single crystal rods at temperatures above room temperature[1]. For all the temperatures at which he measured λ_{100}, however, the values which he obtained are slightly smaller than those obtained in the present experiment. This is, presumably, attributable to the ambiguous domain configuration at the remanent which he preferred as the reference state. In the λ_{100} *vs.* temperature curve, there appear two maxima as seen in Fig. 6; the one appearing at the low temperature was first found in the present measurement, though this is presumably not very essential but only resulted from an appearance of the minimum just mentioned above at the high temperature side. The other one appearing at the high temperature evidently results from rapid decreasing of the intrinsic magnetization near the Curie point.

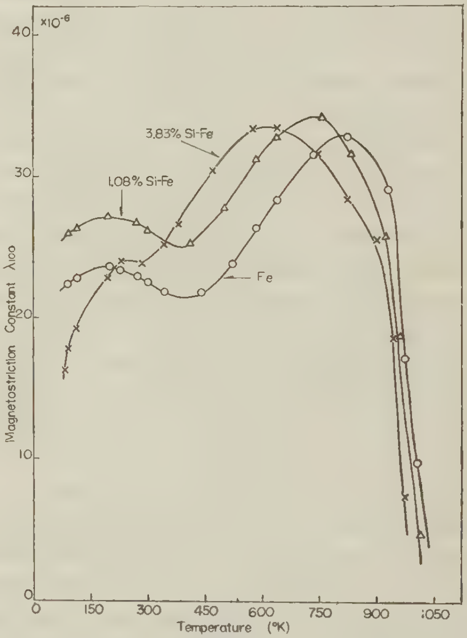

Fig. 6. Temperature dependence of the magnetostriction constant λ_{100}.

By addition of small amount of silicon to iron, the feature of the temperature dependence of λ_{100} is fairly altered, while that of λ_{111} is not changed at all as is seen in Figs. 6 and 7; that is, in the case of λ_{100} the minimum appearing around 400°K has a tendency to disappear, so that even the order in magnitude of the values of λ_{100} for Fe, 1.08% Si-Fe and 3.83% Si-Fe changes at different temperatures, while in the case of λ_{111} the monotonous variation with temperature is preserved so that only the numerical value decreases with increasing temperature. In Fig. 8, the values of λ_{100} and λ_{111} at room temperature are plotted as functions of the amount of silicon. These values also have already been obtained by the authors by means of paper strain gauges[4)]. In this figure, in addition, are plotted the values at room temperature which were obtained by Carr and Smoluchowski[9)] and also are plotted those values at absolute zero which were estimated by extrapolating the λ_{100} or λ_{111} *vs.* temperature curve obtained in the present experiment down to absolute zero temperature. In the case of λ_{100}, however, the estimated values, particularly for 1.08% Si-Fe, do not seem quite accurate, because λ_{100} may possibly happen to decrease rapidly near the liquid air temperature like that of 3.83% Si-Fe. For estimating the values more accurately by extrapolation, it is presumably necessary to measure λ_{100} at temperatures lower than liquid air temperature. In the case of λ_{111}, however, the estimated values may be quite reliable. As is inferred from Fig. 8, both λ_{100} and λ_{111} undoubtedly change their sign inversely at a certain amount of silicon, but it should be noted that the amount is fairly altered with temperature.

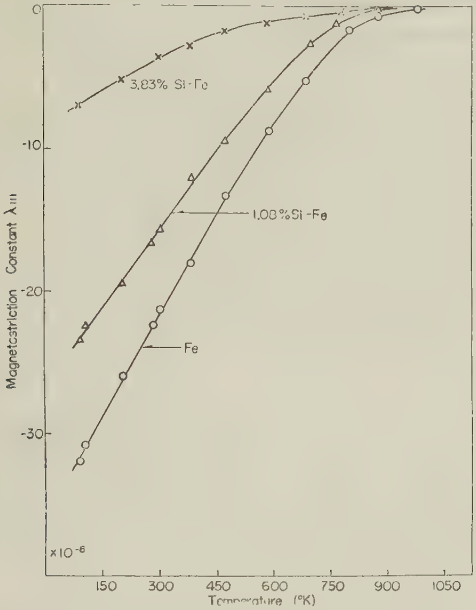

Fig. 7. Temperature dependence of the magnetostriction constant λ_{111}.

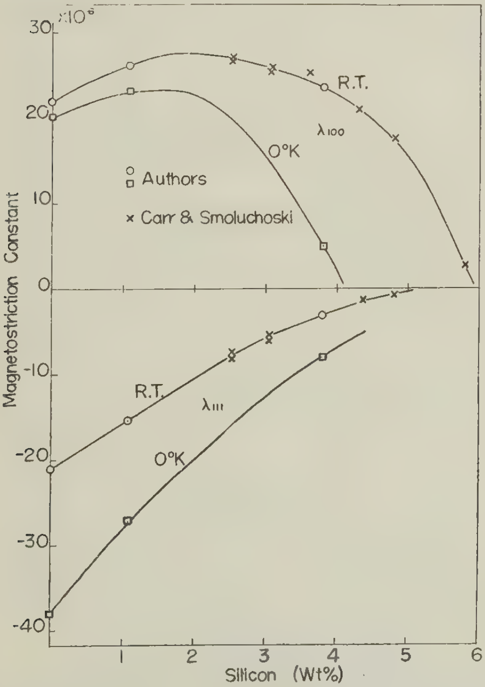

Fig. 8. Dependence of λ_{100} and λ_{111} on the amount of silicon in weight percentage in iron. The values at absolute zero were obtained by extrapolating the λ_{100} and λ_{111} *vs.* temperature curves in Figs. 6 and 7 down to absolute zero.

The formal origin of magnetostriction may be attributable to the interaction between intrinsic magnetization and crystal strain, as has been pointed out by Kittel[10)]. Consequently, the magnetostriction equation can be derived from the interaction energy, i.e. magnetoelastic energy[6)] For a body-centered cubic crystal

$$\begin{aligned} dl/l = {} & h_1(\alpha_1{}^2\beta_1{}^2+\alpha_2{}^2\beta_2{}^2+\alpha_3{}^2\beta_3{}^2-1/3) \\ & +2h_1(\alpha_1\alpha_2\beta_1\beta_2+\alpha_2\alpha_3\beta_2\beta_3+\alpha_3\alpha_1\beta_3\beta_1) \\ & +h_4(\alpha_1{}^4\beta_1{}^2+\alpha_2{}^4\beta_2{}^2+\alpha_3{}^4\beta_3{}^2+2s/3-1/3) \\ & +2h_5(\alpha_1\alpha_2\alpha_3{}^2\beta_1\beta_2+\alpha_2\alpha_3\alpha_1{}^2\beta_2\beta_3 \\ & +\alpha_3\alpha_1\alpha_2{}^2\beta_3\beta_1)+h_3s\,. \end{aligned} \tag{4}$$

with

$$h_1=\frac{B_1}{c_{11}-c_{12}}\,, \qquad h_2=-\frac{B_2}{c_{44}}\,,$$

$$h_4=-\frac{B_4}{c_{11}-c_{12}}\,, \qquad h_5=\frac{B_5}{c_{44}}$$

and

$$s=\alpha_1^2\alpha_2^2+\alpha_2^2\alpha_3^2+\alpha_3^2\alpha_1^2\ ,$$

where h_1, h_2, h_3, h_4 and h_5 are the magnetostriction constants; B_1, B_2, B_4, and B_5 are the magnetoelastic coupling constants as named by Kittel; c_{11}, c_{12} and c_{44} are the elastic moduli. Formally, the first two terms result from quasi dipole-dipole interaction and the other terms from quasi quadrapole-quadrapole interaction. Eq. (1) just corresponds to the first two terms in which h_1 and h_2 can be rewritten as (3/2) λ_{100} and (3/2) λ_{111} respectively. If the practical magnetostriction phenomena are represented more effectively by Eq. (4) than Eq. (1), the observed $(dl/l)_{[100]\text{sat.}}$ and $(dl/l)_{[111]\text{sat.}}$, as previously denoted, are not $(3/2)\lambda_{100}$ and λ_{111}, but h_1+h_4 and $(2/3)h_2+(2/9)h_5$, respectively; $(1/3)h_3$ is omitted, in this case, because of numerical smallness in comparison with the others.

On the other hand, the magnetostriction was formerly calculated classically as atomic dipole-dipole interaction by Akulov(11) and Becker(12), and recently by Néel(13) with somewhat advanced idea. In the case of Becker's calculation, the magnetostriction constants are

$$\left.\begin{aligned}\lambda_{100}&=\frac{2SI_s^2}{c_{11}-c_{12}}\\ \text{and}\qquad&\\ \lambda_{111}&=\frac{4SI_s^2}{3c_{44}}\end{aligned}\right\}\qquad(5)$$

for a body-centered lattice. Here I_s is the intrinsic magnetization, and S a constant depending on the geometry of the crystal lattice, 0.4. Accordingly, as the temperature rises, both λ_{100} and λ_{111} monotonously decrease in proportion to I_s^2. In the case of λ_{100} this is quite different from the results obtained in the present experiment as is shown in Fig. 6. It is presumed that, further addition of quadrapole-quadrapole interaction may improve the discrepancy; in other words, h_4 or h_5 is likely to be responsible for it. Such a presumption has been attempted by S. Taniguchi* but the non monotonous variation of λ_{100} with temperature has not been explained successfully.

The greater part of the observed magnetostriction may be suspected to have its origin in the spin-orbit interaction, as was treated by Van Vleck concerning the crystalline anisotropy. By taking account of both the spin-spin and the spin-orbit interactions, Vonsovski has obtained an interesting result which was quoted by Lee in his article(15). According to this result, the departure from the law of the temperature dependence of magnetostriction proportional to I_s^2 is regarded as due to the effect of spin-orbit interaction. This result does not seem to be incompatible with the temperature dependences of $(dl/l)_{[100]\text{sat.}}$ and $(dl/l)_{[111]\text{sat.}}$ obtained in the present work; but further detailed considerations will not be given here, because unfortunately the authors are not accessible to Vonsovski's original paper.

In conclusion, the magnetostriction constants λ_{100} and λ_{111} vary only if the responsible interaction alters. However, any existing theory does not seem to be successful in interpreting the results obtained in the present experiment.

The authors are indebted to Mr. H. Kimura and Mr. Y. Uchida for the loan of their 3.8% Si-Fe specimens. The present work was partly supported by the Science Research Grant from the Ministry of Education.

Magnetic Hyperfine Spectrum of H_2CO by a Maser

By Hiroshi TAKUMA, Tadao SHIMIZU and Koichi SHIMODA

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received July 4, 1959)

The magnetic hyperfine structure in $J=3$, $K_{-1}=1$, $\Delta J=0$ transition of formaldehyde at 29 Gc/sec was studied by a beam type maser spectrometer. The hyperfine components corresponding to $\Delta F=0$ transitions were observed with good signal-to-noise ratio. The splittings are measured as 23.0 kc/sec and 10.4 kc/sec which are compared with theory. As well as the $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling, spin-spin interaction term $\boldsymbol{I}_1\cdot\boldsymbol{I}_2$ between the two protons is fairly large and cannot be neglected. Coupling constants were determined as $\mu_N{}^2 g_H{}^2 r^{-3}=19.9$ kc/sec and $\sum_g \langle J_g{}^2\rangle(A_{1g}+A_{2g})=54.6$ kc/sec.

§ 1. Introduction

A beam type maser spectrometer was successfully applied to observe the magnetic hyperfine structure of ammonia. However, the application of the technique to other molecules is strongly limited by the focuser action for the molecules. The Q branch transition of formaldehyde shows probably the next strongest emission spectrum to ammonia in the centimeter wave range, because the molecule has small moment of inertia, large dipole moment, and very slight asymmetry to allow closely spaced pairs of levels (K-type doubling). Thus the calculated intensity is very close to get self-sustained oscillation under a typical condition. The microwave absorption spectra of formaldehyde, formaldehyde $-d_1$ and $-d_2$ have been studied[1] in our laboratory as well as their Zeeman effects[2]. Then the study of magnetic hyperfine structure of formaldehyde by the beam type maser spectrometer was planned and the result on the $J=3$ $K_{-1}=1$ line is reported in this paper. Work on other lines of formaldehyde will be reported later.

§ 2. Theoretical Treatment

A theory of the magnetic hyperfine structure of this type of molecule was discussed by Okaya[3], and a more general theory of magnetic hyperfine structure of an asymmetric molecule was developed by Posener[4]. A somewhat different theory which is essentially similar to that of Posener has been developed and is given below. This theory is more suitable to the case of a slightly asymmetric molecule in computing the energy levels.

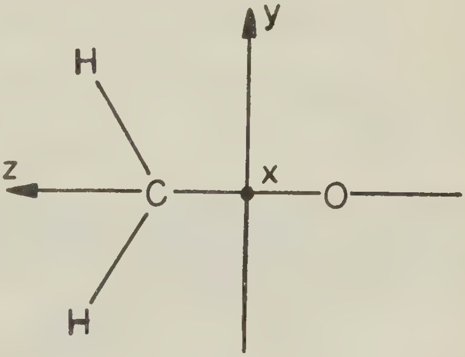

Fig. 1. Molecular axis of H_2CO.

The Hamiltonian of a formaldehyde-type molecule with C_{2v} symmetry in $^1\Sigma$ state based on Pauli approximation can be written as[3-6];

$$\begin{aligned}\boldsymbol{H}=&A(J_z-L_z)^2+B(J_y-L_y)^2+C(J_x-L_x)^2 && (1.0)\\ &+(e\mu_N/c)\sum_{K=1,2}\sum_i r_{Ki}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\{\boldsymbol{v}_i-[1+Z_KM_p/g_KM_K]\boldsymbol{v}_K\}g_K\cdot\boldsymbol{I}_K && (1.1)\\ &-(e\mu_N/c)\sum_{K=1,2}\sum_{K\neq L}Z_Lr_{KL}^{-3}(\boldsymbol{r}_K-\boldsymbol{r}_L)\times\{[1+Z_KM_p/g_KM_K]\boldsymbol{v}_K-\boldsymbol{v}_L\}g_K\cdot\boldsymbol{I}_K && (1.2)\\ &+\mu_N^2r_{HH}^{-3}g_H^2[\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3r_{HH}^{-2}(\boldsymbol{I}_1\cdot\boldsymbol{r}_{HH})(\boldsymbol{I}_2\cdot\boldsymbol{r}_{HH})]\,, && (1.3)\end{aligned}$$

where the notations are the same as in ref. 3) and 6), the capital letter suffix denotes the nucleus, and the small letter the electron. The physical meaning of the term (1.0) in Eq. (1) is the pure rotational energy of nuclear frame, (1.1) represents the energy of the proton spins in the magnetic field produced by electrons in the molecule, (1.2) represents the magnetic energy of protons in the field produced by other nuclear charges, and the last term (1.3) represents the spin-spin interaction energy of two protons in the molecule. For a nearly symmetric prolate top the rotational part of the molecular wave function can be conveniently expanded in a power series of the asymmetric parameter $b(=(C-B)/(2A-B-C)$[7]. The rotational energy can be expressed as;

$$W=A\langle J_z^2\rangle+B\langle J_y^2\rangle+C\langle J_x^2\rangle=\frac{B+C}{2}\,J(J+1)+\left(A-\frac{B+C}{2}\right)w(b)\,, \tag{2.1}$$

where

$$w(b)=K^2+\sum_{n=1}^{\infty}C_nb^n\,. \tag{2.2}$$

The expansion coefficient C_n is tabulated in reference 7). The molecular fixed axis x, y, z are taken for H_2CO as shown in Fig. 1, and $b=-0.0098290$. For the convenience of the later treatment[7,8], $\langle J_x^2\rangle$ etc. are calculated as

$$\left.\begin{aligned}\langle J_z^2\rangle&=\frac{\partial W}{\partial A}=K^2-\sum_{n=1}^{\infty}(n-1)C_nb^n\\ \langle J_y^2\rangle&=\frac{\partial W}{\partial B}=\frac{1}{2}\left\{J(J+1)-K^2-C_1+\sum_{n=1}^{\infty}[(n-1)C_n-(n+1)C_{n+1}]b^n\right\}\\ \langle J_x^2\rangle&=\frac{\partial W}{\partial C}=\frac{1}{2}\left\{J(J+1)-K^2+C_1+\sum_{n=1}^{\infty}[(n-1)G_n+(n+1)C_{n+1}]b^n\right\}.\end{aligned}\right\} \tag{3}$$

The appropriate coupling scheme for the molecule with two identical nuclei with spin I_1 and I_2 should be

$$\bar{I}_1+\bar{I}_2=\bar{I}\,,\qquad \bar{I}+F=J\,,$$

where $\bar{I}_1=-I_1$, $\bar{I}_2=-I_2$ and $\bar{I}=-I$ are used in order to retain proper commutation relations in the molecular fixed system[9]. When the perturbation theory is used to account for the excitation of electronic states due to molecular rotation, the Hamiltonian for the nuclear spin interaction can be written as[3-6];

$$H=\sum_{K=1,2}[A_{Kx}\bar{I}_{Kx}J_x+A_{Ky}\bar{I}_{Ky}J_y+A_{Kz}\bar{I}_{Kz}J_z]+\mu_N^2g_H^2r^{-3}[\boldsymbol{I}_1\cdot\boldsymbol{I}_2r^2-3(\boldsymbol{I}_1\cdot\boldsymbol{r})(\boldsymbol{I}_2\cdot\boldsymbol{r})]r^{-2} \tag{4}$$

where A_{Kx} etc. are constants determined from the electronic states and the molecular structure, $\boldsymbol{r}$ the vector between the two protons, and r the magnitude of $\boldsymbol{r}$.

The energy level shift due to these interactions will be obtained in the first order approximation from the eigenvalue of the matrix

$$\langle I_1I_2IFJ\tau|H|I_1'I_2'I'F'J'\tau'\rangle\,.$$

When the molecule has a C_{2v} symmetry, the nuclear spin part of the eigenfunction is odd or even respectively corresponding to the even or odd symmetry of the rotational part of wave function $|J\tau\rangle$. Therefore, the elements $\langle I|H|I-1\rangle$ will vanish. The total proton spin is $I=1$ for the rotational wave function with odd symmetry, and $I=0$ for even symmetry. Therefore the rotational levels with even symmetry have no magnetic hyperfine splittings, since $I=0$. The magnetic hyperfine structures of transitions between odd rotational levels are considered. The I, J dependent term of the spin-spin interaction between the identical nuclei, $[r^2\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3(\boldsymbol{I}_1\cdot\boldsymbol{r})(\boldsymbol{I}_2\cdot\boldsymbol{r})]r^{-2}$, is shown to be equivalent to[10]

$$\frac{I(I+1)+4I_1(I_1+1)}{(2I-1)(2I+3)(2J-1)(2J+3)}\left[3(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})^2-\frac{3}{2}(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})-\bar{\boldsymbol{I}}^2\cdot\boldsymbol{J}^2\right].$$

On the other hand, J, τ dependent term of the spin-spin interaction is[8]

$$\frac{1}{J(J+1)}\left[\boldsymbol{J}^2-3\sum_g\left(\frac{r_g^2}{r^2}\right)\boldsymbol{J}_g^2\right].$$

Therefore, Eq. (4) is equivalent to the next equation for $I=1$ and $I_1=\frac{1}{2}$*

$$H=\sum_{K=1,2}\sum_{g=x,y,z}A_{Kg}\bar{I}_{Kg}J_g-\frac{3\mu_N^2g_H^2r^{-3}}{2J(J+1)(2J-1)(2J+3)}$$
$$\times\left\{3(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})[2(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})-1]-2\bar{\boldsymbol{I}}^2\boldsymbol{J}^2\right\}\left[\frac{1}{2}J(J+1)-\sum_g\left(\frac{r_g^2}{r^2}\right)J_g^2\right]. \tag{5}$$

Inserting the following relation[11],

$$\bar{I}_{Kg}=\frac{(\bar{\boldsymbol{I}}_K\cdot\bar{\boldsymbol{I}})(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})}{I(I+1)J(J+1)}J_g \tag{6}$$

Eq. (5) is reduced to

$$H=\sum_{K=1,2}\sum_{g=x,y,z}A_{Kg}\frac{(\bar{\boldsymbol{I}}_K\cdot\bar{\boldsymbol{I}})(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})}{2J(J+1)}J_g^2-\frac{3\mu_N^2g_H^2r^{-3}}{2J(J+1)(2J-1)(2J+3)}$$
$$\times\{3(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})[2(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})-1]-2\bar{\boldsymbol{I}}^2\boldsymbol{J}^2\}\left[\sum_g\left(\frac{r_g^2}{r^2}\right)J_g^2-\frac{1}{3}\boldsymbol{J}^2\right]. \tag{7}$$

The matrix element which is diagonal in I, J, τ, is

$$\langle IJ\tau|H|IJ\tau\rangle=\sum_g(A_{1g}+A_{2g})\frac{(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})}{I(I+1)J(J+1)}\langle J_g^2\rangle$$
$$-\frac{(3\mu_N^2g_H^2/r^3)\{3(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})[2(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})-1]-2I(I+1)J(J+1)\}}{2J(J+1)(2J-1)(2J+3)}\left[\sum_g\left(\frac{r_g^2}{r^2}\right)\langle J_g^2\rangle-\frac{1}{3}J(J+1)\right], \tag{8}$$

where $(\bar{\boldsymbol{I}}_K\cdot\bar{\boldsymbol{I}})$ has been replaced by 1 for the state with $I=1$. The first order approximation of the energy level shift W_1 due to magnetic interactions is obtained by putting $2(\bar{\boldsymbol{I}}\cdot\boldsymbol{J})=I(I+1)-F(F+1)+J(J+1)$.

$$\left.\begin{aligned}
W_1&=-\frac{1}{2(J+1)}\sum_g(A_{1g}+A_{2g})\langle J_g^2\rangle+\frac{(3\mu_N^2g_H^2r^{-3})}{2(J+1)(2J+3)}\left[\sum_g\left(\frac{r_g^2}{r^2}\right)\langle J_g^2\rangle-\frac{1}{3}J(J+1)\right],\\
&\qquad\text{for } F=J+1\\
W_1&=\frac{1}{2J(J+1)}\sum_g(A_{1g}+A_{2g})\langle J_g^2\rangle-\frac{(3\mu_N^2g_H^2r^{-3})}{2J(J+1)}\left[\sum_g\left(\frac{r_g^2}{r^2}\right)\langle J_g^2\rangle-\frac{1}{3}J(J+1)\right],\\
&\qquad\text{for } F=J\\
W_1&=\frac{1}{2J}\sum_g(A_{1g}+A_{2g})\langle J_g^2\rangle+\frac{(3\mu_N^2g_H^2r^{-3})}{2J(2J-1)}\left[\sum_g\left(\frac{r_g^2}{r^2}\right)\langle J_g^2\rangle-\frac{1}{3}J(J+1)\right].\\
&\qquad\text{for } F=J-1\,.
\end{aligned}\right\} \tag{4}$$

In the case of Q-branch transitions, $\Delta F=0$ components have appreciable transion probabilities and $\Delta F=\pm1$ transitions are much weaker. The frequency shift $\Delta\nu$ of the hyperfine component of $\Delta J=0$, $\Delta F=0$ transitions, is

$$\Delta\nu_{J+1}=-\sum_g\frac{1}{2(J+1)}(A_{1g}+A_{2g})\Delta\langle J_g^2\rangle+\frac{(3\mu_N^2g_H^2r^{-3})}{2(J+1)(2J+3)}\sum_g\left(\frac{r_g^2}{r^2}\right)\Delta\langle J_g^2\rangle\,,\qquad\text{for } F=J+1$$
$$\Delta\nu_J=\sum_g\frac{1}{2J(J+1)}(A_{1g}+A_{2g})\Delta\langle J_g^2\rangle-\frac{(3\mu_N^2g_H^2r^{-3})}{2J(J+1)}\sum_g\left(\frac{r_g^2}{r^2}\right)\Delta\langle J_g^2\rangle\,,\qquad\text{for } F=J$$
$$\Delta\nu_{J-1}=\sum_g\frac{1}{2J}(A_{1g}+A_{2g})\Delta\langle J_g^2\rangle+\frac{(3\mu_N^2g_H^2r^{-3})}{2J(2J-1)}\sum_g\left(\frac{r_g^2}{r^2}\right)\Delta\langle J_g^2\rangle\,,\qquad\text{for } F=J-1\,,$$

---

* For a more detailed treatment see ref. (4).

where $\Delta\langle J_g^2\rangle$ is the difference of $\langle J_g^2\rangle$ between the two levels involved.

§ 3. Experimental Procedure and the Result

The block diagram of the maser spectrometer is shown in Fig. 2. A one-klystron system with a crystal modulator driven at 45 Mc/sec is used to allow sensitive amplification of the beat frequency from a crystal mixer[12]. The maser tank, beam source and focuser are the same ones as used in the ammonia maser by one of the authors[13].

Preparing of the gaseous formaldehyde has been one of the difficulties encountered, because it polymerizes quite easily even under a low pressure or in the liquid state at a dry ice temperature. Several methods were tried, but no satisfying way was found to supply a constant flow of formaldehyde gas. The simplest and most convenient one was simply to heat the powder of paraformaldehyde.

A cylindrical cavity of TM_{010} mode, 12 cm in length, is rather closely coupled, the loaded Q being about 4000.

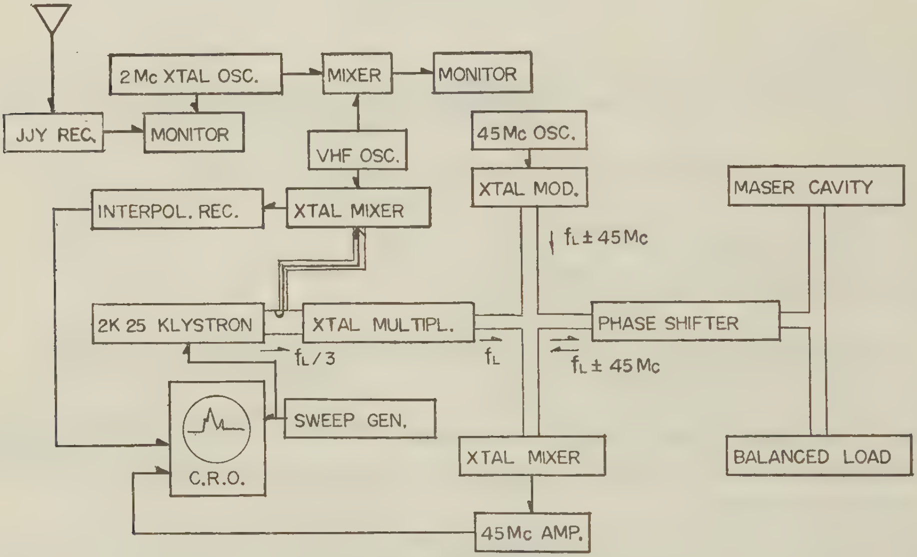

Fig. 2. Block-diagram of the maser spectrometer.

The measured line is the Q-branch transition $3_{12}\rightarrow 3_{13}$, the center frequency of which is about $\nu_0=28{,}974.85$ Mc/sec. The emission spectrum was observed as a triplet, as shown in Fig. 3. At the focuser voltage of 20 kV, the signal-to-noise ratio was about 10, with the effective band-width of 1.5 kc/sec. The line disappeared at the focuser voltage arround 9 kV. The sensitivity of one-klystron system is limited by the difficulty of balancing the signal at two frequencies $\nu_L \pm \nu_{if}$, where ν_L and ν_{if} are respectively the frequency of the

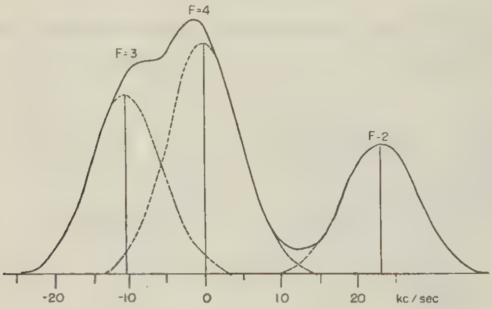

Fig. 3. Calculated hyperfine pattern ($\Delta F=0$) of the $3_{12}\rightarrow 3_{13}$ line of H_2CO.

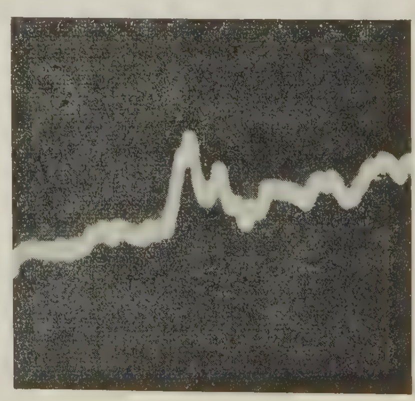

Fig. 4. An oscilloscope pattern of the $3_{12}\rightarrow 3_{13}$ line of H_2CO.

local oscillator and the amplifier. The two-klystron system without crystal modulator should improve the signal-to-noise ratio. However, the frequency fluctuation is found to increase even by using automatic frequency control, when the frequence noise of the two klystrons are not sufficiently small. Signal-to-noise ratio was large enough to observe the hyperfine pattern with the present system. Since the intensity of the $\Delta F=0$ component is approximately proportional to $2F+1$, the triplet is easily assigned as shown in Fig. 4. The splittings $\Delta\nu_2-\Delta\nu_4$, $\Delta\nu_4-\Delta\nu_3$ and the half-width $\Delta\nu$ are determined.

$$\Delta\nu_2-\Delta\nu_4=23.0\pm1.5 \text{ kc/sec}$$

$$\Delta\nu_4-\Delta\nu_3=10.4\pm0.7 \text{ kc/sec}$$

$$\Delta\nu= 5.8\pm0.4 \text{ kc/sec}$$

§ 4. Discussion

The splittings of hyperfine components are obtained from Eq. (11) as

$$\Delta\nu_{J+1}=-\frac{\Delta X}{2(J+1)}+\frac{\Delta Y}{2(J+1)(J+3)}; \quad \text{for } F=J+1$$

$$\Delta\nu_J=\frac{\Delta X}{2J(J+1)}+\frac{\Delta Y}{2J(J+1)}; \quad \text{for } F=J$$

$$\Delta\nu_{J-1}=\frac{\Delta X}{2J}-\frac{\Delta Y}{2J(2J-1)}; \quad \text{for } F=J-1\,,$$

where $\Delta X=\sum_g (A_{1g}+A_{2g})\Delta\langle J_g^2\rangle$, and $\Delta Y=3\mu_N^2 g_H^2 r^{-3}\sum_g (r_g^2/r^2)\Delta\langle J_g^2\rangle$. From the experimental values of hyperfine splittings two constants are obtained as

$$(\Delta X)_{\text{exp.}}=54.6 \text{ kc/sec}\,, \quad (\Delta Y)_{\text{exp.}}=358 \text{ kc/sec}$$

From Eq. (3), neglecting the first order terms of b, we obtain $\langle J_y^2\rangle=\frac{1}{2}J(J+1)-K^2-C_1$, and $\Delta\langle J_y^2\rangle=-\Delta(C_1/2)=J(J+1)/2=6$. Therefore, for $r_x=r_z=0$, and $r_y=r$, the expression can be written as $\Delta Y=18\mu_N^2 g_H^2 r^{-3}$. The observed value of ΔY gives

$$(\mu_N^2 g_H^2 r^{-3})_{\text{exp.}}=19.9\pm1.3 \text{ kc/sec}\,.$$

On the other hand, H–H distance in H_2CO has been known as[1] $r=1.87\text{A}$. Thus the calculated value is

$$(\mu_N^2 g_H^2 r^{-3})_{\text{calc.}}=18.2 \text{ kc/sec}\,.$$

The calculated value of $\mu_N^2 g_H^2 r^{-3}$ is in fairly good agreement with the experimental value. Another constant, ΔX, cannot be calculated because of the lack of knowledge concerning the electronic states of the molecule. Taking the same approximation as in the calculation of ΔY, it may be written as

$$\Delta X=\frac{J(J+1)}{2}(\beta-\alpha)\,,$$

where $\alpha=A_{1x}+A_{2x}$ and $\beta=A_{1y}+A_{2y}$. The experimental value is

$$\beta-\alpha=9.1\pm0.6 \text{ kc/sec}\,.$$

Recently Thaddeus et. al. has observed the magnetic hyperfine structure in the transition, $2_{11}\rightarrow2_{12}$, as*

$$\Delta\nu_1-\Delta\nu_3=22.35\pm0.4 \text{ kc/sec}$$

$$\Delta\nu_3-\Delta\nu_2=12.59\pm0.2 \text{ kc/sec}\,.$$

According to the analysis given above, the constants are obtained as

$$(\mu_N^2 g_H^2 r^{-3})_{\text{exp.}}=20.2 \text{ kc/sec}$$

$$\beta-\alpha= 9.2 \text{ kc/sec}\,.$$

These are in good agreement with our results on the $3_{12}\rightarrow3_{13}$ transition, thus confirming the theory given above.

In conclusion the authors would like to thank Mr. T. Oka for his helpful suggestions and discussions. Thanks are also due to Dr. A. Okaya and Mr. P. Thaddeus for the information of their experiments.

Electrical Polarizabilities of Rare Gas Atoms by the Hartree-Fock Wave Functions

By Shobu KANEKO

Department of Physics, Faculty of Science,
University of Tokyo

(Received July 4, 1959)

The perturbation method is applied to the Hartree-Fock equation to calculate the dipole polarizabilities, the results being a coupled set of integro-differential equations. This theory is applied to helium and makes clear the accuracy of the Sternheimer approximation. The calculated value of the polarizability by this theory is about ten per cent smaller than the value obtained by the Sternheimer approximation. For neon and argon calculations are made by use of the Sternheimer approximation. All the calculated values of the polarizabilities are compared with the values obtained by other authors and the experimental values. The calculated value for helium agrees quite well with the experimental one and for neon and argon the calculated values are about 1.5 times the experimental ones.

§ 1. Introduction

The intermolecular potential of gases has been investigated semiempirically by the theory of the equations of state and transport coefficients[1]. The long range parts of this intermolecular potential, even if they may be a many body force's potential, have close relation to the dipole polarizability[2]; hence the quantum mechanical calculation of it for various molecules has been desired. The calculations of the polarizability have been made by use of the variational method by many authors, i.e. by Kirkwood[3], Buckingham[4], Bravin[5], Pople and Schofield[6], and Wikner and Das[7]. The calculations have been made also by use of the numerical method by Sternheimer[8,9], Sundbom[10] and very recently by Dalgarno and Parkinson[11].

In this article we derive, using the perturbation method, an equation by use of which the polarizability can be calculated within the limits of the Hartree-Fock approximation; and we get a coupled set of integro-differential equations satisfied by the radial parts of the perturbed wave functions under the assumption on them (see (17′) in § 3) which is consistent with the Hartree approximation, for example in case of helium. For helium, as it is the simplest case, the rigorous equation is solved self-consistently to see the accuracy of the Sternheimer approximation (see § 4). But for neon and argon the calculations are so laborious that we treat the problems by the Sternheimer approximation; we will make calculation more exactly in future.

In solving differential equations for the perturbation of the wave functions, the present author used the Parametron Computor PC–1 at the University of Tokyo.

§ 2. Polarizability in a Uniform Electric Field

In the following we consider an atom or ion with q electrons and a nucleus of the charge number N. The normal state of the atomic system is assumed to be in the configuration of the complete shell. The Hamiltonian of the system in the applied electric field $\boldsymbol{E}$, is written as

$$\mathscr{H}=\sum_{i=1}^{q}\left[-\frac{1}{2}\nabla_i^2-\frac{N}{r_i}+(\boldsymbol{E}\cdot\boldsymbol{r}_i)\right]+\sum_{ij}{}'\frac{1}{r_{ij}}\,, \tag{1}$$

in which $\boldsymbol{r}_i$ is the position vector of the i-th electron referred to the nucleus and r_{ij} the distance between the i-th and the j-th electrons; the prime in $\sum_{ij}'$ means that the sum is over all pairs $(j\neq i)$, each pair being counted once; ∇_i^2 is the Laplacian operator for the i-th electron. Hereafter Hartree's atomic units are used throughout in this article.

In the Hartree-Fock method the normalized wave function Ψ of the system is written in the form of Slater determinant as

$$\Psi=\frac{1}{\sqrt{q!}}\begin{vmatrix}\psi_1(\boldsymbol{r}_1)\eta_1(\zeta_1) & \psi_1(\boldsymbol{r}_2)\eta_1(\zeta_2)\cdots\cdots & \psi_1(\boldsymbol{r}_q)\eta_1(\zeta_q)\\ \psi_2(\boldsymbol{r}_1)\eta_2(\zeta_1) & \psi_2(\boldsymbol{r}_2)\eta_2(\zeta_2)\cdots\cdots & \psi_2(\boldsymbol{r}_q)\eta_2(\zeta_q)\\ \vdots & \vdots & \vdots\\ \psi_q(\boldsymbol{r}_1)\eta_q(\zeta_1) & \psi_q(\boldsymbol{r}_2)\eta_q(\zeta_2)\cdots\cdots & \psi_q(\boldsymbol{r}_q)\eta_q(\zeta_q)\end{vmatrix}, \tag{2}$$

where $\psi_i(\boldsymbol{r}_j)$ and $\eta_i(\zeta_j)$ are respectively the orthonormal one-electron orbital wave function and spin function, and ζ_j is the spin coordinate of the j-th electron. The best one-electron wave functions $\psi_i(\boldsymbol{r})$ are determined by the well-known Hartree-Fock equations:

$$\left[-\frac{1}{2}\nabla_1^2-\frac{N}{r_1}+\sum_j\int\frac{|\psi_j(\boldsymbol{r}_2)|^2}{r_{12}}d\boldsymbol{r}_2+(\boldsymbol{E}\cdot\boldsymbol{r}_1)-\mathcal{E}_i\right]\psi_i(\boldsymbol{r}_1)-\sum_{j//}\int\frac{\psi_j^*(\boldsymbol{r}_2)\psi_i(\boldsymbol{r}_2)}{r_{12}}d\boldsymbol{r}_2\psi_j(\boldsymbol{r}_1)=0\ , \tag{3}$$

in which the wave functions were assumed to be transformed so as to diagonalize the energy parameter matrix[12]), and $\mathcal{E}_i$ are its diagonal elements; the summations $\sum_j$ and $\sum_{j//}$ are respectively extended over all occupied states and over all states with parallel spin to the i state including the i state itself; the asterisk means the complex conjugate.

We choose the z-axis parallel to the applied electric field, that is $\boldsymbol{E}=(0,0,E)$, and use the spherical polar coordinate in the following.

Assuming the term Ez_1 to be small compared with the others, we use the perturbation method. The wave functions $\psi_i(\boldsymbol{r})$ and the energy parameters $\mathcal{E}_i$ are expanded with respect to E:

$$\left.\begin{aligned}\psi_i(\boldsymbol{r})&=\psi_i^{(0)}(\boldsymbol{r})+\psi_i^{(1)}(\boldsymbol{r})+O(E^2)\ ,\\ \mathcal{E}_i&=\ \mathcal{E}_i^{(0)}\ +\ \mathcal{E}_i^{(1)}\ +O(E^2)\ .\end{aligned}\right\} \tag{4}$$

Here $\psi_i^{(0)}(\boldsymbol{r})$ and $\mathcal{E}_i^{(0)}$ are the unperturbed wave functions and the energy parameters respectively; $\psi_i^{(1)}(\boldsymbol{r})$ and $\mathcal{E}_i^{(1)}$ are the first order perturbed wave functions and the energy parameters respectively which are of the order of E.

Substituting the expansions (4) into the equations (3), we obtain

$$\left[-\frac{1}{2}\nabla_1^2-\frac{N}{r_1}+\sum_j\int\frac{|\psi_j^{(0)}(\boldsymbol{r}_2)|^2}{r_{12}}d\boldsymbol{r}_2-\mathcal{E}_i^{(0)}\right]\psi_i^{(0)}(\boldsymbol{r}_1)-\sum_{j//}\int\frac{\psi_j^{(0)*}(\boldsymbol{r}_2)\,\psi_i^{(0)}(\boldsymbol{r}_2)}{r_{12}}d\boldsymbol{r}_2\psi_j^{(0)}(\boldsymbol{r}_1)=0 \tag{5}$$

from the zero-th order terms with respect to E, and

$$\begin{aligned}&\left[-\frac{1}{2}\nabla_1^2-\frac{N}{r_1}+\sum_j\int\frac{|\psi_j^{(0)}(\boldsymbol{r}_2)|^2}{r_{12}}d\boldsymbol{r}_2-\mathcal{E}_i^{(0)}\right]\psi_i^{(1)}(\boldsymbol{r}_1)\\ &\quad+\left[\sum_j\int\frac{\psi_j^{(1)*}(\boldsymbol{r}_2)\psi_j^{(0)}(\boldsymbol{r}_2)+\psi_j^{(0)*}(\boldsymbol{r}_2)\psi_j^{(1)}(\boldsymbol{r}_2)}{r_{12}}d\boldsymbol{r}_2+Ez_1-\mathcal{E}_i^{(1)}\right]\psi_i^{(0)}(\boldsymbol{r}_1)\\ &\quad-\sum_{j//}\int\frac{\psi_j^{(0)*}(\boldsymbol{r}_2)\psi_i^{(0)}(\boldsymbol{r}_2)}{r_{12}}d\boldsymbol{r}_2\psi_j^{(1)}(\boldsymbol{r}_1)\\ &\quad-\sum_{j//}\int\frac{\psi_j^{(1)*}(\boldsymbol{r}_2)\psi_i^{(0)}(\boldsymbol{r}_2)+\psi_j^{(0)*}(\boldsymbol{r}_2)\psi_j^{(1)}(\boldsymbol{r}_2)}{r_{12}}d\boldsymbol{r}_2\psi_j^{(0)}(\boldsymbol{r}_1)=0\end{aligned} \tag{6}$$

from the first order terms. The conditions of orthonormality on $\psi_i(\boldsymbol{r})$ become

$$\int\psi_j^*(\boldsymbol{r})\psi_i(\boldsymbol{r})\,d\boldsymbol{r}=\int\psi_j^{(0)*}(\boldsymbol{r})\psi_i^{(1)}(\boldsymbol{r})d\boldsymbol{r}+\int\psi_j^{(1)*}(\boldsymbol{r})\psi_i^{(0)}(\boldsymbol{r})\,d\boldsymbol{r}+O(E^2)=0\ . \tag{7}$$

The zero-th order equations (5) are the normal Hartree-Fock equation in the absence of the perturbing electric field and its solutions are usually written in the central field type

$$\psi_i^{(0)}(\boldsymbol{r})=\frac{P_0(n_il_i:r)}{r}Y_{l_im_i}(\vartheta,\varphi)\ . \tag{8}$$

Here n_i, l_i and m_i are respectively the principal, azimuthal and magnetic quantum numbers of the i state; $P_0(nl\colon r)$ is the radial wave function and $Y_{lm}(\vartheta, \varphi)$ is the spherical harmonics of the l-th order. They are normalized according to

$$\left.\begin{aligned}&\int_0^\infty P_0(nl\colon r)P_0(n'l\colon r)\,dr=\delta_{n,n'}\,,\\&\int_0^\pi\int_0^{2\pi} Y^*_{l,m}(\vartheta,\varphi)Y_{l'm'}(\vartheta,\varphi)\sin\vartheta\,d\vartheta\,d\varphi=\delta_{l,l'}\cdot\delta_{m,m'}\,.\end{aligned}\right\}\tag{9}$$

The equations (6) determine the perturbed wave functions $\psi_i^{(1)}(r)$ under the suitable boundary conditions and are investigated in detail in the next section.

According to the expansion of $\psi_i(r)$, the wave function Ψ of the system is also expanded in the form

$$\begin{aligned}\Psi&=\Psi^{(0)}+\ \Psi^{(1)}\ +O(E^2)\\&=\Psi^{(0)}+\sum_{i=1}^{q}\Psi_i^{(1)}+O(E^2)\,,\end{aligned}\tag{10}$$

where

$$\Psi^{(0)}=\frac{1}{\sqrt{q!}}\begin{vmatrix}\psi_1^{(0)}(r_1)\eta_1(\zeta_1) & \psi_1^{(0)}(r_2)\eta_1(\zeta_2)\cdots\cdots\cdots & \psi_1^{(0)}(r_q)\eta_1(\zeta_q)\\ \vdots & \vdots & \vdots\\ \psi_q^{(0)}(r_1)\eta_q(\zeta_1) & \psi_q^{(0)}(r_2)\eta_q(\zeta_2)\cdots\cdots\cdots & \psi_q^{(0)}(r_q)\eta_q(\zeta_q)\end{vmatrix}$$

and

$$\Psi_i^{(1)}=\frac{1}{\sqrt{q!}}\begin{vmatrix}\psi_1^{(0)}(r_1)\eta_1(\zeta_1) & \psi_1^{(0)}(r_2)\eta_1(\zeta_2)\cdots\cdots\cdots & \psi_1^{(1)}(r_q)\eta_1(\zeta_q)\\ \vdots & \vdots & \vdots\\ \psi_i^{(1)}(r_1)\eta_i(\zeta_1) & \psi_i^{(1)}(r_2)\eta_i(\zeta_2)\cdots\cdots\cdots & \psi_i^{(1)}(r_q)\eta_i(\zeta_q)\\ \vdots & \vdots & \vdots\\ \psi_q^{(0)}(r_1)\eta_q(\zeta_1) & \psi_q^{(0)}(r_2)\eta_q(\zeta_2)\cdots\cdots\cdots & \psi_q^{(0)}(r_q)\eta_q(\zeta_q)\end{vmatrix}\,.\tag{11}$$

Then the perturbation of the charge distribution of the system is given by

$$\Psi^*\Psi-\Psi^{(0)*}\Psi^{(0)}=2\,\mathrm{Re}\,(\Psi^{(0)*}\Psi^{(1)})+O(E^2)\,,\tag{12}$$

in which Re stands for the real part. Hence the induced dipole moment P_{ind} of the system is expressed in the form

$$P_{\mathrm{ind}}=-2\sum_{k=1}^{q}\sum_{i=1}^{q}\int\mathrm{Re}\,(\Psi^{(0)*}\Psi_i^{(1)})z_k\,dr_1\cdots dr_q\,,\tag{13}$$

and the polarizability α is given by

$$\alpha=\frac{P_{\mathrm{ind}}}{E}=-\frac{2}{E}\sum_{k=1}^{q}\sum_{i=1}^{q}\int\mathrm{Re}\,(\Psi^{(0)*}\Psi_i^{(1)})z_k\,dr_1\cdots dr_q\,.\tag{14}$$

By use of (7) and (11) this is expressed in terms of the one-electron function as

$$\alpha=-\frac{1}{E}\sum_i\int\mathrm{Re}\,(\psi_i^{(0)*}z\psi_i^{(1)})\,dr\,.\tag{15}$$

We make use of the expansion for the spherical harmonics[13)]

$$\cos\vartheta\,Y_{lm}(\vartheta,\varphi)=\sum_{l'}\sqrt{\frac{2l+1}{2l'+1}}(10l0|1ll'0)(10lm|1ll'm)Y_{l'm}(\vartheta,\varphi)\tag{16}$$

in which $(l_1m_1l_2m_2|l_1l_2lm)$ is the Clebsch-Gordan coefficient, and expand $\psi_i^{(1)}(r)$ in terms of spherical harmonics $Y_{lm}(\vartheta,\varphi)$ as

$$\psi_i^{(1)}(\mathbf{r})=\sum_{l_i'm_i'}C(l_i\to l_i':m_i')\frac{P_1(n_il_i\to l_i':r)}{r}Y_{l_i'm_i'}(\vartheta,\varphi)\,. \tag{17}$$

Substituting these expressions into the equation (15) we see that only the terms proportional to $Y_{l_i+1m_i}(\vartheta,\varphi)$ and $Y_{l_i-1m_i}(\vartheta,\varphi)$ contribute to the polarizability α. Then if we choose the coefficients $C(l_i\to l_i':m_i)$ for $l_i'=l_i+1$ and $l_i'=l_i-1$ as

$$C(l_i\to l_i':m_i)=-E\sqrt{\frac{2l_i+1}{2l_i'+1}}(10l_i0|1l_il_i'0)(10l_im_i|1l_il_i'm_i)\,, \tag{18}$$

the polarizability is given by

$$\alpha=\sum_{n_il_im_i\zeta_il_i'}2\left(\frac{2l_i+1}{2l_i'+1}\right)(10l_i0|1l_il_i'0)^2(10l_im_i|1l_il_i'm_i)^2I(n_il_i\to l_i')\,,$$

where we have used the notation

$$I(nl\to l')=\int_0^\infty P_0(nl:r)P_1(nl\to l':r)r\,dr\,. \tag{19}$$

Using the values of the Clebsch-Gordan coefficients (see for example Condon and Shortley[14)]) and performing the summation over m_i, we finally obtain

$$\begin{aligned}\alpha&=\frac{4}{3}\sum_{nl}[(l+1)I(nl\to l+1)+lI(nl\to l-1)]\\&=\sum_n\frac{4}{3}I(ns\to p)+\sum_n\left[\frac{4}{3}I(np\to s)+\frac{8}{3}I(np\to d)\right]\\&\quad+\cdots\cdots\cdots\,.\end{aligned} \tag{20}$$

Here the sums extend over the occupied shells; this form of expression was first derived by Sternheimer[8)] from the one-electron point of view.

§ 3. Perturbed Hartree-Fock Equation

In this section we consider the first order equations (6) in detail and use an assumption on the symmetry of the perturbed wave functions $\psi_i^{(1)}(\mathbf{r})$:

$$\begin{aligned}\psi_i^{(1)}(\mathbf{r})=&C(l_i\to l_i+1:m_i)\frac{P_1(n_il_i\to l_i+1:r)}{r}Y_{l_i+1m_i}(\vartheta,\varphi)\\&+C(l_i\to l_i-1:m_i)\frac{P_1(n_il_i\to l_i-1:r)}{r}Y_{l_i-1m_i}(\vartheta,\varphi)\,.\end{aligned} \tag{17'}$$

Without this assumption the equations for $P_1(n_il_i\to l_i':r)$ are all coupled with each other through the third and fourth terms of the equations (6). Here we note that the equations obtained under the assumption (17′) are exact within the limits of Hartree approximation, because the couplings arise from the perturbations of the exchange interactions between electrons.

As usual it is convenient to use the expansion of $1/r_{12}$ in terms of r_1, r_2 and $\cos\vartheta_{12}$, namely

$$\frac{1}{r_{12}}=\sum_k U_k(r_1,r_2)Y_k(\vartheta_{12})\sqrt{\frac{4\pi}{2k+1}}\,, \tag{21}$$

in which

$$U_k(r_1,r_2)=\begin{cases}r_1^k/r_2^{k+1} & \text{for}\quad r_1<r_2\\ r_2^k/r_1^{k+1} & \text{for}\quad r_1>r_2\,.\end{cases} \tag{22}$$

$Y_k(\vartheta)$ is the abbreviation of $Y_{k0}(\vartheta, \varphi)$ and ϑ_{12} is the angle between r_1 and r_2, i.e.

$$\cos\vartheta_{12}=\cos\vartheta_1\cos\vartheta_2+\sin\vartheta_1\sin\vartheta_2\cos(\varphi_1-\varphi_2)\ .$$

Now let us consider the first terms of the equations (6). The Coulomb interaction terms composed of the unperturbed wave functions are written, by substituting (8) and using (21), as

$$\sum_j\int\frac{|\phi_j^{(0)}(\boldsymbol{r}_2)|^2}{r_{12}}\,d\boldsymbol{r}_2=\sum_{n_jl_j}2(2l_j+1)\int_0^\infty P_0(n_jl_j:r)^2U_0(r_1, r_2)dr_2\ ,$$

where we have used the property of the spherical harmonics[13]:

$$\sum_{m_j}Y^*_{l_jm_j}(\vartheta, \varphi)Y_{l_jm_j}(\vartheta, \varphi)=\frac{2l_j+1}{4\pi}\ .$$

Hence the first terms of the equations (6) become

$$\left[-\frac{1}{2}\nabla_1{}^2-\frac{N}{r_1}+\sum_j\int\frac{|\phi_j^{(0)}(\boldsymbol{r}_2)|^2}{r_{12}}\,d\boldsymbol{r}_2-\varepsilon_i^{(0)}\right]\phi_i^{(1)}(\boldsymbol{r}_1)$$
$$=\sum_{l_i'}C(l_i\to l_i':m_i)\frac{Y_{l_i'm_i}(\vartheta_1, \varphi_1)}{r_1}\left[-\frac{1}{2}\frac{d^2}{dr_1{}^2}-\frac{Y(r_1)}{r_1}+\frac{l_i'(l_i'+1)}{2r_1{}^2}-\varepsilon^{(0)}_{n_il_i}\right]P_1(n_il_i\to l_i':r_1)\ . \tag{23}$$

Here the summation extends over $l_i'=l_i+1$ and $l_i'=l_i-1$; the function $Y(r)$ is defined by

$$Y(r)=N-\sum_{nl}2(2l+1)Y_0^{(0)}(nl, nl:\ r)\ , \tag{24}$$

in which

$$Y_k^{(0)}(nl, n'l':\ r)\equiv r\int_0^\infty U_k(r, s)P_0(nl:\ s)P_0(n'l':\ s)\,ds\ . \tag{25}$$

From the expression (23) we see that the angular dependence of the first terms of the equations (6) is only through the spherical harmonics $Y_{l_i+1,m_i}(\vartheta, \varphi)$ and $Y_{l_i-1,m_i}(\vartheta, \varphi)$. Hence it is sufficient for our purpose to consider only terms having the same angular dependence in the equations (6). We use this fact in the following calculation.

We next consider the contributions from the second terms separately. If we use the equations (8), (17) and (21) again, the first term may be expressed in the form

$$\sum_j\int\frac{\phi_j^{(1)*}(\boldsymbol{r}_2)\phi_j^{(0)}(\boldsymbol{r}_2)+\phi_j^{(0)*}(\boldsymbol{r}_2)\phi_j^{(1)}(\boldsymbol{r}_2)}{r_{12}}\,d\boldsymbol{r}_2\phi_i(\boldsymbol{r}_1)=4\,\mathrm{Re}\sum_{n_jl_jm_j}\sum_{kl_j'}C(l_j\to l_j':m_j)\frac{P_0(n_jl_j:r_1)}{r_1}$$
$$\cdot\int_0^\infty P_0(n_jl_j:\ r_2)P_1(n_jl_j\to l_j':\ r_2)U_k(r_1, r_2)\,dr_2\sqrt{\frac{4\pi}{2k+1}}\,Y_{l_im_i}(\vartheta_1, \varphi_1)$$
$$\cdot\int_0^\pi\int_0^{2\pi}Y^*_{l_jm_j}(\vartheta_2, \varphi_2)Y_{l_j'm_j}(\vartheta_2, \varphi_2)Y_k(\vartheta_{12})\sin\vartheta_2\,d\vartheta_2\,d\varphi_2\ . \tag{26}$$

Owing to the addition theorem of the spherical harmonics[13],

$$Y_k(0)Y_k(\vartheta_{12})=\sum_{m_k}Y^*_{k,m_k}(\vartheta_2, \varphi_2)Y_{k,m_k}(\vartheta_1, \varphi_1)\ , \tag{27}$$

the integral on angular variables appeared in (26) is reduced to

$$Y_{l_im_i}(\vartheta_1, \varphi_1)\int_0^\pi\int_0^{2\pi}Y^*_{l_jm_j}(\vartheta_2, \varphi_2)Y_{l_j'm_j}(\vartheta_2, \varphi_2)Y_k(\vartheta_{12})\sin\vartheta_2\,d\vartheta_2\,d\varphi_2$$
$$=\frac{Y_{l_im_i}(\vartheta_1, \varphi_1)Y_{k,0}(\vartheta_1, \varphi_1)}{Y_k(0)}\int_0^\pi\int_0^{2\pi}Y^*_{l_jm_j}(\vartheta_2, \varphi_2)Y_{l_j'm_j}(\vartheta_2, \varphi_2)Y_{k,0}(\vartheta_2, \varphi_2)\sin\vartheta_2\,d\vartheta_2\,d\varphi_2$$
$$=\frac{Y_{10}(\vartheta_1, \varphi_1)Y_{l_im_i}(\vartheta_1, \varphi_1)}{Y_1(0)}\sqrt{\frac{3(2l_j+1)}{4\pi(2l_j'+1)}}(10l_j0|1l_jl_j'0)(10l_jm_j|1l_jl_j'm_j)\ ,$$

where the equation (16) has been used. Performing the summation over m_j we get the result in the form

$$\sum_j \int \frac{\psi_j^{(1)*}(r_2)\psi_j^{(0)}(r_2)+\psi_j^{(0)*}(r_2)\psi_j^{(1)}(r_2)}{r_{12}}\, dr_2 \psi_i^{(0)}(r_1)=4 \sum_{n_j l_j l_j'} C(l_j\to l_j':m_j)\frac{Y_{l_i' m_i}(\vartheta_1, \varphi_1)}{r_1}$$
$$\cdot P_0(n_j l_j:r_1)\left[\frac{l_j+1}{3}\frac{Y_1^{(1)}(n_j l_j, n_j l_j\to l_j+1:r_1)}{r_1}+\frac{l_j}{3}\frac{Y_1^{(1)}(n_j l_j, n_j l_j\to l_j-1:r_1)}{r_1}\right] \tag{28}$$

where the function $Y_k^{(1)}(n_1l_1, n_2l_2\to l_2': r)$ is defined by

$$Y_k^{(1)}(n_1l_1, n_2l_2\to l_2': r)\equiv r\int_0^\infty U_k(r, s)P_0(n_1l_1: s)P_1(n_2l_2\to l_2': s)\, ds\ . \tag{29}$$

The contribution from the term $Ez_1\psi_i^{(0)}(r_1)$ is easily found to be

$$Ez_1\psi_i^{(0)}(r_1)=-r_1P_0(n_il_i: r)\sum_{l_i'} C(l_i\to l_i': m_i)Y_{l_i' m_i}(\vartheta_1, \varphi_1)\ , \tag{30}$$

and there is no contribution from the term $\mathcal{E}_i^{(1)}\psi_i^{(0)}(r)$ because it has the angular dependence of $Y_{l_i m_i}(\vartheta_1, \varphi_1)$.

Next we consider the contributions from the third terms of the equation (6). As in the case treated above these terms become, by use of equations (8), (17) and (21),

$$\sum_{j//} \int \frac{\psi_j^{(0)*}(r_2)\psi_i^{(0)}(r_2)}{r_{12}}\, dr_2\psi_j^{(1)}(r_1)=\sum_{n_j l_j m_j}\sum_{k l_j'} C(l_j\to l_j': m_j)\frac{P_1(n_jl_j\to l_j': r_1)}{r_1}\, Y_{l_j' m_j}(\vartheta_1, \varphi_1)$$
$$\cdot \int_0^\infty P_0(n_jl_j: r_2)P_0(n_il_i: r_2)U_k(r_1, r_2)\, dr_2$$
$$\cdot \sqrt{\frac{4\pi}{2k+1}}\int_0^\pi\int_0^{2\pi} Y^*_{l_j m_j}(\vartheta_2, \varphi_2)Y_{l_i m_i}(\vartheta_2, \varphi_2)Y_k(\vartheta_{12})\sin\vartheta_2\, d\vartheta_2\, d\varphi_2\ . \tag{31}$$

By use of the addition theorem and the expression for the product of two spherical harmonics[15],

$$Y_{l_1 m_1}(\vartheta, \varphi)Y_{l_2 m_2}(\vartheta, \varphi)=\sum_l \sqrt{\frac{(2l_1+1)(2l_2+1)}{4\pi(2l+1)}}(l_10l_20|l_1l_2l0)(l_1m_1l_2m_2|l_2l_2lm)Y_{lm}(\vartheta, \varphi)\ , \tag{32}$$

the integral on the angular variables of the equation (31) is reduced to

$$\sum_{m_j} C(l_j\to l_j': m_j)\sqrt{\frac{4\pi}{2k+1}}\, Y_{l_j' m_j}(\vartheta_1, \varphi_1)\int_0^\pi\int_0^{2\pi} Y^*_{l_j m_j}(\vartheta_2, \varphi_2)Y_{l_i m_i}(\vartheta_2, \varphi_2)Y_k(\vartheta_{12})\sin\vartheta_2\, d\vartheta_2\, d\varphi_2$$
$$=\frac{4\pi}{2k+1}\sqrt{\frac{(2l_i+1)(2k+1)}{4\pi(2l_j+1)}}\sum_{m_j m_k}(-1)^{m_k}C(l_j\to l_j': m_j)(l_i0k0|l_ikl_j0)(l_im_ik-m_k|l_ikl_jm_j)$$
$$\cdot Y_{km_k}(\vartheta_1, \varphi_1)Y_{l_j' m_j}(\vartheta_1, \varphi_1)\ . \tag{33}$$

Here again using the formula (32) and choosing the term proportional to $Y_{l_i' m_i}(\vartheta_1, \varphi_1)$, we can substitute the product $Y_{km_k}(\vartheta_1, \varphi_1)\ Y_{l_j' m_j}(\vartheta_1, \varphi_1)$ by

$$\sqrt{\frac{(2k+1)(2l_j'+1)}{4\pi(2l_i'+1)}}(k0l_j'0|kl_j'l_i'0)(km_kl_j'm_j|kl_j'l_i'm)Y_{l_i' m_i}(\vartheta_1, \varphi_1)\ .$$

Then the right-hand side of the equation (33) is transformed into

$$\sqrt{\frac{(2l_i+1)(2l_j'+1)}{(2l_i'+1)(2l_j+1)}}(l_i0k0|l_ikl_j0)(k0l_j'0|kl_j'l_i'0)(10l_j0|1l_jl_j'0)Y_{l_i' m_i}(\vartheta_1, \varphi_1)$$
$$\cdot\sum_{m_j m_k}(-1)^{m_k}(l_im_ik-m_k|l_ikl_jm_j)(10l_jm_j|1l_jl_j'm_j)(km_kl_j'm_j|kl_j'l_i'm_i)\ .$$

Here from the property of the Clebsch-Gordan coefficient $(l_im_ik-m_k|l_ikl_jm_j)$[15], we get the relation $m_i = m_j + m_k$. Then the summations over m_j and m_k are not independent but they reduce to a summation over one variable only, say m_k, if we consider m_i to be given. This sum can be represented by the Racah coefficient. Namely, by use of the symmetry relations of the Clebsch-Gordan coefficient[15)]

$$\begin{aligned}(l_1m_1l_2m_2|l_1l_2l_3m_3) &= (-1)^{l_1+l_2-l_3}(l_2m_2l_1m_1|l_2l_1l_3m_3)\\ &= (-1)^{l_1+l_2-l_3}(l_1-m_1l_2-m_2|l_1l_2l_3-m_3)\\ &= (-1)^{l_1-m_1}\sqrt{\frac{2l_3+1}{2l_2+1}}\,(l_1m_1l_3-m_3|l_1l_3l_2-m_2)\\ &= (-1)^{l_2+m_2}\sqrt{\frac{2l_3+1}{2l_1+1}}\,(l_3-m_3l_2m_2|l_3l_2l_1-m_1)\,,\end{aligned} \tag{34}$$

and a property of the Racah coefficient $W(abcd\colon ef)$,[15)]

$$\begin{aligned}&\sum_{\beta}(a\alpha b\beta|abe\alpha+\beta)(e\alpha+\beta d\gamma-\alpha-\beta|edc\gamma)(b\beta d\gamma-\alpha-\beta|bdf\gamma-\alpha)\\ &\qquad =\sqrt{(2e+1)(2f+1)}\,(a\alpha f\gamma-\alpha|afc\gamma)W(abcd\colon ef)\,,\end{aligned} \tag{35}$$

we can reduce the summation appeared in the equation (33) to

$$(-1)^k\sqrt{(2l_j+1)(2l_j'+1)}\,(10l_im_i|1l_il_i'm_i)W(l_ik1l_j'\colon l_jl_i')\,.$$

Hence finally we obtain the result as follows

$$\begin{aligned}\sum_{j//}\int\frac{\phi_j^{(0)*}(r_2)\phi_i^{(0)}(r_2)}{r_{12}}\,dr_2\phi_j^{(1)}(r_1) &= -E\sum_{n_jl_j}\sum_{kl_j'}(-1)^k\sqrt{(2l_j+1)(2l_j'+1)}\sqrt{\frac{2l_i+1}{2l_i'+1}}\\ &\quad\cdot(l_i0k0|l_ikl_j0)(k0l_j'0|kl_j'l_i'0)(10l_j0|1l_jl_j'0)(10l_im_i|1l_il_i'm_i)\\ &\quad\cdot W(l_ik1l_j'\colon l_jl_i')\frac{P_1(n_jl_j\to l_j'\colon r_1)}{r_1}Y_{l_i'm_i}(\vartheta_1,\varphi_1)\frac{Y_k^{(0)}(n_il_i,\,n_jl_j\colon r_1)}{r_1}\,.\end{aligned} \tag{36}$$

The Racah coefficients are calculated and tabulated by Biedenharn et al.[16)] and Obi et al.[16)]

The contributions from the other terms may be calculated analogously, so only the results are given here:

$$\begin{aligned}\sum_{j//}\int\frac{\phi_j^{(1)*}(r_2)\phi_i^{(0)}(r_2)}{r_{12}}\,dr_2\phi_j^{(0)}(r_1) &= -E\sum_{n_jl_j}\sum_{kl_j'}(-1)^{k+1}(2l_j+1)\sqrt{\frac{2l_i+1}{2l_i'+1}}\,(l_i0k0|l_ikl_j'0)\\ &\quad\cdot(k0l_j0|kl_jl_i'0)(10l_j0|1l_jl_j'0)(10l_im_i|1l_il_i'm_i)W(l_ik1l_j\colon l_j'l_i')\\ &\quad\cdot\frac{P_0(n_jl_j\colon r_1)}{r_1}Y_{l_i'm_i}(\vartheta_1,\varphi_1)\frac{Y_k^{(1)}(n_il_i,\,n_jl_j\to l_j'\colon r_1)}{r_1}\,,\end{aligned} \tag{37}$$

$$\begin{aligned}\sum_{j//}\int\frac{\phi_j^{(0)}(r_2)\phi_i^{(1)}(r_2)}{r_{12}}\,dr_2\phi_j^{(0)}(r_1) &= \sum_{n_jl_j}\sum_{kl_i'}\left(\frac{2l_j+1}{2l_i'+1}\right)(l_j0k0|l_jkl_i'0)^2\\ &\quad\cdot C(l_i\to l_i'\colon m_i)\frac{P_0(n_jl_j\colon r_1)}{r_1}Y_{l_i'm_i}(\vartheta_1,\varphi_1)\frac{Y_k^{(1)}(n_jl_j,\,n_il_i\to l_i'\colon r_1)}{r_1}\,.\end{aligned} \tag{38}$$

Then using the results obtained above we finally get the equations satisfied by $P_1(n_il_i\to l_i'\colon r)$ as follows

$$\begin{aligned}&\left[-\frac{1}{2}\frac{d^2}{dr^2}-\frac{Y(r)}{r}+\frac{(l_i+1)(l_i+2)}{2r^2}-\varepsilon^{(0)}_{n_il_i}\right]P_1(n_il_i\to l_i+1\colon r)=rP_0(n_il_i\colon r)\\ &\qquad -\frac{4}{3}\frac{P_0(n_il_i\colon r)}{r}\sum_{n_jl_j}\Big[(l_j+1)Y_1^{(1)}(n_jl_j,\,n_jl_j\to l_j+1\colon r)+l_jY_1^{(1)}(n_jl_j,\,n_jl_j\to l_j-1\colon r)\Big]\\ &\qquad +\frac{1}{(10l_i0|1l_il_i+10)}\sum_{n_jl_jkl_j'}(-1)^k\sqrt{2l_j+1}\,(10l_j0|1l_jl_j'0)\left[\sqrt{2l_j'+1}\,(l_i0k0|l_ikl_j0)\right.\end{aligned}$$

$$
\begin{aligned}
&\cdot (k0l_j'0|kl_j'l_i+10)\,W(l_ik1l_j':\,l_jl_i+1)\,\frac{P_1(n_jl_j\to l_j':r)}{r}\,Y_k^{(0)}(n_il_i,\,n_jl_j:r)\\
&-\sqrt{2l_j+1}\,(l_i0k0|l_ikl_j'0)(k0l_j0|kl_jl_i+10)\,W(l_ik1l_j:l_j'l_i+1)\\
&\cdot\frac{P_0(n_jl_j:r)}{r}\,Y_k^{(1)}(n_il_i,\,n_jl_j\to l_j':r)\Big]+\frac{1}{2l_i+3}\sum_{n_jl_jk}(2l_j+1)\\
&\cdot (l_j0k0|l_jkl_i+10)^2\,\frac{P_0(n_jl_j:r)}{r}\,Y_k^{(1)}(n_jl_j,\,n_il_i\to l_i+1:r)\,, \qquad (39)
\end{aligned}
$$

and

$$
\begin{aligned}
\Big[-\frac{1}{2}\frac{d^2}{dr^2}-\frac{Y(r)}{r}+\frac{(l_i-1)l_i}{2r^2}-\varepsilon^{(0)}_{n_il_i}\Big]&P_1(n_il_i\to l_i-1:r)=rP_0(n_il_i:r)\\
&-\frac{4}{3}\frac{P_0(n_il_i:r)}{r}\sum_{n_jl_j}\Big[(l_j+1)Y_1^{(1)}(n_jl_j,\,n_jl_j\to l_j+1:\,r)+l_jY_1^{(1)}(n_jl_j,\,n_jl_j\to l_j-1:r)\Big]\\
&+\frac{1}{(10l_i0\,|\,1l_il_i-10)}\sum_{n_jl_jkl_j'}(-1)^k\sqrt{2l_j+1}\,(10l_j0|1l_jl_j'0)\Big[\sqrt{2l_j'+1}\,(l_i0k0|l_ikl_j0)\\
&\cdot (k0l_j'0|kl_j'l_i-10)\,W(l_ik1l_j':\,l_jl_i-1)\,\frac{P_1(n_jl_j\to l_j':r)}{r}\,Y_k^{(0)}(n_il_i,\,n_jl_j:\,r)\\
&-\sqrt{2l_j+1}\,(l_i0k0|l_ikl_j'0)(k0l_j0|kl_jl_i-10)\,W(l_ik1l_j:l_j'l_i-1)\\
&\cdot\frac{P_0(n_jl_j:r)}{r}\,Y_k^{(1)}(n_il_i,\,n_jl_j\to l_j':r)\Big]+\frac{1}{2l_i-1}\sum_{n_jl_jk}(2l_j+1)\\
&\cdot (l_j0k0|l_jkl_i-10)^2\,\frac{P_0(n_jl_j:r)}{r}\,Y_k^{(1)}(n_jl_j,\,n_il_i\to l_i-1:r)\,. \qquad (40)
\end{aligned}
$$

The boundary conditions for $P_1(nl\to l':\,r)$ are

$$
P_1(nl\to l':\,r)=\begin{cases} 0 & \text{for}\quad r=0\\ \text{const. }\exp-\sqrt{|\varepsilon^{(0)}_{nl}|}\,r & \text{for}\quad r\to\infty\,,\end{cases} \qquad (41)
$$

which come from the demand on the wave function. These equations are coupled with each other and can be solved self-consistently by the method of successive approximation, but in this article we solve them only for helium.

§ 4. Sternheimer Approximation

Starting from a one-electron point of view, Sternheimer[8] obtained, instead of (6), the following equation for $\phi_i^{(1)}(\boldsymbol{r})$

$$
\begin{aligned}
\Big[-\frac{1}{2}\nabla_1^2-\frac{N}{r_1}+\sum_j\int\frac{|\phi_j^{(0)}(\boldsymbol{r}_2)|^2}{r_{12}}\,d\boldsymbol{r}_2-\sum_{j\parallel}\int\frac{\phi_j^{(0)*}(\boldsymbol{r}_2)\,\phi_i^{(0)}(\boldsymbol{r}_2)}{r_{12}}\,d\boldsymbol{r}_2\,\frac{\phi_j^{(0)}(\boldsymbol{r}_1)}{\phi_i^{(0)}(\boldsymbol{r}_1)}-\varepsilon_i^{(0)}\Big]&\phi_i^{(1)}(\boldsymbol{r}_1)\\
=-Ez_1\phi_i^{(0)}(\boldsymbol{r}_1)\,.&\qquad (42)
\end{aligned}
$$

This equation can be written by use of (8), (17) and (21) in the form

$$
\Big[-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l'(l'+1)}{2r^2}+\{V^{(0)}_{nl}(r)-\varepsilon^{(0)}_{nl}\}\Big]P_1(nl\to l':r)=rP_0(nl:r)\,, \qquad (43)
$$

which corresponds to (39) and (40). Here $V^{(0)}_{nl}(r)$ is the potential energy appeared in the equation (42).

Comparing the equation (42) with the rigorous equations (6), we see that Sternheimer neglected the influence on the perturbation of $\phi_i(\boldsymbol{r})$ from the perturbations of the other orbitals.

In practical calculation, however, the set of equations (39) and (40) is not so easy to treat as the Sternheimer's equation; for the former is a coupled set of integro-differential equations whereas the latter is an uncoupled set of ordinary differential equations. We adopt

Sternheimer's approximation in this article except for helium, for which we shall solve the exact equation (39) self-consistently in order to estimate the accuracy of the Sternheimer approximation.

§ 5. Method of Calculation

Next we describe our method of solving the differential equation (43). The unperturbed radial wave functions $P_0(nl:r)$ are solutions of the Hartree-Fock equation

$$\left[-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l(l+1)}{2r^2}+\{V_{nl}^{(0)}(r)-\varepsilon_{nl}^{(0)}\}\right]P_0(nl:r)=0\ , \tag{5'}$$

and are tabulated for each atom[17),18),22),19)] but the potentials $V_{nl}^{(0)}(r)$ are not given for neon and argon. So we use the method given by Sternheimer[8)], which we shall modify slightly for convenience.

We define a function $U_{nl}(r)$ as follows

$$U_{nl}(r)=\frac{l(l+1)}{r^2}+2\{V_{nl}^{(0)}(r)-\varepsilon_{nl}^{(0)}\}\ , \tag{44}$$

and approximate the second derivative of $P_0(nl:r)$ with respect to r by the second difference according to Lagrange's three-point method of interpolation, that is by

$$\frac{2}{\delta_{n-1}(\delta_{n-1}+\delta_n)}\left[\frac{\delta_{n-1}}{\delta_n}P_0(nl:r_{n+1})-\left(1+\frac{\delta_{n-1}}{\delta_n}\right)P_0(nl:r_n)+P_0(nl:r_{n-1})\right],$$

in which $\delta_n=r_{n+1}-r_n$. Then $U_{nl}(r)$ is given by the equation (5′) as follows:

$$U_{nl}(r_n)=\frac{2}{P_0(nl:r_n)\delta_{n-1}(\delta_{n-1}+\delta_n)}\left[\frac{\delta_{n-1}}{\delta_n}P_0(nl:r_{n+1})-\left(1+\frac{\delta_{n-1}}{\delta_n}\right)P_0(nl:r_n)+P_0(nl:r_{n-1})\right]. \tag{45}$$

The differential equation (43) can be written by use of the function $U_{nl}(r)$ in the form

$$\frac{d^2}{dr^2}P_1(nl\to l':r)=U'_{nl}(r)P_1(nl\to l':r)-I_{nl}(r)\ ,$$

where

$$U'_{nl}(r)=U_{nl}(r)+[l'(l'+1)-l(l+1)]/r^2\ ,$$

$$I_{nl}(r)=2rP_0(nl:r)\ .$$

Replacing again the second derivative with respect to r by the Lagrange approximation, we obtain

$$\begin{aligned}P_1(nl\to l':r_{n+1})=P_1(nl\to l':r_n)&+\frac{\delta_n}{\delta_{n-1}}[P_1(nl\to l':r_n)-P_1(nl\to l':r_{n-1})]\\&+\frac{\delta_n(\delta_{n-1}+\delta_n)}{2}[U'_{nl}(r_n)P_1(nl\to l':r_n)-I_{nl}(r_n)]\ .\end{aligned} \tag{46}$$

We use this formula for the outward integration of the equation (43) starting from the neighbourhood of $r=0$. The correspoding formula for the inward integration is

$$\begin{aligned}P_1(nl\to l':r_{n-1})=P_1(nl\to l':r_n)&+\frac{\delta_{n-1}}{\delta_n}[P_1(nl\to l':r_n)-P_1(nl\to l':r_{n+1})]\\&+\frac{\delta_{n-1}(\delta_{n-1}+\delta_n)}{2}[U'_{nl}(r_n)P_1(nl\to l':r_n)-I_{nl}(r_n)]\ .\end{aligned} \tag{47}$$

For excitations $ns\to p$ and $np\to s$ except for $1s\to p$, the equation (43) is integrated outward with starting values obtained in the following. For small r the equation (43) becomes[20)]

$$\left[-\frac{d^2}{dr^2}-\frac{2N}{r}+\frac{l'(l'+1)}{r^2}+2\{v_{nl}^{(0)}-\mathcal{E}_{nl}^{(0)}\}+\mathrm{O}(r^2)\right]P_1(nl\to l':r)=2Ar^{l+2}+\mathrm{O}(r^{l+3})\,,$$

where $v_{nl}^{(0)}$ and A are constants. The right-hand side of this equation can be neglected as compared with the left-hand side in the neighbourhood of $r=0$. Then this equation is the same as the equation for $P_0(nl':r)$ except for the constant term $2\{v_{nl}^{(0)}-\mathcal{E}_{nl}^{(0)}\}$. But this constant term is negligible compared with $l'(l'+1)/r^2$ and $2N/r$ in the neighbourhood of $r=0$. Hence $P_1(nl\to l':r)$ is approximately proportional to $P_0(nl':r)$ for small r; and the proportional constant is to be determined by the boundary condition (41). In practice we start integration of the equation (43) by use of the equation (46) from two points near $r=0.05$.

For the excitation $1s\to p$, the integration is started from the origin and the gradient of the solution at that point is determined so as to satisfy the boundary condition (41).

For the excitation $np\to d$ singularity at the origin is strong compared with the above-mentioned case; hence we use the inward integration of the equation (43) starting from a large radius R. Let the equation (43) be written for simplicity as

$$\left.\begin{aligned}&\frac{d^2}{dr^2}P_1(nl\to l':r)=F(r)P_1(nl\to l':r)\,,\\&F(r)=U'_{nl}(r)-\frac{I_{nl}(r)}{P_1(nl\to l':r)}\,.\end{aligned}\right\}\tag{48}$$

Then $F(r)$ is certainly positive and not too rapidly varying in the neighbourhood of $r=R$; at large distances from the nucleus it is nearly a constant and is given by $-2\mathcal{E}_{nl}^{(0)}$. So we can assume that $F(r)$ is constant for $r>R$. Then an approximate solution of the equation (48) satisfying the boundary condition is given by

$$\begin{aligned}P_1(nl\to l':r)&\sim P_1(nl\to l':R)\exp\left[-\int_R^r\sqrt{F(r)}\,dr\right]\\&\sim P_1(nl\to l':R)\exp\left[-\sqrt{F(R)}(r-R)\right].\end{aligned}\tag{49}$$

In practical calculation, if $P_1(nl\to l':R)$ is assumed, $F(R)$ is calculated from the equation (48) and $P_1(nl\to l':R+\delta)$ is obtained from the equation (49). Then the numerical integration can be performed by use of the integration formula (47). The correct value of $P_1(np\to d:R)$ is determined so as to satisfy the boundary condition at the origin.

Since for helium the potential field $V_{1s}^{(0)}(r)$ effective for an electron is published, we can solve the equation (43) for 1s state by the Störmer-Levy method(27). Thus we can estimate the accuracy of our method explained above. Thereby starting values near $r=0$ can be assumed to be proportional to the unperturbed wave function $P_0(2p:r)$ and the proportional constant is to be determined from the boundary condition (41).

Also for helium, we solve the rigorous equation self-consistently to estimate the accuracy of the Sternheimer approximation. In this case the equation (39) becomes

$$\begin{aligned}&\left[-\frac{1}{2}\frac{d^2}{dr^2}-\frac{2}{r}+\frac{Y_0^{(0)}(1s,1s:r)}{r}+\frac{1}{r^2}-\mathcal{E}_{1s}^{(0)}\right]P_1(1s\to p:r)\\&\qquad=rP_0(1s:r)-\frac{2}{3}P_0(1s:r)\frac{Y_1^{(1)}(1s,1s\to p:r)}{r}\,.\end{aligned}\tag{50}$$

The second term of the right-hand side of this equation represents the perturbation of the Coulomb interaction energy due to the applied electric field. This is an integro-differential equation which is solved self-consistently by the successive approximation method. First $Y_1^{(1)}(1s,1s\to p:r)$ is estimated by use of $P_1(1s\to p:r)$ which has been obtained by the Sternheimer approximation, and next the equation (50) is solved by the method explained above. Then, using the solution $P_1(1s\to p:r)$ so obtained, we calculate

$Y_1^{(1)}(1s, 1s\to p:r)$ again and compare it with the former one. This procedure is to be carried out until the self-consistency is obtained.

§ 6. Results and Discussions

By the method described above the functions $P_1(nl\to l':r)$ in the Sternheimer approximation are calculated for each orbital of the atoms. In the course of numerical calculation the Parametron Computor PC-1 has been employed to solve the equations (43).

After the perturbations $P_1(nl\to l':r)$ have been obtained, the integrals $I(nl\to l')$ are evaluated, and the polarizability α is calculated from the equation (20). The results of the calculation are presented in Table I. Contribution of the outermost shell to the polarizability α is predominant, as already mentioned by Pauling[21], Buckingham[4] and Sternheimer[8]. For neon values of the present author are obtained by use of the unperturbed wave functions found by Brown[18], who takes account of the exchange interaction only between $2p$ electrons; his wave functions are more loosely bounded than the exact solutions of Hartree-Fock equation. Owing to this charactor of the unperturbed wave function, our value of the polarizability is expected larger than the value obtained by the more rigorous unperturbed functions. After the calculations are over, we find a new solution of Hartree-Fock equation for neon obtained by Worsley[22] and the calculation of the polarizability by Dalgarno and Parkinson[11] who used an analytic wave function adjusted so as to approximate the Worsley's function. Their values are cited in Table II, agreement with the experimental value being very good compared with ours. By comparison between the two values for neon, we see that the accuracy of the calculated value of the polarizability depends sensitively on the accuracy of the unperturbed wave function used.

For comparison's sake, the experimental values[23],[24] and the values calculated by different methods from ours are shown in Table II. For helium, a calculation was made by Sternheimer[9] with use of Löwdin's[25] analytical function which was an approximation to Hartree's wave function; and as an example of the variational method to this problem the value calculated by Wikner and Das[7] is quoted. For neon and argon the calculations were made by use of the variational method by Bravin[5] and Pople and Schofield[6], and by use of the statistical model of atoms by Gombás[26].

For helium a calculated value of the polarizability obtained by the Störmer-Levy method[27] for the perturbed wave function is also shown in Table II as Kaneko (S.L). The agreement between calculated values by both methods is very good, so we can suppose the error resulted from using the integration formulae (46) and (47) to be at most few per cent for neon and argon, even if we consider the fact that they have wave functions with nodes in contrast to helium which has only nodeless 1*s* wave function.

Also for helium the calculated value of the polarizability obtained by use of the solution of the equation (50) is shown in Table II as Kaneko. This is the most rigorous theoretical value of the polarizability for helium within the limits of Hartree-Fock approximation. From this result we see that the rigorous theory gives the polarizability about ten per cent smaller. Hence we may deduce from this result that if we take account of the influence due to the perturbation of the interelectronic potential energy the Sternheimer approximation will be improved considerably. We are new planning to solve the integrodifferential equations (39) and (40) for neon and argon.

In conclusion the author wishes to express his sincere thanks to Prof. T. Kihara for his continual guidance and for his kindness in reading the original manuscript, and to Prof. M. Kotani for many suggestions and guidances. Thanks are also due to Prof. H. Takahasi and members of his laboratory for helps in programming and operating the Parametron Computor PC–1.

Note added in proof. The polarizability for helium has just been calculated in a similar way by A. Dalgarno: Proc. Roy. Soc. **A, 251** (1959) 282.

Luminescence Processes in the KCl:Tl Phosphor in a Multidimensional Configuration Space

By Hiroshi KAMIMURA and Satoru SUGANO

Department of Physics, Faculty of Science, University of Tokyo
Tokyo, Japan

(Received July 3, 1959)

In order to explain the 3050Å and 4750Å emissions of KCl:Tl phosphor which are raised by excitation in any of the absorption bands, a multidimensional configuration coordinate model is introduced. This is achieved by taking into account the Jahn-Teller effect for the excited states of the thallium ion. The Jahn-Teller effect is treated by means of an intermediate coupling scheme within the *6s6p* configuration, because the mixing of the ^3P and ^1P states by the spin-orbit interaction is essential to understand the optical properties. It is shown that introduction of a tetragonal distortion of the emission center is able to explain the luminescence processes of this phosphor both semi-quantitatively and qualitatively: Under the tetragonal and trigonal distortions, both the crossing of the pure spin singlet ^1P and triplet ^3P curves and the appearance of two minima in the $^3P_1$ energy curves are expected. The former accounts for the non-radiative transition from the $^1P_1$ state to the $^3P_1$ state and the latter does for the two emission bands. The two types of distortions are equally able to give semi-quantitative agreement of the relative strengths of the absorption and emission bands with experiments, but only the tetragonal distortion explains the polarization of the 3050Å emission observed.

Finally Johnson and Williams' model is criticized.

§ 1. Introduction

Alkali halide thallium phosphors have been widely investigated by many authors, because they are physically simplest among luminescent materials. Among them, KCl : Tl has been most fully examined. In a potassium chloride crystal, a thallium introduces two clearly resolved absorption bands peaking at 1960Å and 2490Å with subsidiary one at 2060Å and two emission bands with peaks at 3050Å and 4750Å. Excitation in any of the three absorption bands results in emission in both two emission bands.[1)]

Seitz[2)] has suggested that the $^1P_1$, $^3P_2$ and $^3P_1$ excited states of the Tl$^+$ ions, suitably modified in the crystal, are responsible for the 1960Å, 2060Å and 2490Å absorption bands respectively. More recently Williams[3)] has calculated energies of the $^1S_0$ ground state and the $^3P_1$ excited state by using the properties of the free ion. The energies are given as a function of the distance Δa between the thallium ion and the neighboring chlorine ion in the one-dimensional configuration coordinate. For the $^1P_1$ state Johnson and Williams[1)] have derived a similar curve from the experimental data. The curve thus derived intersects with the $^3P_1$ curve near the minimum in order that the emission by excitation in any of the $^3P_1$ and $^1P_1$ bands may take place.

If the similar treatment to Williams' is also applied to the $^1P_1$ curve, however, it would not intersect with the $^3P_1$ curve but be nearly parallel to it. The reason is that his treatment does not involve the spin effects explicitly. In facts, using the same mathematical calculation as Williams', Knox and Dexter[4)] have found that the $^1P_1$ curve simply displaces upward by about three electron volts from the $^3P_1$ curve. Thus, insofar as spin effects may be neglected, the one-dimensional configuration coordinate model will not be suitable for explaining the experimental facts.

The purpose of the present investigation is to propose an alternative way to explain the experimental facts by considering the Jahn-Teller effect of the excited states of the thallium ion. In doing so, it is necessary to introduce multidimensional configuration coordinate curves for these states. The excited states with the *6s6p* configuration in cubic crystals have orbital degeneracies. Therefore, they undergo the Jahn-Teller effect to remove the degeneracies. Öpik and Pryce[5] have already considered such a Jahn-Teller effect only for the ^3P state. In the thallium ion, however, the departure from Russell-Saunders coupling is considerable and the mixing of the ^3P and ^1P states by spin-orbit interactions is essential to understand the optical spectrum. Therefore, we deal here with the Jahn-Teller effect of the excited states by means of an intermediate coupling scheme.

§ 2. The Secular Matrix for the Excited State (6s6p)

We take the following Hamiltonian for the excited states with the *6s6p* electron configuration :

$$\mathscr{H}=\sum_{i=1,2}\left\{-\frac{\hbar^2}{2m}\Delta_i+v(r_i)+V_{crys}(r_i)+\zeta_i l_i\cdot s_i\right\}+\frac{e^2}{r_{12}}+W+V, \qquad (2.1)$$

where $v(r_i)$ is the potential energy due to core electrons and thallium nucleus, $V_{crys}(r_i)$ that of the cubic crystal field* to which *6s* and *6p* electrons are exposed, $l_i\cdot s_i$ the spin-orbit interaction, W the term of the Jahn-Teller effect and V the quasi-elastic potential energy. In our treatment, V_{crys} is considered to include all the effects computed by Williams.

If we restrict our attention to the thallium ion and its six neighboring chlorine ions, even vibrations of the system are A_{1g}, E_g and T_{2g} whose normal coordinates are expressed by (Q_1), (Q_2, Q_3) and (Q_4, Q_5, Q_6) respectively. They are given in Fig. 1. Then, W and V are expanded in terms of these normal coordinates as follows :

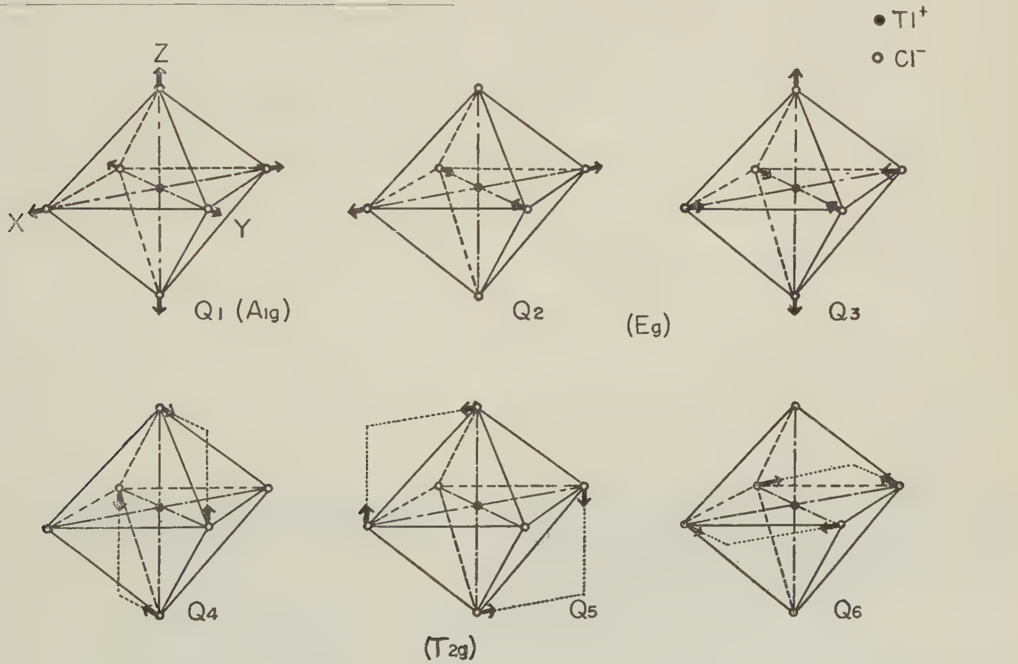

Fig. 1.

$$W=V_1Q_1+V_2Q_2+V_3Q_3+V_4Q_4+V_5Q_5+V_6Q_6,$$
$$V=1/2\cdot\alpha Q_1^2+1/2\cdot\beta(Q_2^2+Q_3^2)+1/2\cdot\gamma(Q_4^2+Q_5^2+Q_6^2), \qquad (2.2)$$

where V_i's $(i=1,\ldots,6)$ represent the coupling between the electrons and nuclear displacements. Since the term of Q_1 in W appears equally in all the diagonal elements of the secular matrix for $\mathscr{H}$, it will be included in V_{crys} as $V_{crys}(r, Q_1)$, which has already been calculated by Williams.

The excited states with the *6s6p* configuration consist of three triplet states $^3P_0$, $^3P_1$ and $^3P_2$ and one singlet state $^1P_1$. Let $|LSJM>$

---

* The cubic crystal field can be expanded in terms of *Cubic Harmonics*. *s* and *p* electrons feel only the first term, the spherically symmetric one.

Table I. The matrix elements of the Hamiltonian (2.1). The diagonal

		$E_3-\frac{\sqrt{3}}{2\sqrt{2}}AQ_3$	$-\frac{1}{2\sqrt{6}}B(Q_5-iQ_4)$	$\frac{3}{2\sqrt{2}}AQ_2+\frac{i}{2}BQ_6$	0	$-\frac{3\sqrt{3}}{2\sqrt{2}}AQ_3$
			$E_3-\sqrt{\frac{3}{2}}AQ_3$	$\frac{1}{2\sqrt{6}}(Q_5-iQ_4)$	$\frac{\sqrt{3}}{2}AQ_2+\frac{i}{\sqrt{6}}BQ_6$	$\frac{\sqrt{3}}{2\sqrt{2}}B(Q_5+iQ_4)$
				$E_3-\frac{3}{2\sqrt{2}}AQ_3$	$\frac{1}{2}B(Q_5-iQ_4)$	$-\frac{3}{2\sqrt{2}}AQ_2+\frac{i}{2}BQ_6$
					$E_3+\sqrt{\frac{3}{2}}AQ_3$	0
						$E_2-\frac{\sqrt{3}}{2\sqrt{2}}AQ_3$

be the eigenvectors of these states. Then in terms of these eigenvectors the secular matrix for $\mathscr{H}$ is given as Table I shows, where we have omitted the common terms

$$\sum_{i=1,2} V_{crys}(r_i,\ Q_1)+V \tag{2.3}$$

in the diagonal elements to save space.

In the table, the constants A and B are defined in terms of eigenvectors $|1,m>$ of the single p-electron as follows,

$$A=-1/\sqrt{6}\cdot<1,0\,|\,v_3\,|\,1,0>\ ,$$
$$B=\sqrt{3}/2\cdot<1,0\,|\,v'_6\,|\,1,0>\ , \tag{2.4}$$

v_3 and v'_6 being the single electron part of V_3 and V'_6 respectively. In the expression of B, the quantization axis is referred to the trigonal axis of the crystal and $V'_6=1/\sqrt{3}\cdot(V_4+V_5+V_6)$. E's are given by

$$E_1=F_0-G_1-\zeta_p\ ,$$
$$E_2=F_0-G_1-1/2\cdot\zeta_p\ ,$$
$$E_3=F_0-G_1+1/2\cdot\zeta_p\ , \tag{2.5}$$
$$E_4=F_0+G_1\ ,$$

F_0 and G_1 being Slater integrals, ζ_p a constant of the spin-orbit coupling for a 6p-electron. It should be remarked that these constants are considered not to be those of a free thallium ion but of a thallium ion in the crystal. Therefore, as we shall see later, they are determined empirically in our theory.

elements of the term $V_{crys}(r_i,Q_1)+V$ are omitted to save space.

					$E_4+\sqrt{\frac{3}{2}}AQ_3$

§ 3. Multidimensional Configuration Coordinate Energy Surface

The secular matrix of (2.1) has 12 dimensions and so it is difficult to solve it generally. In this paper, however, we confine ourselves to the cases of special distortions, that is, tetragonal and trigonal distortions of the octahedron $Tl^+(Cl^-)_6$. For these cases the matrix can be solved rather easily. Such a treatment seems to be justified by Öpik and Pryce's proof[5] that the energy of the stationary point of a lower symmetry always lies between those of the tetragonal and trigonal stationary points for the *P*-state.

For tetragonal distortions, we can put $Q_2=Q_4=Q_5=Q_6=0$. Then the matrix is reduced to two 3-dimensional, two 2-dimensional and two 1-dimensional matrices. From these, arise four non-degenerate and four doubly degenerate energy levels.

The results of trigonal distortions turn out to be equivalent to those of tetragonal distortions if one replaces A with $-\sqrt{2}/3\cdot B$, Q_3 with $Q'_6=1/\sqrt{3}\cdot(Q_4+Q_5+Q_6)$, β with γ and takes the trigonal axis as the quantization axis. It is, therefore, sufficient for us to discuss only the case of the tetragonal distortion.

In order to solve the secular matrices and illustrate the multidimensional configuration coordinate energy surfaces of the excited states, it becomes necessary to know the values of the parameters G_1 and ζ_p. Since the orbital functions of the *6s* and *6p* electrons are considered to be significantly affected by the surrounding ions, values of the parameters G_1 and ζ_p are determined so as to get the best fit of relative positions of the $^1P_1$, $^3P_2$ and $^3P_1$ crystal states to the observed three absorption peaks (1960Å, 2060Å and 2490Å) instead of using values of a free thallium ion. They are given in Table II.

Table II. The values of G_1, ζ_P, λ and R_{Abs} determined by various methods

	Free ion (Hartree)	Free ion (Matched with exp.)	Williams et al.	Ours.	Obs.
G_1	1.70_5 eV	1.04_6	-0.10_5	0.20_4	
ζ_P	0.64_0 eV	1.01_5	1.02	0.76_5	
λ	(1.00)	0.87_2	0.87	(1.00)	
R_{abs}	184	27.8	2	3.9	5

Then, using these values of G_1 and ζ_p, we can obtain configuration coordinate curves without quasi-elastic terms for the excited states in a sub-space (Q_1-space) by taking $X=\sqrt{6}/2\cdot AQ_3$ as abscissa. These curves are illustrated in Fig. 2. This figure is considered to represent a section of the multidimensional configuration space passing through a fixed Q_1-point* and being perpendicular to the ordinary one-dimensional configuration coordinate space (Q_1-space). In Fig. 2, only the relative energies among the excited states are given and those to the ground state are out of our consideration. Each energy curve is designated by the notation $\mathcal{E}_i{}^M$ according to the quantum number *SLJM* associated with it at $Q_3=0$. The superscript *M* is a good quantum number even at $Q_3\neq 0$ and the subscript *i* is arranged in such a way that $i=1$, 2, 3, and 4 correspond to $^1P_1$, $^3P_2$, $^3P_1$ and $^3P_0$ respectively. The dashed lines associated with $\mathcal{E}_1{}^{\pm1}$, $\mathcal{E}_1{}^0$, $\mathcal{E}_3{}^{\pm1}$ and $\mathcal{E}_3{}^0$ states show the energy levels of the corresponding states obtained by neglecting the non-diagonal elements of the secular matrix. They are important to discuss non-radiative transitions from the $^1P_1$ curve to the $^3P_1$ curve as seen later.

As pointed out in the first section, $V_{crys}(r, Q_1)$ is considered to cause parallel shifts of the excited states, if it is independent of the spin associated with these states and if all the states are constructed from the same *s*- and *p*- crystal orbitals. Therefore, as far as we deal with the relative energies among the excited states as treated here, it is not necessary to calculate $V_{crys}(r, Q_1)$.**

When one attempts to complete the configuration coordinate curves by adding the quasi-elastic term $V=\beta/3A^2\cdot X^2$ to the curves

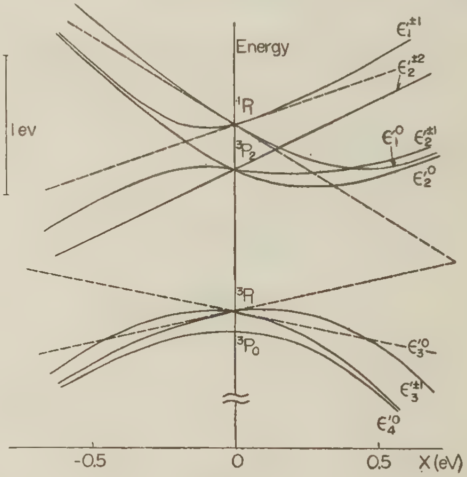

Fig. 2.

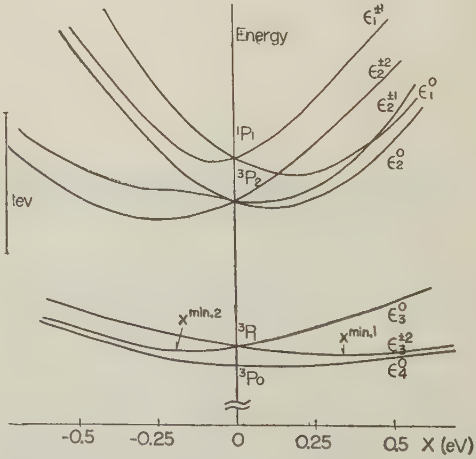

Fig. 3.

---

* When we use the configuration coordinate curves in the Q_3-space for the comparison with experiments, a fixed Q_1-point should be considered as the stationary point in the Q_1-space.

** Of course, $V_{crys}(r, Q_1)$ has a different form for each of the *P* excited and *S* ground states. Therefore, in case that the relative energies of the excited states to the ground state should be dealt with, it will become necessary to know $V_{crys}(r, Q_1)$ together with F_0, as was done by Williams.[3)] of Fig. 2, it becomes necessary to know the value of β/A^2. This parameter is determined empirically by the method which will be described in the next section. The curves thus completed are given in Fig. 3. In this figure, we can see that the $^3P_1$ state has two minima, $X^{\min,1}$ and $X^{\min,2}$, at the positive and negative sides of X respectively.

§4. Comparison with Experiments

(4.1) *Assignments of the emission bands*

The energy levels expressed by dashed lines of Fig. 2 repulse each other at the crossing region and curve into $\mathcal{E}_1{}^M$ and $\mathcal{E}_3{}^M$, because there exist non-diagonal elements between the states corresponding to these lines. The electronic wavefunctions, therefore, depend strongly upon Q_3 in the neighborhood of the crossing. This fact will be responsible for non-radiative transitions between the $\mathcal{E}_1{}^M$ and $\mathcal{E}_3{}^M$ states.[6] Hence, we may reasonably suppose that the luminescent center relaxes to the respective minima of the energy levels $\mathcal{E}_3{}^{\pm 1}$ and $\mathcal{E}_3{}^0$ after being excited in any of the 1960Å and 2490Å absorption bands. Since the energy levels $\mathcal{E}_3{}^{\pm 1}$ and $\mathcal{E}_3{}^0$ contain the $^1P_1$ character by virtue of the spin-orbit interaction, emissions are allowed from both $\mathcal{E}_3{}^{\pm 1}$ and $\mathcal{E}_3{}^0$ levels. Moreover, we can see that, since the absolute value of $X^{\min,1}$ is larger than that of $X^{\min,2}$ (see Fig. 3), the emission from the minimum $X^{\min,2}$ of the $\mathcal{E}_3{}^0$ excited level will locate at the shorter wavelength side than the other when we assume the parabolic dependence of the ground state upon Q_3. This feature is considered to be general because it is valid for any reasonable values of the parameters assumed. Hence, we assign the 3050Å and 4750Å emissions to the transitions from the stationary points $X^{\min,2}$ and $X^{\min,1}$ respectively.

(4.2) *Quantitative comparison*

In order to justify the values of the parameters ζ_p and G_1 determined in the previous section (Table II), the ratio of the oscillator strength of the 1960Å absorption to that of the 2490Å absorption, R_{abs}, is calculated by using these values. Such a ratio has been calculated in various ways by several authors. Knox and Dexter[4] computed this ratio by using Hartree's wavefunction of the gaseous Tl$^+$ ion, and they found that the result was considerably larger than the experimental one. This clearly means that the wavefunctions are significantly deformed in the crystal. More recently, the ratio was calculated by Williams et al[7] by using for ζ_p the free ion value and for G_1 the value determined to fit the relative positions of the $^1P_1$ and $^3P_1$ crystal states to those of the observed absorption peaks 1960Å and 2490Å. The reason they mentioned was that, though the wavefunctions were modified in the crystal from those of the gaseous state, the change would not be significant in the vicinity of the thallium nucleus where the value of ζ_p had to be almost determined. This, however, seems to be unreasonable, because the wavefunctions in the vicinity of the nucleus will also be affected by the change in the normalization constants of the wavefunctions caused by a deformation of the tails of the wavefunctions. All these calculated values of the ratio are collected in Table II together with those of the parameters ζ_p and G_1 used. The ratio we have obtained shows the best agreement with the experimental one.

The ratio of the transition probabilities of the two emissions* is given by expanding the wavefunctions at $X^{\min,1}$ and $X^{\min,2}$ in terms of ψ_1, ψ_2 and ψ_3, eigenfunctions of the $^1P_1$, $^3P_2$ and $^3P_1$ states respectively, as follows,

$$\begin{aligned}\phi_3{}^{\pm 1} &= a_3{}^{\pm 1}(X^{\min,1})\ \psi_1 + b_3{}^{\pm 1}(X^{\min,1})\psi_2 \\ &\quad + c_3{}^{\pm 1}(X^{\min,1})\ \psi_3, \qquad (4.1)\\ \phi_3{}^0 &= a_3{}^0(X^{\min,2})\ \psi_1 + c_3{}^0(X^{\min,2})\ \psi_3\ ,\end{aligned}$$

and by inserting $a_3{}^0$ and $a_3{}^{\pm 1}$ into the following expression,

$$S_{\text{emiss}} = \frac{a_3{}^0\,(X^{\min,2})^2\ \nu_{3050}{}^3}{2a_3{}^{\pm 1}\,(X^{\min,1})^2\ \nu_{4750}{}^3}\ , \qquad (4.2)$$

ν_{3050} and ν_{4750} being the frequencies of the 3050Å and 4750Å emissions respectively.

Determination of the stationary points $X^{\min,1}$ and $X^{\min,2}$ is achieved by adjusting the single parameter β/A^2 so as to make the energy difference of the two excited levels at $X^{\min,1}$ and $X^{\min,2}$ to be 0.02 eV, which has been experimentally obtained from the temperature dependence of the ratio of the two emission strengths.

At these stationary points, the expansion coefficients in (4.1) are computed as

---

* These emissions are considered as spontaneous emissions.

$$a_3^{\pm 1}(X^{\mathrm{min},1})=0.27_5 \qquad a_3^{0}(X^{\mathrm{min},2})=-0.41_6$$
$$b_3^{\pm 1}(X^{\mathrm{min},1})=-0.39_4 \qquad c_3^{0}(X^{\mathrm{min},2})=0.90_9$$
$$c_3^{\pm 1}(X^{\mathrm{min},1})=-0.87_7$$

which give

	(calc.)	(obs.)
S	= 4.3	6.

The quantitative feature that the 3050Å emission is stronger than the 4750Å one is thus explained.

The values of $Q_3^{\mathrm{min},1}$ and $Q_3^{\mathrm{min},2}$ which correspond to $X^{\mathrm{min},1}$ and $X^{\mathrm{min},2}$ respectively are obtained by seeking separately the values of β and A in β/A^2. The vibrational frequency of the excited state responsible for the emission has been given as $\nu_e=4.6\times 10^{12}$ c/s from the observed band widths of the 3050Å emission band both at low and high temperatures.[8] If we assume the ν_e to belong to the E_g mode of vibrations, the force constant β is given by the formula, $\beta=(2\pi)^2 \nu_e^2 M$, M being the mass of the single Cl^+ ion as far as we deal with the $Tl^+(Cl^-)_6$ octahedron. Then, using the empirical values of ν_e and β/A^2, we find β to be 0.86 and $|A|$ to be 0.37, where a.u. and eV are used for the units of length and energy respectively. From the X^{min} and $|A|$ thus determined, $|Q_3^{\mathrm{min},1}|$ and $|Q_3^{\mathrm{min},2}|$ are given as follows

$$|Q_3^{\mathrm{min},1}|=0.77\ \text{a.u.} \qquad |Q_3^{\mathrm{min},2}|=0.35\ \text{a.u.}\ .$$

These values are of the order of magnitudes of vibrational amplitudes and considered reasonable.

Let us turn to the case of the trigonal distortion. In this case, we assume the empirically determined ν_e to be the frequency of the T_{2g} vibration. Then, γ is connected to the ν_e by the formula, $\gamma=(2\pi)^2\ \nu^2 M/4$, which gives γ as $\gamma=\beta/4$. Bearing in mind the fact that the previously given discussion on the assignment and relative intensities of the emission bands is valid also in the case of the trigonal distortion if we assume the relations $X=-1/\sqrt{3}\cdot BQ_6'$, $V=3\gamma/2B^2\cdot X^2$ and $3\gamma/2B^2=\beta/3A^2$, the value of $|B|$ is derived as $|B|=3/2\sqrt{2}\cdot|A|=0.39$. Then we find the relation $|Q_6'|=\sqrt{2}\,|Q_3|$.

Theoretical estimate of the values of A and B is feasible, if one restricts himself to the $Tl^+(Cl^-)_6$ octahedron and adopt a point-charge model, in which the effective charges of the central positive ion and the surrounding negative ion are assumed to be +1 and −1 respectively. Then A and B are given in the a.u. by the following formulae.

$$A=-\sqrt{2}/10R^2\cdot(6\overline{r^2}/R^2-25\overline{r^4}/R^4),$$
$$B=3/5R^2\cdot(2\overline{r^2}/R^2-5\overline{r^4}/R^4)\quad, \tag{4.3}$$

where $\overline{r^2}$ and $\overline{r^4}$ denote respectively the mean square and mean fourth power radius of the *6p* orbit.

In order to estimate A and B numerically, we evaluate $\overline{r^2}$ and $\overline{r^4}$ by using the numerical Hartree's *6p* function of the excited gaseous Tl^+ ion.[9] R is the distance between the Tl^+ and Cl^- ions and assumed here to be the lattice constant of the pure KCl crystal. Then, from the numerical values, $R^2=35.16$ a.u., $\overline{r^2}/R^2=0.442$ and $\overline{r^4}/R^4=0.313$, we get the following values for A and B in the unit previously used for the empirical values of A and B.

	A	B
Calc.	0.56	−0.32
Emp.	±0.37	±0.39

These values show fair agreement with those determined empirically. Since the model adopted here is a crude one, we cannot decide at this stage any preference between the tetragonal and trigonal distortions.

(4.3) *Polarization of the emission*

Recently Klick and Compton[10] have found that at liquid helium temperature the 3050Å emission shows polarization by excitation with the polarized light of the 2490Å absorption band. According to their result, the emission shows most remarkable polarization when the electric vector of the exciting light is oriented along the cubic axis of the KCl crystal and it is polarized in such a way that the emission is most intense when the electric vector of the emitting light is parallel to that of the exciting light. The polarization disappears at liquid nitrogen temperature.

Such an experimental fact may be accounted for by our model as follows. Let us take the (001) axis of the KCl crystal as the z-axis and suppose that the exciting light is polarized along this axis. In our model, the tetragonal distortion has three equivalent sets of distortions corresponding to the tetragonal axis being along the x-, y-, or z-axis of the crystal. Let d-A be a name of the distortion where the tetragonal axis being along the z-axis, and d-B, d-C names of the distortions where it is along the x- and y-axes respectively. The excitation polarized in the z-axis causes the transition to the $\mathcal{E}_3{}^0$ level for the d-A distortion and transitions to the $\mathcal{E}_3{}^{\pm 1}$ level both for the d-B and d-C. Since the transition from the stationary point $X^{\mathrm{min},2}$ of the $\mathcal{E}_3{}^0$ level has been ascribed to the 3050Å emission, such an excitation will stimulate the 3050Å emission polarized in the z-axis. At the same time, it will stimulate the 4750Å emission which is polarized to some degree but not so perfectly as the 3050Å emission is. The reason is that, since the $\mathcal{E}_3{}^{\pm 1}$ level is degenerate in our model, the z-polarized excitation will stimulate the 4750Å emission whose electric vector lies in the yz- and xz-planes for the d-B and d-C distortions respectively. Therefore, if one observes the emission light propagating along the x-axis, the former is seen depolarized and the latter polarized in the z-axis.

The polarization of the 3050Å emission thus derived from our model is qualitatively accordant with the experimental one, if the tetragonal distortion of the emission center is assumed. It is evident that the trigonal distortion is unable to account for the observed polarization. However, there remain some questions for the 4750Å emission, because Klick and Compton have reported that the 4750Å emission is depolarized even at liquid helium temperature while our model gives a slight polarization in the z-axis.

Throughout the above-mentioned discussion, the effects of lattice vibrations have been out of our consideration. It is obvious that lattice vibrations act so as to depolarize the emission, because slightly split components of the levels mix with each other by the effect of lattice vibrations so as to smear out the anisotropy associated with each component. This means breakdown of an adiabatic approximation.

At present, however, we are unable to answer the question why the emission of the KCl:Tl phosphor is not perfectly depolarized by the effect of lattice vibrations, but we should like to mention the following facts: The energy of a vibration qnantum in the excited states is estimated as about 150 cm^{-1} from the frequency ν_e already mentioned, and the energy minima of the $\mathcal{E}_3{}^0$ and $\mathcal{E}_3{}^{\pm 1}$ levels are lower than the energy at $Q_3=0$ by about 400 cm^{-1} and 240 cm^{-1} respectively.

Therefore, we are able to define one or two vibrational levels associated with the electronic states corresponding to the stationary points.

§ 5. Concluding Discussions

As far as one sticks to the important experimental fact that both the 3050Å and 4750Å emissions are stimulated by excitation in any of the absorption bands, it becomes necessary to set up two minima on the low lying ${}^3P_1$ curve or its "progeny" before it intersects with the ground state energy curve, and to let the emission center excited by the 1960Å absorption light relax to the ${}^3P_1$ progeny with high efficiency.

In Johnson and Williams' model, such a requirement is fulfilled by depressing the ${}^1P_1$ curve across the ${}^3P_1$ curve. In our model, the two minima of the ${}^3P_1$ curve are naturally derived by considering the splitting of this level by the action of the Jahn-Teller effect. Furthermore, the crossing of the ${}^1P_1$ and ${}^3P_1$ curves, though it does not really occur because of the repulsion due to spin-orbit interactions, is caused by such situation that the dependence of the M component of the ${}^1P_1$ state upon Q_3, apart from the non-diagonal elements of the secular matrix and the quasi-elastic term, is equal to that of the corresponding M component of the ${}^3P_1$ state multiplied by minus two. This situation was illustrated in Fig. 2 by dashed lines. The crossing of the two states is important for the emission center in the excited ${}^1P_1$ state to relax to the ${}^3P_1$ state with high efficiency.

As pointed out in the first section of this paper, insofar as one may neglect dependence of the effects of the surroundings on the spin associated with the excited states of the thallium ion, the ${}^3P_1$ and ${}^1P_1$ curves will be nearly parallel. Then it is clear that Johnson and Williams' model is not suitable for this problem. We cannot, however, exclude the possibility that the surroundings would cause the effects on the thallium ion depending strongly upon its spin. Such effect might be interpreted as follows: Let us consider the excited states in which an electron is transferred from one of the neighboring chlorine ions to the thallium ion and makes a homopolar cevalent binding between the thallium and chlorine atoms. There are six equivalent such excited states corresponding to the six equivalent chlorine ions. Then, taking into account a resonance among these states, we obtain the $^1A_{1g}$, $^1T_{1u}$ and ^1E_g states as the group theory shows. If the $^1T_{1u}$ state thus obtained has energy comparable* to that of the ^1P state of the Tl^+ ion, configuration mixing can be interpreted as the effects of the surroundings on the thallium ion depending strongly upon its spin.

The above-mentioned discussion seems to show that a definite preference of one model over another should be given in a more advanced stage where detailed calculations of the $^1P_1$ state as a function of the Q_1 configuration coordinate have been performed. At the present stage, however, our model would be more interesting than Johnson-Williams' because of the theoretical fact that the Jahn-Teller effect has always to act on degenerate levels and of the experimental fact that the 3050Å emission is polarized at liquid helium temperature as expected from our model.

It would also be interesting to point out Patterson and Klick's finding that the treatment of one-dimensional configuration coordinate curves cannot account for all the absorption and emission data in a self-consistent way. That is, the ratio of the frequencies of vibrations in the excited and ground states can be empirically determined in two ways; one is from an analysis of the temperature variation of the emission and absorption band widths, and the other is from the ratio of the low temperature band widths of the absorption and emission bands. They have found that such two ways give different results. Then they discussed that this self-inconsistency might be related to such approximation as the use of a one-dimensional configuration coordinate model. This self-inconsistency might be avoided by the use of a multidimensional configuration coordinate model like ours.

Finally we should like to notice that no attempt has been made in this paper to explain concentration dependence of the relative intensities of the 3050Å and 4750Å emission bands and the slight difference of their excitation spectra. These effects might be interpreted to be due to interactions between thallium ions. In any way, it seems impossible to interpret these effects, especially the former, by using any models which treat only the single thallium ion.

Note added in proof

Recently Williams and Johnson (Phys. Rev. **113** (1959) 97) have reported a newly revised model. They assume the following empirical relation, for the energy curves of the pure spin states in a configuration coordinate space.

$$E=\eta_1(q-q_0)^2+\eta_2^2(q-q_0)^3+E_0\ ,$$

q being a configuration coordinate. Then, the parameters q_0, E_0, η_1 and η_2 are suitably adjusted after including the spin-orbit interaction so as to give the energy configuration coordinate diagram which explains reasonably many experimental informations. The essential point of this will be in that the energy curves of the pure spin singlet and triplet states intersect with each other. In this sense, the revised model is not different from their earlier one, but entirely different from ours. Therefore, the discussion given in the last section of our paper can also be applied to the revised model.

* In pure crystals, the energy required for an electron to be transfered from a chlorine ion to a neighboring potassium ion is considered to correspond approximately to the energy of the first exciton peak, 7.6 eV. If the potassium ion is substituted by a thallium impurity, the required energy will change by the amount of the difference between the first ionization energies of potassium and thallium atoms as far as lattice distortions induced by the substitution are neglected. By using values 4.3 eV and 6.1 eV for the ionization energies of potassium and thallium atoms respectively, the energy required for KCl:Tl is given as 5.8 eV. Though this does not include the energies of resonance and spin-pairing, it is comparable to the energies of the absorption bands of KCl:Tl.

Photoconductivity and Luminescence of the F and M Centers in Potassium Chloride

By Goro KUWABARA, Akira MISU, Toshimitsu WATANABE, and Yoshio NISHIYAMA

Department of Physics, Faculty of Science, University of Tokyo

(Received July 3, 1959)

The photoconductivity and luminescence of additively colored KCl crystals by excitation with light in the F band were measured at room temperature as a function of the M center concentration. With the growth of the M band, the photocurrent decreased, while the emission intensity increased. This result would suggest that for a crystal containing M centers the photoconductivity due to the F center and the luminescence due to the M center are the competing processes in the excited state of F centers.

§ 1. Introduction

The potassium chloride crystal containing only F centers luminesces by excitation with light in the F band at low temperatures below about −50°C[1,2]. The emission intensity, increasing rapidly with the decrease of temperature, attains a saturation value at about −180°C, and in some cases its quantum efficiency attains as high as 0.9.[3]

On the other hand, this crystal shows photoconductivity above −180°C by irradiation with the F light, and the photocurrent increases with the rise of temperature.[4] These two phenomena, i.e. the photoconductivity and luminescence of the F center are interpreted as the competing processes with each other in the excited state of the F center.

When a crystal contains only the F band, nearly all of the excited F centers are considered to be ionized at room temperature. This may be confirmed by the analysis of temperature dependence of luminescence and photoconductivity or by the quantum efficiency for the conversion of F to F'.[5]

However, if the M band is grown in a crystal by irradiating with the strong F light, the crystal becomes luminescent even at room temperature by excitation with the F light.

This luminescence, which has a peak at about 1.06 μ is partially polarized perpendicularly to the polarization of the exciting F light and is considered to be due to the M center. Its quantum efficiency, increasing with the increase of M center concentration, attains about 30 percent of the efficiency of the F emission observed at low temperatures for the same crystal containing only F centers.[2]

The mechanism, by which the energy absorbed by the F center is emitted as the luminescence of the M center has not been fully understood as yet. For this problem it may be useful to investigate the relation between the luminescence and photoconductivity.

When the M band is grown in the crystal, it is expected that the ionization probability of an excited F center decreases at room temperature, because the considerable amount of the absorbed energy by the F center is reemitted as the luminescence as described above.

Therefore, the photocurrent which here means the product of quantum efficiency η and Scubweg w for unit electric field strength, should also decrease.

However, contrary to this expectation, Barth[6] has recently reported that the photocurrent induced by the F light at room temperature is entirely independent of the amount of M centers. In his paper no comment has been given on the luminescence. But if his crystal containing M centers was also luminescent at room temperature by excitation with light in the F band, his result might be explained as follows. At least at room temperature the absorbed energy by the F center is transfered to the M center *via* conduction electrons, or with the growth of the M band the Schubweg increases so that the photocurrent remains constant. If the former is the case, the polarization of the M luminescence is unlikely to occur.

In order to clarify this point, we measured simultaneously the photocurrent and emission intensity at room temperature by the excitation with the F light as a function of M center concentration.

§2. Experimental Procedures

The experimental arrangement is shown in Fig. 1.

A capacitor was charged with the photocurrent due to electrons released by a flash of light (duration is −0.02 sec) and its potential rise was determined by a D.C. amplifier with an electrometer tube. The minimum detectable charge was ca. 2×10^{-14} coul.

In order to avoid the current flowing over the surface of a crystal, the so-called blocking electrode arrangement was adopted, i. e. a specimen was mounted between two Nesa electrodes so that it did not touch the electrodes. To minimize the effect of space charge, the amount of illuminating light was reduced as far as possible and further, between successive measurements the applied voltage was reduced to zero and the crystal was irradiated with light until the photocurrent in the reverse direction, which flows by the space charge potential, entirely disappeared. With these precautions, the results were fairly reproducible, and the photocurrent was quite linear both to the number of the absorbed quanta and the applied voltage.

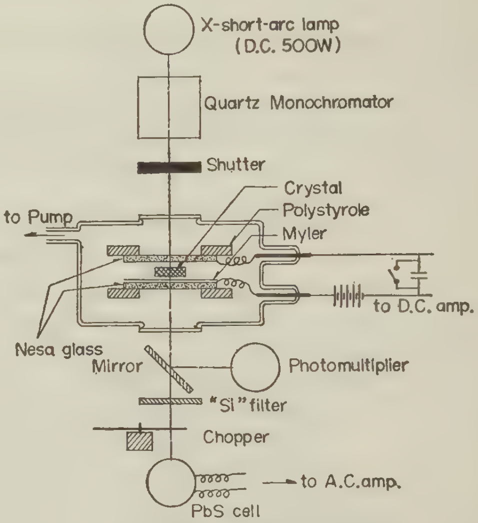

Fig. 1. Experimental arrangement

For the irradiation, the light from Xenon arc lamp passed through a quartz double monochromator was used, and the luminescence passed through an infrared transmitting filter (a slice of a Si crystal) was measured with a PbS cell. In the case of photoconductivity measurement, the slit width of the monochromator was 6 mμ in wave length.

The potassium chloride crystal was additively colored and quenched in liquid air to remove the bands other than the F. In order to create photoelectrons as uniformly as possible throughout a crystal, the initial number of the F center was controlled to be of the order of 3×10^{-16} cm^{-3}, and the thickness of specimens was about 1 mm.

§3. Results and Discussions

An example of absorption and spectral photoconductivity curves for the same crystal with and without the M band were shown in Fig. 2 (a) and (b).

From these curves, it may be safe to conclude that the photoelectrons measured in our experiment were liberated from F or M centers.

In this case the ratio of the photoconductivity (ηw) due to M centers to that due to F centers was calculated as 1/13. This value scattered considerably from specimens to specimens, but the mean value was 1/10. This result agrees with that obtained by Barth. The Schubweg w may be the same for electrons from F and M centers in the same crystal, so this value can be taken as the ratio of quantum efficiencies at room temperature.

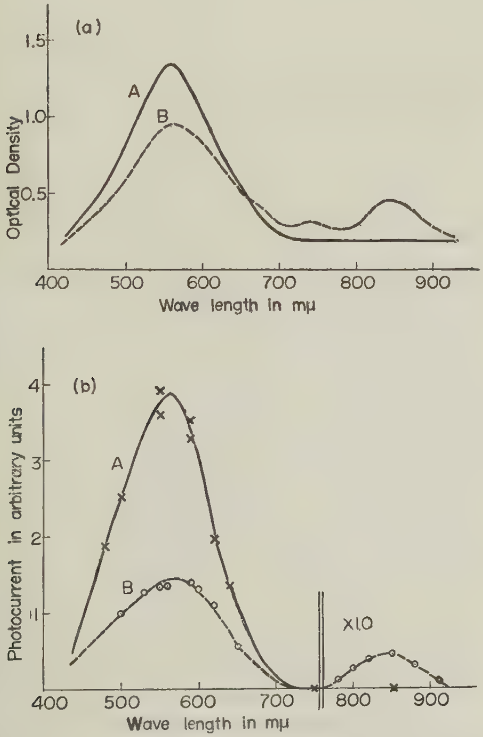

Fig. 2. Absorptions (a) and spectral resposes of photoconductivity (b) for an additively colored KCl crystal

In Fig. 3, the photoconductivity and emission intensity at room temperature for light in the F band were plotted against the M center concentration. This shows that when the M band grows up the photoconductivity due to F centers decreases to 1/3～1/5 of that for the same crystal containing only F centers.

Of course, we cannot solely ascribe the decrease of photoconductivity to the decrease of quantum efficiency η, because the possibility of variation of Schubweg w is not excluded. However, our result clearly contradicts with that obtained by Barth and is in conformity with the fact that a part of the absorbed energy in F centers is emitted as luminescence due to M centers.

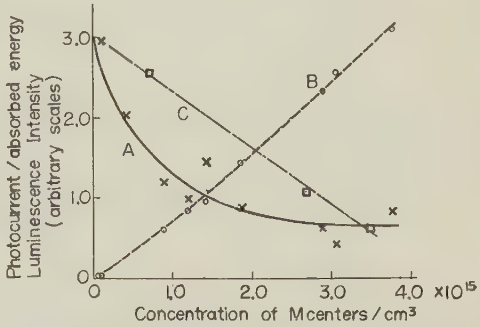

Fig. 3. Photocurrent (A) and luminescence intensity (B) at room temperature for light in the F band *vs* concentration of M centers. (C) is the intensity of luminescence due to the F center at low temperature.

The decrease of the photoconductivity seemed to be more rapid than the increase of the luminescence, which varied almost linearly with the concentration of M centers. This might be due to the decrease of Schubweg.

As to the mechanism of the luminescence of M centers, two explanations have been proposed, i.e. overlapping of the second M band with the F band, or transfer of energy from F to M centers by some interactions between them.

In order to get a clue for this problem, the efficiency of the F emission at low temperatures (−170°) was measured for one crystal and was shown in Fig. 3. It decreased with the growth of the M band, even though we take into account the amount of the F light absorbed in the second M band hidden under the F. This preliminary experiment might support the latter explanation, because according to the former the efficiency of the F emission is expected to be constant irrespectively of the presence of M centers. In this case, however, because of the low thermal ionization probability of excited M centers, the contribution of these centers to the photoconductivity by the F light may be negligible.

Multiplet Structure and Hyperfine Structure of the Spectrum of Mercury

By Kiyoshi MURAKAWA

Aeronautical Research Institute, University of Tokyo, Komaba-machi, Meguro-ku, Tokyo

(Received July 11, 1959)

Analysis of the spectrum of Hg I resulted in locating the level $5d^9 6s^2 6p$ $^1F_3$ in the range 4392—4139 cm^{-1} measured from the ionization limit or 79792—80045 cm^{-1} measured from the normal state. The compositions of some levels of the configurations $5d^9 6s^2 6p$ and $5d^{10} 6s 6p$ were calculated.

The hfs of some lines of the mercury spectrum was measured, using enriched isotope as well as natural mercury. The quadrupole moment of Hg^{201} that was deduced from the hfs of $5d^9 6s^2 6p$ $^1D_2$ is 0.43 barn (1 barn$=10^{-24}$ cm^2), the shielding correction being neglected. If the correction is introduced, this becomes somewhat smaller, but is still in reasonable agreement with the value 0.4_2 barn that was published previously by the author. The agreement seems to indicate that the wave functions for the configuration $5d^9 6s^2 6p$ given in the present work are accurate enough for calculating the quadrupole moment. It is concluded that $Q(\mathrm{Hg}^{201})=0.4_2$ barn, the shielding correction being included.

I. Multiplet Structure of the Spectrum of Hg I.

§ 1. Configuration $5d^9 6s^2 6p$

In the year 1935 the author[1)] published a list of the wave-lengths of the spectrum of Hg I in the red and infra-red region (this work will be referred to as MS 1), and found the level $5d^9 6s^2 6p$ $^1D_2=5507.4$ cm^{-1} (measured from the ionization limit of Hg I). In the second paper[2)] (to be referred to as MS 2) further study of the spectrum of Hg I was made, and the level $5d^9 6s^2 6p$ $^3F_4=7238.5$ was found. In the third paper[3)] (to be referred to as MS 3) the level $5d^9 6s^2 6p$ $^3D_3=11064.9$ was found. The level $5d^9 6s^2 6p$ $^1F_3$ was very difficult to detect and the supposition was made that this level would lie near the ionization limit [$^1F_3 \sim 0$(?)]. It is to be noted that the above mentioned symbols for the levels of Hg I are only conventional ones and have no definite physical meaning. From the point of view of their Stark-effect investigations, Ishida and Hiyama[4)] discussed the levels found in MS1 and MS2 and came to the conclusion that their findings are in agreement with the existence of the above-mentioned levels. The paper MS3 was overlooked by Ishida and Hiyama, and concerning the level $5d^9 6s^2 6p$ $^3D_3$ no paper other than MS3 was published until recently Lichten[5)] found that this level is metastable.

The purpose of the present chapter is to discuss about the level $5d^9 6s^2 6p$ $^1F_3$ whose

Table I. Term-values and effective quantum numbers

m	$^1F_3$	6942.6	4438.8	3077.6	2258.8	1728.8	1363.7	1103.7	910.7	765.4
	n^*	3.9757	4.9721	5.9713	6.9702	7.9674	8.971	9.971	10.977	11.974
m $^3F_3-$ m $^1F_3$		2.1	0.3	1.9	1.0	0.1	0.6	0.3	1.5	0.7

position has still remained in doubt.

In order to discuss the perturbation in $6smf$ $^3F_3$ and $^1F_3$, the term values and the effective quantum numbers are given in Table I. They were taken, without any change, from MS3, but this time the difference of m^2F_3 and m^1F_3 is also given. As was mentioned in MS3, no perturbation can be noticed (within the limit of experimental error) near the end of the series. The irregularities in $m^3F_3-m^1F_3$ for $m\geqq 9$ that are noticed in Table I lie outside the limit of experimental error and have no physical meaning. On the other hand irregularities in $m^3F_3-m^1F_3$ for $m=6$ and 7 are undoubtedly meaningful. We may assume that the level d^9s^2p $^1F_3$ lies near and somewhat higher than $6f^1F_3$. This assumption is also in agreement with the solution of the energy matrix for $J=3$ of the configuration $5d^96s^26p$. The combination $6d^1D_2-d^9s^2p$ $^1F_3$ can be expected to appear in the wave-length region somewhat shorter than λ11885. A search was made for unclassified lines in this region on the plates which were the basis of MS2, but they were too weak to be measured. The wave-lengths of the lines in question were therefore taken from articles of other authors,[6,7] and are listed in Table II. At present it is impossible to decide which of them really corresponds to $6d^1D_2-d^9s^2p$ $^1F_3$, so that we have to be satisfied with the rather vague answer that the level d^9s^2p $^1F_3$ lies between 4392 and 4139 cm^{-1} measured from the ionization limit of Hg I, that is, between 79792 and 80045 cm^{-1} measured from the normal state of Hg I.

§ 2. Wave Function of $5d^96s^26p$ and $5d^{10}6s6p$

In the section §6 we shall be interested in calculating the quadrupole moment (Q) of Hg^{201}. For that purpose we need the compositions of the wave functions of the levels belonging to the configurations $5d^96s^26p$ and $5d^{10}6s6p$. In Hg I these two configurations overlap and must not be considered separately. The energy matrix published by Hume and Crawford[8] in the analysis of Pb III will be adopted in the present work. The same notations as theirs will be used here, except that we write ζ instead of their a.

The levels of the configuration $5d^96s^26p$ (Hg I) can be assumed to be of jj-coupling in a rough approximation. All the levels of this configuration converging to $d^9s^2{}^2D_{5/2}$ (Hg II) have been detected, but very few converging to d^9s^2 $^2D_{3/2}$ (Hg II) are known at present.[9] It is therefore impossible to get accurate parameter values, but we shall see in §6 that in spite of this difficulty wave functions accurate enough for calculating the value of Q can be obtained.

Fitting the observed levels to the energy matrix, the value of $\zeta(6p)$ was found to be 4300 for the configuration $6s6p$, and 3700 for the configuration $5d^96s^26p$. $F_2=550$ and $\zeta(5d)=6000$ were found for the latter.

Apparently we have

$$^3F_4'(d^9p)=K_1\ {}^3F_4(d^9p)+K_2\ {}^3F_4(sf)\ ,$$

$$K_1=0.979_3,\ K_2=-0.202_1,\ C=215.6\ ,$$

in which $^3F_4'(d^9p)$ means the wave function of the level which we designate as $d^9s^2p^3F_4$

for brevity.

The wave function of the levels with $J=3$ can then be calculated. For example, we get

$$ {}^3D_3'(d^9p)=K_1\,{}^3D_3(d^9p)+K_2\,{}^3F_3(d^9p)+ K_3{}^1F_3(d^9p)+K_4\,{}^3F_3(sf)+K_5\,{}^1F_3(sf)\ , $$

$$ K_1=0.325_1,\ K_2=0.732_9,\ K_3=-0.595_5,\ K_4=-0.038_4,\ K_5=0.031_2. \qquad (1) $$

From this we calculate $g_J({}^3D_3')$ to be 1.08_0. This is to be compared with the value $g_J({}^3D_3')=1.0871\pm0.0005$ observed by Lichten and McDermott.[10] The agreement can be considered good.

The level $d^9p\ {}^1D_2$ is perturbed somewhat by $d^{10}s\ mp{}^3P_2$ (see MS1), but if we neglect the perturbation, we get the wave function

$$ {}^1D_2'(d^9p)=K_1{}^3P_2(d^9p)+K_2\,{}^3D_2(d^9p)+K_3\,{}^1D_2(d^9p) +K_4\,{}^3F_2(d^9p)\ , $$

$$ K_1=0.435_8,\ K_2=-0.509_3,\ K_3=0.619_1,\ K_4=-0.333_7. \qquad (2) $$

Table III. g-factors of $6s6p$ levels of Hg I

Level	g (calculated)	g (observed)	reference
${}^3P_2$	1.500	1.5016 ± 0.0004	10
${}^3P_1$	1.476	1.479	13
${}^1P_1$	1.012	1.019	13

The wave functions for the levels of $6s6p$ were the most difficult to calculate, owing to the presence of the perturbation. In determining the composition, the g-values published by Nagaoka and Mishima[11] and Green and Loring[12] were also used. [The g-values (see Table III) are listed in the review article by Moore[13]]. The value of $g({}^3P_2)$ was most accurately measured by Lichten and McDermott.[10]

In the author's previous calculation for the interaction constant B for ${}^3P$, Langer's formula for the series-perturbation was used. In the mean time this method has turned out to give a value of B that is not accurate enough for our purpose, so extrapolation from Pb III and Tl II has been used. We get in this way $B=2500$. Then the wave function for $sp{}^3P_2$ is given by

$$ P_2'(sp)=K_1{}^3P_2(sp)+K_2{}^3P_2(d^9p)\ , \qquad K_1=0.996,\quad K_2=-0.088. \qquad (3) $$

From the observed value of $g({}^3P_2)$ we see that neither ${}^3D_2(d^9p)$ nor ${}^3F_2(d^9p)$ is appreciably mixed with ${}^3P_2(sp)$, so this was considered in constructing (3).

In determining the composition of ${}^3P_1'(sp)$, the uncertainty regarding the value of B is partly eliminated by taking the observed value[13] of $g({}^3P_1)$ into consideration. In this way we get

$$ {}^3P_1'(sp)=K_1\,{}^3P_1(sp)+K_2\,{}^1P_1(sp)+K_3\,{}^3P_1(d^9p) +K_4\,{}^1P_1(d^9p)+K_5\,{}^3D_1(d^9p)\ , $$

$$ K_1=0.906_8,\ K_2=-0.307_2,\ K_3=0.264_0,\ K_4=0.116_9,\ K_5\approx0. \qquad (4) $$

The composition of ${}^1P_1(sp)$ published previously was

$$ {}^1P_1(6s6p)=K_1\,{}^3P_1(6s6p)+K_2\,{}^1P_1(6s6p) +K_3\,{}^1P_1(6s7p)+K_4\,{}^1P_1(d^9p), $$

$$ K_1=-0.158,\ K_2=0.883,\ K_3=0.286,\ K_4=0.336. \qquad (5) $$

It is somewhat unsatisfactory that the coefficient of ${}^3P_1(d^9p)$ vanishes, and this would probably explain why the calculated g is slightly smaller than the observed g, even if allowance is made for the electrodynamic correction.

It is to be remarked that all the wave functions that are given here neglect the mixing of $5s5d^{10}6s^26p$, and therefore they predict values of magnetic hyperfine structure splittings with rather unsatisfactory accuracy, so they can be used only for calculating Q.

II. Hyperfine Structure of the Spectrum of Mercury.

§ 3. Experimental Arrangement

In a previous paper by Suwa and the author[14] (to be referred to as HF1) the regularity in the hyperfine structure (hfs) of the spectra of Hg I and Hg II was studied. In a later year the author had the chance of utilizing an enriched isotope "196" (see Table IV), which was suited for studying the components due to the isotopes 204 as well as 196. The result of the measurement of the

Table IV. Isotopic constitution (%) of the samples of mercury

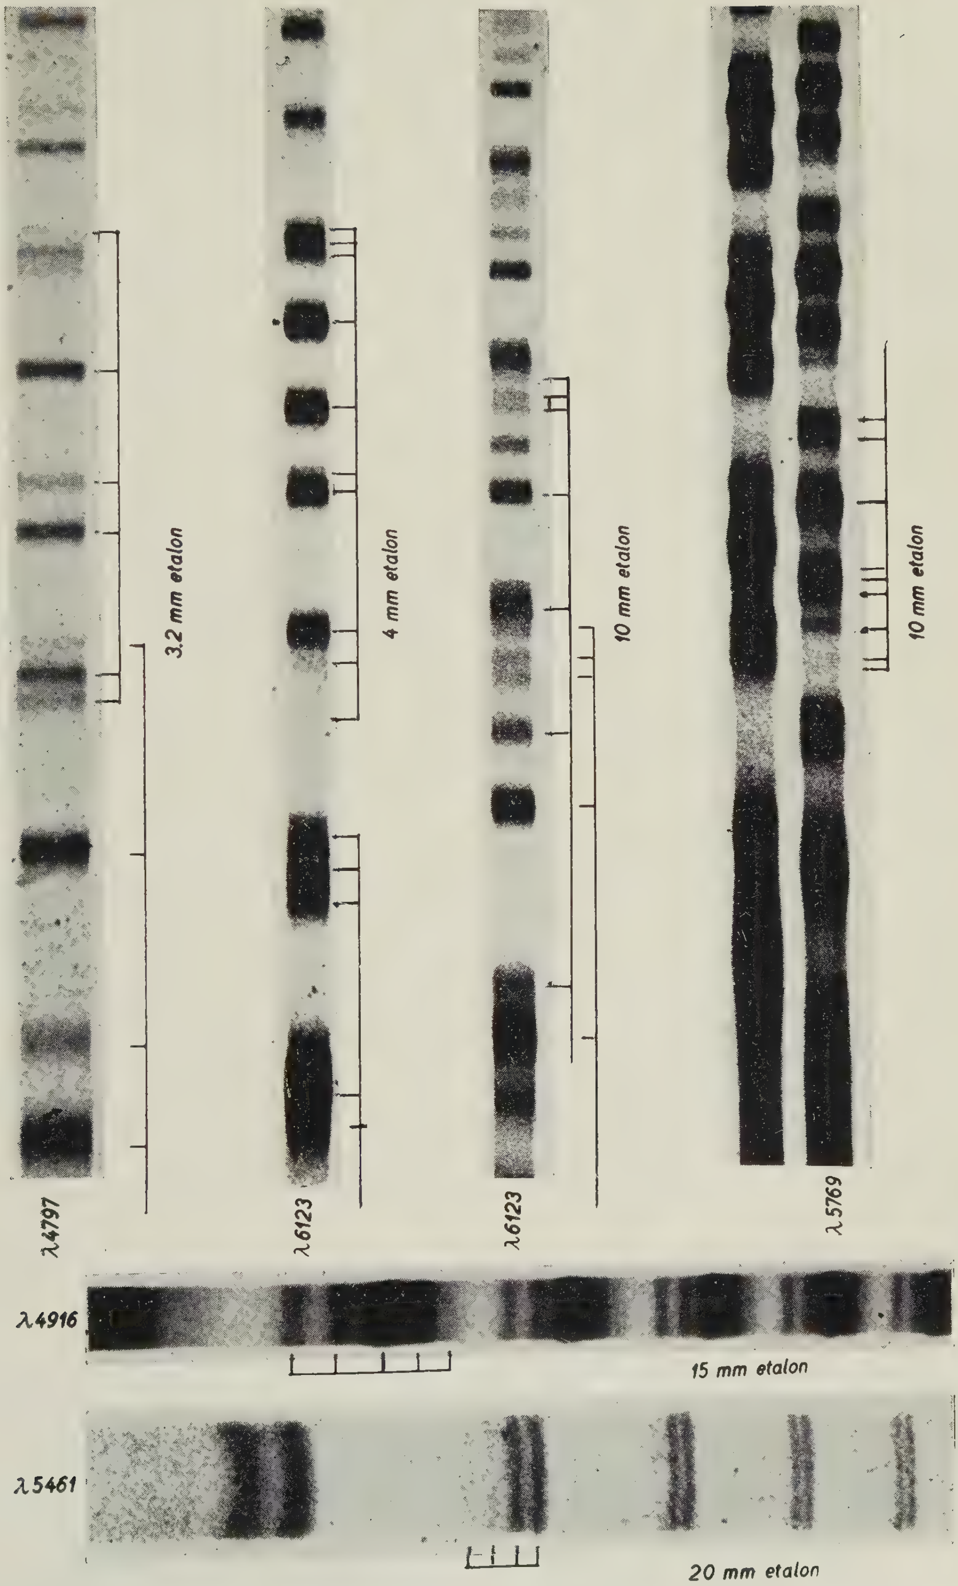

Fig. 1. Enlargement of interference patterns in the spectrum of mercury. The picture of λ5461 in this figure was taken using the enriched isotope 196. The others were taken using natural mercury.

hfs of Hg II λ6150, Hg I λ5461 and λ6123 and Hg III λ4797 was published[15] (this paper will be referred to as HF2). It was found that the hfs of Hg III λ4797 is especially suited for studying the isotope shift, although this line could not be excited by the discharge using the enriched isotope. Taking the configuration mixing into account, the value of $Q(\mathrm{Hg}^{201})$ was calculated to be 0.45 ± 0.04 barn ($1\ \mathrm{barn} = 10^{-24}\ \mathrm{cm}^2$)[16] (this paper will be referred to as HF3). In a subsequent paper[17] (to be referred to as HF4) the shielding correction was treated somewhat more rigorously, and $Q(\mathrm{Hg}^{201}) = 0.4_2 \pm 0.04$ barn was deduced.

The object of the present paper is to describe in somewhat more detail the results which were obtained by improving the light source since the publication of HF1.

In the experimental investigations that were performed in Tokyo, natural mercury only was used. A liquid air cooled hollow cathode discharge tube was used for exciting the lines of Hg I, and a high frequency electrodeless discharge tube similar to that of Lacroute[18] was employed for exciting the lines of Hg III, Hg II and also Hg I λ6123. In order to resolve the hfs, a (silvered or multi-layer dielectric coated) Fabry-Pérot etalon was employed, but in some cases a Lummer plate had to be crossed in order to avoid overlapping of orders.

In the investigations that were performed in Wisconsin, enriched isotope "196" as well as natural mercury were used, a liquid air cooled discharge tube having an iron hollow cathode being employed. The discharge current was extremely small, so only lines due to Hg I and the line Hg II λ6150 could be excited.

Interference patterns of some lines of mercury are reproduced in Fig. 1.

§ 4. Hyperfine Structure of Hg III λ4797.

The interpretation of the hfs of Hg III λ4797 was given by Mrozowski[19] and the classification was given by Foster.[20] Foster[21] also measured the hfs of this line, but the resolution attained by him was not so satisfactory.

The complete resolution was achieved and published in HF2, and the hfs together with the ratio of the distances of the neighboring isotopes is given in Fig. 2; see also Fig. 1. The respective components due to 199 and 201 do not split practically, so the measured positions of 199 and 201 represent their centers of gravity respectively. Since the isotope shift in λ4797 is large, the ratio given in Fig. 2 might be regarded as the most accurate one available since the publication of HF2. Blaise, Chabbal and Jacquinot[22] deduced the ratio from the hfs of Hg I λ15295 ($7s\,{}^3S_1 - d^9s^2p\,{}^3P_2$). In this line the distance 200—202 is given as $0.1431\ \mathrm{cm}^{-1}$, which is to be compared with the corresponding distance $0.6043\ \mathrm{cm}^{-1}$ of λ4797 given in Fig. 2.

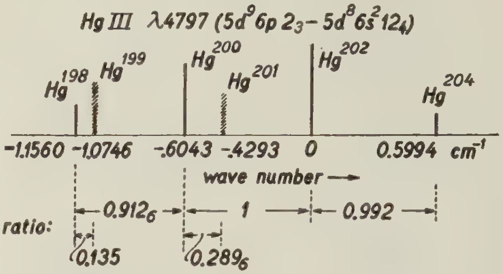

Fig. 2. Hfs of Hg III λ4797. The accuracy of measurement is $\pm 0.0012\ \mathrm{cm}^{-1}$.

§ 5. Hyperfine Structure of Hg I.

In the previous work HF1, the splitting of $6p\,{}^1P_1$ of Hg^{199} deduced from the hfs of different lines was somewhat inconsistent; and the splitting $0{,}175\ \mathrm{cm}^{-1}$ was tentatively adopted, the final decision pending on future detailed study. In the mean time the inconsistency was found to be due to the shift of some hfs components of Hg^{199}, the amount of shift depending on the strength of the discharge current and the construction of the hollow cathode. The discharge current was therefore made as small as possible, and it was found that the above-mentioned splitting is $-0.179_9\mathrm{cm}^{-1}$ (see HF3).

The distance $F = 1/2 - 3/2$ (Hg^{201}) was measured in two lines and the result is

λ5769 ($6^1P_1 - 6^3D_2$), $a-b$ (Fig. 3, HF1): $0.042_6\mathrm{cm}^{-1}$

λ5790 ($6^1P_1 - 6^1D_2$), $g-h$ (Fig. 2, HF1): 0.043_0

mean: $0.042_8\mathrm{cm}^{-1}$.

These values allow us to interpret the hfs of λ4916 accurately; see Fig. 3. The calculated position is in parentheses. The centers of gravity of 199- and 201-components were at first calculated. Then the positions of the even isotopes were calculated, using the ratio given in Fig. 2. The isotope shift predicted in this way is in reasonable agreement with the observation made by McClung and Holmes.[23]

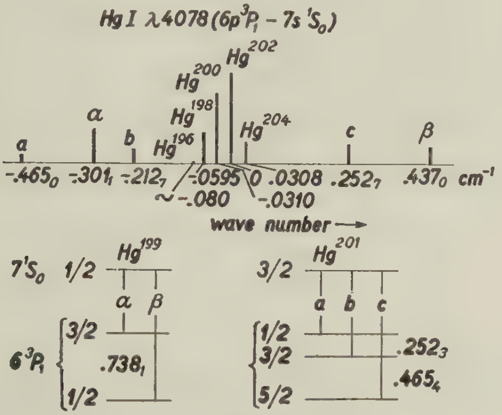

Fig. 3. Hfs of Hg I λ4916.

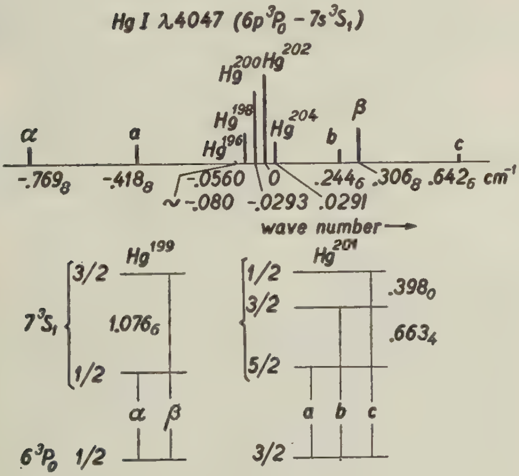

Fig. 4. Hfs of Hg I λ4047.

The hfs of λ4047 ($6p\ ^3P_0-7s^3S_1$) was studied with the utmost care. It was found that the shift (accompanied by intensity modification) of the hfs components caused by an inadequate discharge condition was most conspicuous for Hg^{199} ($I=1/2$), but not negligible for Hg^{201} ($I=3/2$). Within the limit of experimental error no shift of the same cause was detected for the components arising from the even isotopes. The hfs measured in the present work is shown schematically in Fig. 4. It is almost identical with the result given in HF1, but the present one is slightly more accurate, and also indicates the position of Hg^{196}, although this could not be measured so accurately.

The hfs of λ4078 ($6p\ ^3P_1-7s^1S_0$) is shown in Fig. 5. The hfs splittings of the odd isotopes for the lower level $6p\ ^3P_1$ can be deduced as shown in the figure; within the limit of experimental error, they are in agreement with those published by Blaise and Chantrel[24] and by Sagalyn, Melissinos and Bitter.[25]

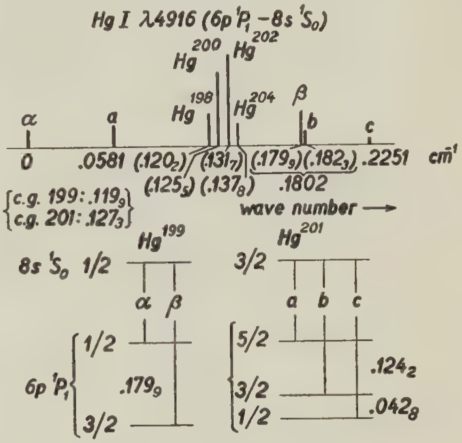

Fig. 5. Hfs of Hg I λ4078.

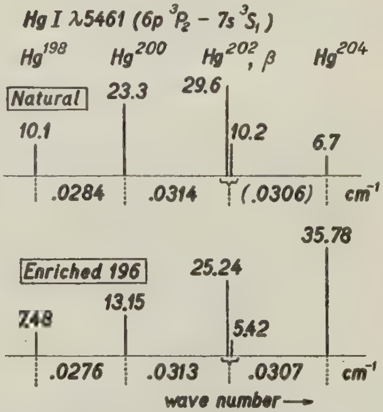

Fig. 6. Result of measurement of the central components of λ5461.

The determination of the hfs of λ5461 ($6p\ ^3P_2-7s^3S_1$) was very time-consuming. The main difficulty arises from the fact that the Hg^{202}-line has superposed on it a partial component of Hg^{199} that is called β in Fig. 6. Not only the intensity but also the position of β is changed by the discharge condition. In order to eliminate this uncertainty a very weak excitation just sufficient to start the discharge was employed. The abstract of the final solution was published in HF2. The position of β was predicted by measuring the hfs splitting of 199 in the line $\lambda 3654$ ($6\,^3P_2-6^3D_2$) accurately. It was found that β should be $0.001_1\ \text{cm}^{-1}$ distant from 202 on the violet side. This finding makes it possible to determine the position of 202 accurately. The result of measurement of the positions of the even isotope components is shown schematically in Fig. 6.

The hfs of 6^3P_2 of the odd isotopes has been measured very accurately (with a magnetic resonance method) by Lichten and his coworkers.[26] Assuming that the velocity of light is

$$c=(2.997923\pm 0.000008)\times 10^{10}\ \text{cm/sec},$$

their findings can be summarized as

$$\Delta\nu\ (\text{Hg}^{199},\ ^3P_2,\ F=5/2-F=3/2)$$
$$=22666.559\pm 0.005\ \text{Mc.}$$
$$=0.7560755\ \text{cm}^{-1},$$
$$\Delta\nu\ (\text{Hg}^{201},\ ^3P_2,\ F=7/2-F=5/2)$$
$$=11382.629\pm 0.001\ \text{Mc.}$$
$$=0.3796839\ \text{cm}^{-1},$$
$$\Delta\nu\ (\text{Hg}^{201},\ ^3P_2,\ F=5/2-F=3/2)$$
$$=8629.522\pm 0.001\ \text{Mc.}$$
$$=0.2878501\ \text{cm}^{-1},$$
$$\Delta\nu\ (\text{Hg}^{201},\ ^3P_2,\ F=3/2-F=1/2)$$
$$=5377.492\pm 0.002\ \text{Mc.}$$
$$=0.1793740\ \text{cm}^{-1}.$$

These values combined with the hfs of $\lambda 4047$ make it possible to calculate the positions of the hfs components of the odd isotopes in $\lambda 5461$. This is presented in Fig. 7 in which only the even isotopes and the components α, g, f, h and γ were measured. Other components were calculated. In Fig. 7 the hfs splittings of the lower level are given only four decimal places, (although the original data given by Lichten et al have far larger accuracy), because the accuracy attained by the technique of present day spectroscopy rarely surpasses this.

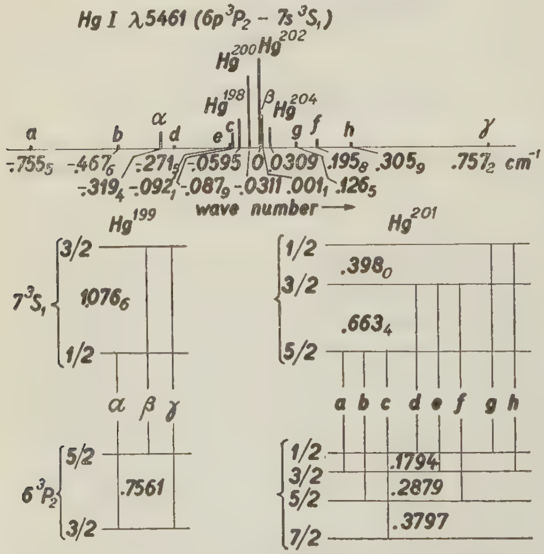

Fig. 7. Hfs of Hg I $\lambda 5461$ constructed.

Finally the hfs of $\lambda 6123$ is shown in Fig. 8, which is, it is hoped, superior to Fig. 6 of HF1. This was achieved by use of high-frequency electrodeless discharge through mercury vapor of very low pressure, the increased intensity and the narrow line breadth being favorable for hfs work. The 198-component has superposed on it a partial component of 201, if the resolution is not high enough. It was therefore decided to employ a 20 mm etalon crossed by a Lummer plate, but this naturally reduced the intensity very much. With this arrangement only the components 198, 200, 202 and β could be photographed. The distance 198–200 is now 0.1941 instead of $0.1886\ \text{cm}^{-1}$ published in HF2.

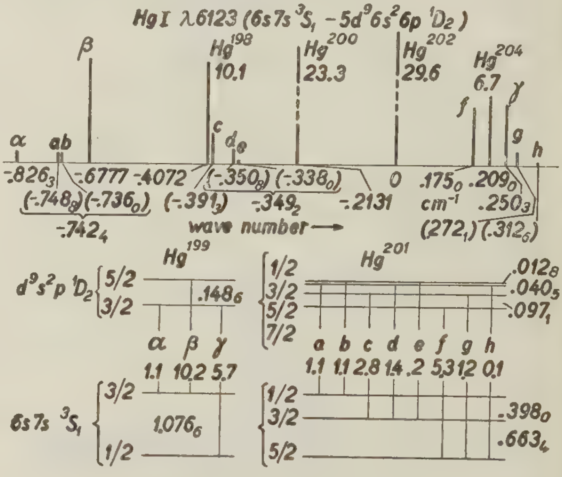

Fig. 8. Hfs of Hg $\lambda 6123$.

The ratio of isotopic shifts of the spectrum of mercury calculated by use of data given in the present work is listed in Table V, in which the results of other authors[27, 38] are quoted for comparison.* The ratio can be considered to be constant for every line observed.

---

* The positions of the odd isotopes in Hg III $\lambda 4797$ published by the author in HF2 seems to have been overlooked by Blaise.[28]

§ 6. Quadrupole Moment of Hg^{201}

The quadrupole coupling constant $B(Hg^{201})$ of each of the levels 6^3P_2, 6^3P_1, 6^1P_1 and $d^9s^2p\ {}^1D_2$ is given in Table VI. The constant B given in this table is defined by the formula of Casimir:[29]

$$\nu=\nu_0+\frac{A}{2}K+B\left[\frac{\frac{3}{8}K(K+1)-\frac{1}{2}I(I+1)J(J+1)}{I(2I-1)J(2J-1)}\right],$$

$$K=F(F+1)-I(I+1)-J(J+1).$$

The quadrupole coupling constant which is convenient for treating experimental data and was used by the author in previous publications will be denoted by B' in the present paper. Since B' is given by

$$\nu=W_0+\frac{A}{2}K+B'\,K(K+1)\ ,$$

we have the relation

$$B=B'\,\frac{8}{3}\,I(2I-1)\,J(2J-1)\,.$$

Use of B instead of B' has the merit that it does not include I and J explicitly.

The quadrupole moment is given by

$$Q=-\frac{B\ 0.7455}{\sum\frac{\zeta<3\cos^2\theta-1>_{Av}}{Z^*H(1+\varDelta)}}\ , \qquad (6)$$

in which B is measured in units of $10^{-3}cm^{-1}$, and Q in units of barn $(=10^{-24}cm^2)$. $\sum$ means that the expression should be summed with respect to $p, d, f, \cdots$ electrons. H is the relativity correction,[29] and $\varDelta$ is the shielding correction (radial plus angular corrections) introduced by Sternheimer.[30] Sternheimer's $1/(1-R)$ is our $1+\varDelta$. Z^* is the effective charge (in the case of Hg I $Z^*(6p)=80-5=75$, $Z^*(5d)=80-20=60$). We shall put $\omega=3\cos^2\theta-1$ for brevity. The relativity correction factors for $<r^{-3}>$ in the case of Hg I are $R'=1.29$, $S=1.56$, $R_2'=1.065$, $R_2''=1.228$, $S_2=1.065$.

The data published by Lichten et al[26] indicate that Hg^{201} may have a magnetic octupole moment, but since at present it is not possible to calculate accurately the hfs perturbation of 6^1P_1, 6^3P_1 and 6^3P_0 on 6^3P_2, no attempt was made to calculate the octupole coupling constant C from their data.

The method of calculation of Q from 6^3P_2 was published in HF2. Using the new wave function (3), we get $Q'=0.46$ barn, where Q' means that the shielding correction is neglected. This value is equal to the one given in HF2.

For the level ${}^3P_1$, we have the formulas:
For sp configuration

$$({}^3P_1|\omega/r^3|{}^3P_1)=\frac{1}{15}(-R'+4S)<r_p{}^{-3}>,$$

$$({}^1P_1|\omega/r^3|{}^1P_1)=-\frac{2}{15}(R'+2S)<r_p{}^{-3}>, \qquad (7)$$

$$({}^3P_1|\omega/r^3|{}^1P_1)=\frac{\sqrt{2}}{15}(R'-S)<r_p{}^{-3}>.$$

For pd configuration (for the configuration d^9p we need only reverse the sign for the d-part)

$$({}^3P_1|\omega/r^3|{}^3P_1) = \frac{1}{250}(-12R_2'+13R_2''+24S_2)<r_d^{-3}> + \frac{1}{150}(11R'-8S)<r_p^{-3}>\ ,$$

$$({}^1P_1|\omega/r^3|{}^1P_1) = -\frac{1}{125}(12R_2'+7R_2''+6S_2)<r_d^{-3}> - \frac{1}{75}(R'+2S)<r_p^{-3}>\ , \tag{8}$$

$$({}^3P_1|\omega/r^3|{}^1P_1) = \frac{3\sqrt{2}}{250}4R_2'-R_2''-(3S_2)<r_d^{-3}> + \frac{\sqrt{2}}{30}(R'-S)<r_p^{-3}>\ .$$

Putting values of R', S, R_2', R_2'', S_2 and ζ_p and ζ_d in the formulas (7), (8) and (4), and then together with the value of $B({}^3P_1)$ in (6), we get $Q'=0.46$ barn which agrees completely with Q' obtained from 6^3P_2.

Blaise and Chantrel[24] and Sagalyn et al[25] deduced from 6^3P_1 a value of Q' higher than 0.5. But this value seems to be inaccurate, owing to the use of inadequate wave function.

The value of Q' obtained from $6p\,{}^1P_1$ was published in HF2, and is listed in Table VI.

In order to treat $d^9s^2p\ {}^1D_2$, we need the following formulas for the configuration pd:

$$({}^3P_2|\omega/r^3|{}^3P_2) = \frac{1}{125}(-36R_2'-R_2''+12S_2)<r_d^{-3}> + \frac{1}{25}(3R'-4S)<r_p^{-3}>\ ,$$

$$({}^3D_2|\omega/r^3|{}^3D_2) = -\frac{1}{525}(92R_2'+7R_2''-24S_2)<r_d^{-3}> + \frac{1}{45}(R'+8S)<r_p^{-3}>\ ,$$

$$({}^1D_2|\omega/r^3|{}^1D_2) = -\frac{2}{175}(12R_2'+7R_2''+6S_2)<r_d^{-3}> + \frac{2}{15}(R'+2S)<r_p^{-3}>\ ,$$

$$({}^3F_2|\omega/r^3|{}^3F_2) = -\frac{16}{18375}(23R_2'+343R_2''+84S_2)<r_d^{-3}> - \frac{4}{525}(7R'+29S)<r_p^{-3}>\ ,$$

$$({}^3P_2|\omega/r^3|{}^3D_2) = -\frac{1}{175\sqrt{15}}(108R_2'-7R_2''+74S_2)<r_d^{-3}> - \frac{1}{5\sqrt{15}}(R'+2S)<r_p^{-3}>\ , \tag{9}$$

$$({}^3P_2|\omega/r^3|{}^3F_2) = -\frac{4}{875\sqrt{21}}(36R_2'-49R_2''+38S_2)<r_d^{-3}> - \frac{4}{25\sqrt{21}}(R'+2S)<r_p^{-3}>\ ,$$

$$({}^3D_2|\omega/r^3|{}^3F_2) = -\frac{4}{525\sqrt{35}}(44R_2'+49R_2''+57S_2)<r_d^{-3}> + \frac{4}{45\sqrt{35}}(R'+17S)<r_p^{-3}>\ ,$$

$$({}^3P_2|\omega/r^3|{}^1D_2) = -\frac{2}{175\sqrt{10}}(12R_2'+7R_2''-19S_2)<r_d^{-3}> - \frac{2}{5\sqrt{10}}(R'-S)<r_p^{-3}>\ ,$$

$$({}^3D_2|\omega/r^3|{}^1D_2) = \frac{2}{25\sqrt{6}}(-4R_2'+R_2''+3S_2)<r_d^{-3}> + \frac{2}{15\sqrt{6}}(R'-S)<r_p^{-3}>\ ,$$

$$({}^3F_2|\omega/r^3|{}^1D_2) = -\frac{8}{175\sqrt{210}}(16R_2'-49R_2''+33S_2)<r_d^{-3}> + \frac{8}{15\sqrt{210}}(R'-S)<r_p^{-3}>\ .$$

By use of the formulas (2), (9), (6) combined with the constant B (Table VI), we get $Q'=0.43$ barn.

The shielding correction factor Δ is not known accurately in the case of Hg I. But for $6s6p$ of heavy elements it is most likely (HF4) that $\Delta=-0.1$. If this is assumed, we get $Q(\mathrm{Hg}^{201})=0.4_2$ barn from the levels ${}^3P_2$ and ${}^3P_1$.

Concerning the configuration d^9s^2p, the value of Δ is unknown. Δ_p would be probably -0.1, and Δ_d would be negative. If this is assumed, we get a value of Q somewhat smaller than 0.43 barn. In view of the above-mentioned uncertainty, the agreement with 0.4_2 barn may be considered to be not poor. We may assume therefore that the wave function for $d^9s^2p\ {}^1D_2$ given by (2) is essentially adequate for calculating Q.

As a summary we may conclude that

$$Q(\mathrm{Hg}^{201})=0.4_2 \text{ barn.}$$

This is in agreement with the result of

Pound and Wertheim[32] who obtained $Q(\mathrm{Hg}^{201}) = 0.46\ (+0.28,\ -0.11)$ barn.

The kindness of Dr. Lichten in showing me the results of his experiments prior to publication is greatly appreciated.

Infrared Absorption of α-$Ag_2Te_xS_{1-x}$

By Shin-ya MIYATANI
Department of Physics, Faculty of Science, Niigata University

(Received August 31, 1959)

The α–β transition temperature of $Ag_2Te_xS_{1-x}$ i.e. the mixture of Ag_2Te and Ag_2S which is prepared by melting $(Ag_2Te)_x$ and $(Ag_2S)_{1-x}$ sealed in a fused silica tube, is lowered by mixing so that it is below room temperature for the mixing ratio x between 0.2 and 0.8. Since the ionic conductivity due to mobile Ag ions is large in the α phase (e.g. 0.16 $\Omega^{-1}cm^{-1}$ at 15°C for $x=0.7$)[1], Ag ions and the same number of electrons can be easily supplied to or removed from the specimen of such a mixing ratio at room temperature by sending a proper current accross the galvanic cell Ag|AgI+5%AgCl| specimen|Pt, which has the e.m.f. E related to the reduced Fermi energy η as given by $\eta=\eta_s-eE/kT$ where η_s is η in Ag-saturated state[1]. Further this mixture is so soft that it can be easily rolled or pressed to thin foil (up to several microns) thin enough to get large interference effect at the transmission of infrared ray. From the distance of interference fringes[2] in the transmission curve recorded against wave number $1/\lambda$, we obtain the value of the refractive index n and accordingly the reflectivity as 4.0 and (3/5)[2], respectively, (the extinction coefficient $\ll n$) and then we obtain the value of the absorption coefficient α. Thus the curves of α vs $1/\lambda$ are obtainable for various electrical conductivities σ_e or Fermi energies of one specimen, keeping it on the specimen-holder of spectrograph (Hilger's double beam). Fig. 1 shows an example of such measurements for $x=0.7$ where (a) shows σ_e vs eE/kT or η and (b) α vs $1/\lambda$ corresponding to (a), where the value of η_s is estimated by comparing the σ_e vs eE/kT plots with theoretical curve $F_{1/2}$ (Fermi function of order 1/2) vs η, assuming the relaxation time τ is energy-independent. (a) shows also $R\sigma_e$ (mobility), making use of which we obtain m_e (effective mass of electron)$=0.08\,m$ and $\tau=6.6\times10^{-14}$ sec.

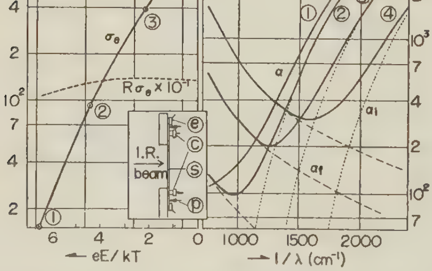

Fig. 1. (a) $\sigma_e(\Omega^{-1}cm^{-1})$ and $R\sigma_e(cm^2s^{-1}v^{-1})\times10^{-1}$ vs eE/kT or η for $x=0.7$ at 20°C, where R is Hall coefficient. (b) α (cm^{-1}) vs $1/\lambda$ or $h\nu/kT$ at 20°C. The broken line is α_f extrapolated under the assumption of α_f proportional to λ^2 and the dotted line is $\alpha-\alpha_f$ that is α_i. The arrangement of the specimen (s), Ag|AgI+5% AgCl (c), probe for measuring σ_e (p), and Pt electrode (e) is also shown schematically. This result is confirmed by changing the thickness of specimen as 9.2, 17, 26, and 40 μ.

The absorption is now, as seen in Fig. 1 (b), attributed to two effects; the free electron absorption α_f dominant in the small $1/\lambda$ region and the intrinsic absorption $\alpha_i=\alpha-\alpha_f$ dominant in the large $1/\lambda$ region. As for the former, Drude-Zener's formula[2,3] holds well, yielding the value of τ as 5.4×10^{-14} sec (compare with 6.6×10^{-14} sec). As for the latter, the change of α_i due to the degeneracy is to be given by Eq. (5.4) in the reference (2). Plotting $\log(\alpha_{i0}(\nu)/\alpha_i(\nu)-1)$ against η, taking $h\nu/kT$ as parameter, we see that this equation is in fact valid, where α_{i0} is defined as α_i in non-degenerate state and so taken as equal to α_i for the curve No. 1. We obtain thus $m_h/(m_e+m_h)=0.6$ and $E_G/kT=6.4$ (E_G is the energy gap.). Next, α_{i0}, that is, α_i for the curve No. 1 seems to be accounted for by the plane wave approximation, i.e. Eq. (2.15) in the reference (2), yielding the values of $m_em_h/(m_e+m_h)$ and E_G/kT as $0.44m$ and 6.4 respectively. Similar absorption curves are also obtained for other mixing ratios, showing the increase of E_G with decreasing x.

Finally, the electrical properties of this system (e.g. the relation between E and the concentration of excess Ag, the η-dependence of $R\sigma_e$ and Nernst coefficient etc.) indicate that the simplifying assumptions such as the standard form of conduction band and the energy-independence of τ are not exactly valid, necessitating the reinvestigation of the absorption curve, which is left to the future.

The Aging of Permeability in Manganese-Zinc Ferrite

By Syôhei MIYAHARA and Tokio YAMADAYA
Department of Physics, Hokkaido University.

(Received August 27, 1959)

Though the presence of continued decrease of the effective permeability after sintering has been well known in Mn–Zn ferrites, its origin has not yet been made clear. As Mn–Zn ferrite is not stable in air at lower temperatures, it is made usually by rapid cooling, therefore it is to be expected that in Mn–Zn ferrite certain irreversible changes such as oxidation, precipitation, etc, might progress further at room temperature. On the other hand, it is also possible that it is due to disaccomodation, since there are some evidences for the presence of disaccomodation in some ferrites[1-4].

In order to make clear whether the decrease of permeability after sintering arises from irreversible structural change or from disaccomodation, we performed the following experiment.

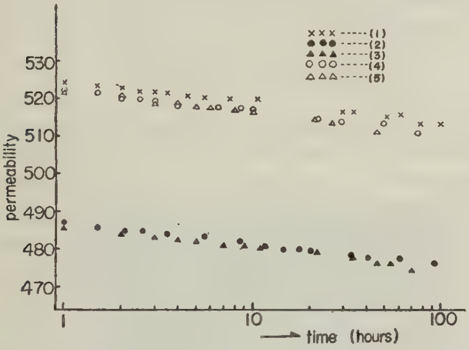

Fig. 1. Changes of Permeability with time at room temperature after sintering. All measurements in this figure were made for the same specimen.

(1) Permeability changes after sintering without any disturbance.

(2) Permeability changes after A. C. demagnetization following the measurements (1).

(3) Permeability changes after A. C. demagnetization following the measurements (2).

(4) Permeability changes after thermal demagnetization following the measurements (3).

(5) Permeability changes after thermal demagnetization following the measurements (4).

Ring specimens were made by the usual ceramic techniques from $MnCo_3$, ZnO and Fe_2O_3.

The final sintering was made in Air at 1300°C and cooled rapidly. Nominal composition of the pecimens was $(Mn_{0.5}\ Zn_{0.5})\ O\cdot Fe_2O_3$.

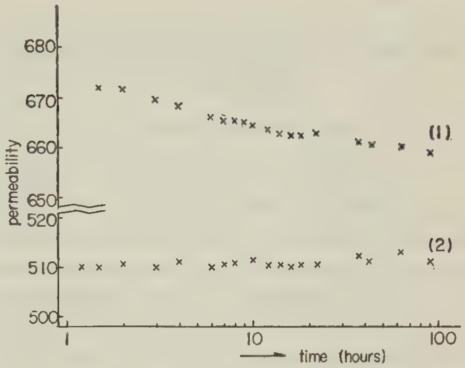

Fig. 2. Comparison of the permeability changes of two equal specimens number different measuring conditions.

(1) Permeability changes after sintering.

(2) Permeability changes after sintering. In this case A. C. demagnetization is applied in every measurement at one minute before the measuement.

All measurements were carried out by using an A. C. Bridge at 1 kc/sec with measuring field of less than one millioersted. Demagnetization was done either by A.C field of 50 c/sec with maximum field of about 10 oersteds, or by heating up the specimen to 100°C and cooling slowly. Results are shwn in Fig. 1 and Fig. 2.

From Fig. 1, it can be concluded that the time decrease of permeability after sintering is reproduced again by applying a thermal demagnetization to the same specimen.

It is also shown in Fig. 1 that the curves after thermal demagnetization are very similar to those after A. C. demagnetization. The continued decrease of permeability after sintering is not found if we demagnetize the specimen at every measurement as shown in Fig. 2.

From these results we may conclude that the decrease of permeability after sintering (the so called natural aging) does not arise from irreversible structural change, but from disaccomodation.

Diffusion of Nickel in Single Crystals of Copper

By Akira Ikushima

Department of Physics, University of Tokyo

(Received September 19, 1959)

In order to investigate the behaviour of iron-group transition elements as an impurity in noble metals, several experiments of tracer diffusion have been performed[1-4]. In this note, the diffusion data of nickel in single crystals of 99.99% pure copper is reported.

As the experimental techniques used in this work were nearly the same as the one described in detail in Mackliet's paper[1], the details will not be mentioned here.

The penetration plots are shown in Fig. 1, and the diffusion coefficients calculated from these plots are given in Table I.

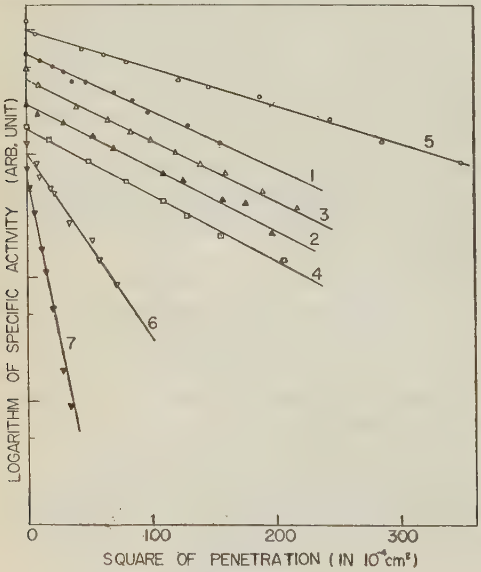

Fig. 1. Penetration plots.

Table I. Diffusion of Ni^{63} in Copper

No.	Temperature (°C)	Diffusion Time (sec.)	Diffusion Coefficient. (cm²/sec.)
1	1061	1.19×10^{4}	2.00×10^{-9}
2	1031	1.83×10^{4}	1.17×10^{-9}
3	973	6.67×10^{4}	4.04×10^{-10}
4	906	1.78×10^{5}	1.15×10^{-10}
5	852	1.02×10^{6}	3.47×10^{-11}
6	758	2.17×10^{6}	3.36×10^{-12}
7	695	4.01×10^{6}	5.45×10^{-13}

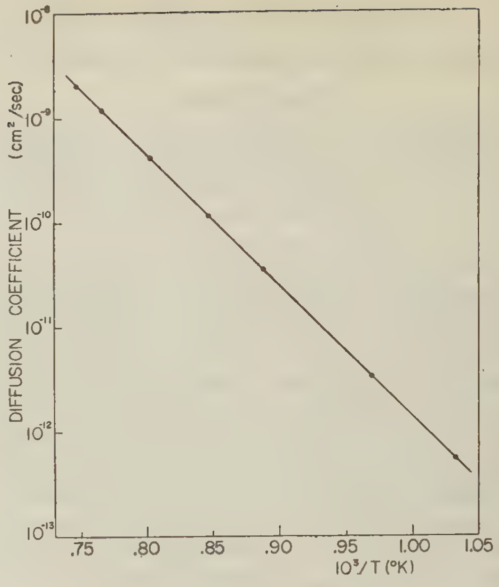

Fig. 2. Plot of $\log D$ *vs* $1/T$.

The plot of the diffusion coefficients *vs* temperature is shown in Fig. 2. Under the assumption that the diffusion coefficient can be described by $D=D_0\exp(-Q/RT)$, these data are fitted to the formula by the least square calculation with

$$\log_{10}D_0=0.58\pm0.02$$

$$(\text{i.e. } D_0=3.8\pm0.2\,\text{cm}^2/\text{sec.})\ ,$$

$$Q=56.8\pm0.1\,\text{kcal/mole}\ .$$

D_0 and Q of the present results are in good agreement with the earlier data reported by Mackliet[1]. If Lazrrus' formura of Q[5] with the screened coulomb potential around the impurity atom calculated by Alfred an March[6] is used, the present result of Q indicates that the excess valence of the nickel atom as an impurity in copper is about minus one with respect to copper. This suggests that the electronic structure of the nickel atom in this case would be $(3d)^{10}(4s)^0$. This is also consistent with other data.[7-9]

The author wishes to thank Professor Y. Tomono for help and advice during the course of the study.

This work is partly supported by the Scientific Expenditure from the Ministry of Education.

Microwave Investigation of Plasma in Shock Tube*

By Mikio TAKEYAMA, Shiro Hamamura
and Toshiatsu ODA

*Department of Physics, Faculty of Science,
Hiroshima University, Hiroshima*

(Received September 9, 1959)

A microwave investigation was carried out on the plasma produced in shock tube as shown in Fig. 1. The shock tube used consisted of an X band microwave rectangular guide section whose one end was connected with one of the side arms of a magic Tee. The higher pressure chamber of the shock tube, 60 cm in length, was filled with hydrogen gas of about 8 atm. and the lower, 100 cm long, with argon gas of 10 mmHg. The diaphragm used in the tube was of cellophane 0.04 mm thick.

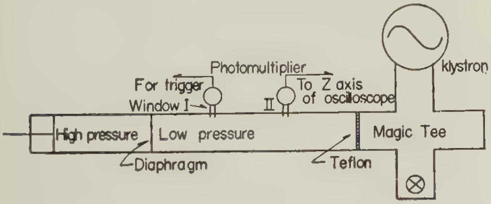

Fig. 1. Schematics of shock microwave tube.

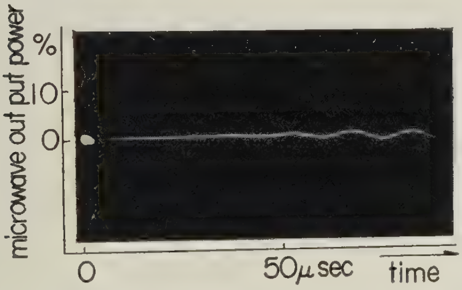

Fig. 2. Oscilloscope trace of microwave signal reflected from shock wave of low temperature.

When the electron density of the plasma produced is relatively small, the microwave reflection due to the complex dielectric constant of the plasma is slight, but when the density is so large that the plasma frequency exceeds the microwave frequency and the plasma works as a metal disk, the microwave is almost totally reflected, provided that the width of plasma is comparable with the guide wave length of the microwave.

In the present experiment, the magic Tee was initially balanced. Since the microwave exists as standing wave in the shock tube, it is reflected every time shock front travels one half wave length. The frequency of the reflected microwave signal can be a measure of the shock velocity. The photomultiplier tubes I and II are set at the window on one side of the tube. The tube I is used for triggering an ocilloscope and the tube II to provide a marker for the optical measurement of the shock velocity. The gain of the D. C. amplifier of the oscilloscope was adjusted to be so low as to be insensible to the dielectric reflection and the shock sonic noises by hydrogen gas.

The experimental results obtained by the microwave of wave length 3.4 cm are shown in Fig. 2 and Fig. 3. The zero point on the time axis in Fig. 2 indicates the time when the shock front passes at the window I. As is seen in this figure, the intensity of the reflection gradually increases with time. It shows a gradual increase of the ionization of argon gas behind the shock front, and the shock wave velocity (1.7 mm/μ sec.) derived from the frequency of the reflected signal agreed with the value by optical measurement (1.8 mm/μ sec.).

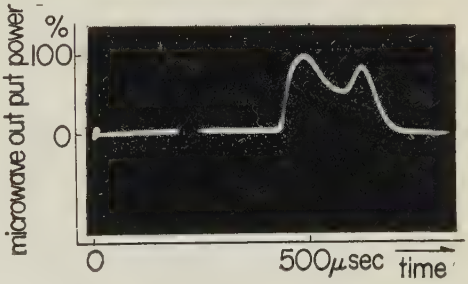

Fig. 3. Typical oscilloscope trace of microwave signal totally reflected from hot plasma.

It has been confirmed from the position of marker in Fig. 3 that the total reflection of the microwave begins with the shock front reaching the end of the tube. It seems to be plausible that the plasma frequency is lower than the microwave frequency before the shock front reaches the end of the tube, while the former becomes higher than the latter after the shock front is reflected from the end, since the temperature of the reflected shock wave is expected to be more than twice as high as that of the incident one, from the theoretical consideration,[1,2] and the electron density in the reflected plasma to be higher than that in the incident one. The duration of the total reflection of microwave was about 200 μ sec.

The two peaks appearing in the photograph of of Fig. 3, which were reproducible in every observation, have not yet been analysed in detail, but it seem that this phenomenon is caused by the interaction between the reflected shock front and the contact discontinuity.

Etch-Figure in CdS Single Crystals

By Makoto KIKUCHI and Sigeru IIZIMA
Electrotechnical Laboratory, Tokyo, Japan

(Received September 16, 1959)

Recently, several works have been reported on the growth of large solid single crystals of CdS[1]. We have succeeded in making large CdS single crystals by Reynolds-Czyzak method[2]. Powder of luminescent grade cadmium sulphide was sealed in vacuum in fused quartz ampoule, which was then heated at 1225°C for 100 hrs.

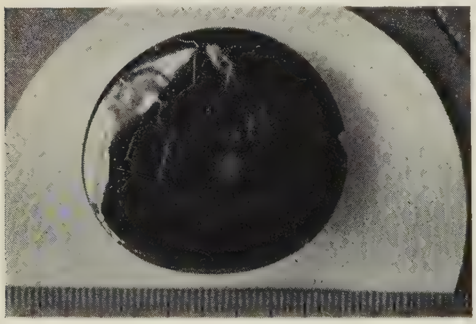

Fig. 1. Single crystals of cadmium sulphide. (Scale; 1 mm per division.)

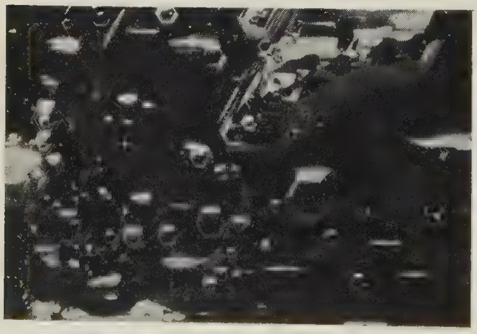

Fig. 2. Photomicrograph of etched surface of (1000).

As is shown in the photograph of Fig. 1, the disk obtained by this method consists of large single crytals bounded by grain boundaries. Some of these cystals have direction of growth parallel to the *c* axis. This has been confirmed by etching the crystals in conc. HCl. Photomicrograph of the etched surface of (1000) plane which contacted with the wall of the ampoule is shown in Fig. 2.

It has been found out that the method oridinarily used for determining the crystal orientation of germanium single crystals etched with superoxol etchant[3] was quite useful also for CdS crystals when the surfaces were subjected to proper etching. The light-figure pattern of the surface etched with conc. HCl is illustrated in Fig. 3. As is shown, sixfold symmetry is clearly revealed.

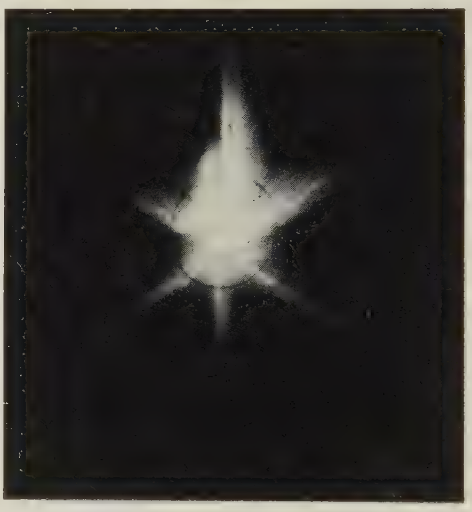

Fig. 3. Light-figure pattern of etched (1000) surface.

The experimental details of growing flaky, prismatic, or solid CdS crystals by controlling temperature, firing time, volume of CdS powder etc. will be presented in the near future with their electrical and optical properties.

Note on the Effect of Oxygen Molecules Contained in Solid Hydrogen on the Rate of Ortho-para Conversion

By Kazuko Motizuki and Takeo Nagamiya
Department of Physics, Osaka University

(Received August 17, 1959)

A few years ago we made a theoretical study of the ortho-para conversion in solid H_2 and solid D_2 and the results were published in J. Phys. Soc. Japan **11** (1956) 93, **11** (1956) 654 and **12** (1957) 163 (quoted as I, II and III).

In these papers the effect of oxygen molecules dissolved in solid hydrogen was closely examined, beside the natural convesion process due to the interaction between hydrogen molecules. The oxygen molecule in its ground state has a spin of magnitude one and the corresponding magnetic moment has two Bohr magnetons. Therefore, due to the dipole-dipole interaction between the oxygen molecule and the nuclear spin moments of the ortho-H_2 molecules or the para-D_2 molecules, the ortho or para molecules convert into para or ortho molecules, respectively. In our previous papers, we assumed that the direction of the oxygen spin does not change during the ortho-para conversion process. However, it is also possible that the spin of the oxygen molecule can change its direction, since the anisotropy energy for this spin is expected to be much smaller than the rotational level difference between ortho and para states.

The interaction Hamiltonian between the oxygen molecule and the ortho hydrogen molecule is the same as H_{rs} of Eq. (2.6) of I, i.e., the interaction between the proton spin moments of one hydrogen molecule and the magnetic moment due to rotation of the other hydrogen molecule, except that the rotational magnetic moment of the oxygen molecule. Thus, taking the change of spin direction of the oxygen molecule into account, the transition probability in the case of H_2 can be calculated by Eq. (B. 6) of I, W_i (2) being given by Eq. (B. 11), provided that the common factor $\mu_p{}^4[4+(\mu_R/\mu_p)^2]$ of the coefficients C_i is now replaced by $\mu_p{}^2\mu_{0_2}^2$. The term 4 in the square blaket of the former has come from the proton-proton dipolar interaction. Similar replacement has be done in the case of D_2 (Eq. (3.3) of III). Furthermore, the nomalization factor $9\times 9=81$ of Eq. (A. 5) of I and Eq. (3.4) of III is to be replaced by $9\times 3=27$.

Therefore the conversion rate obtained previously should be modified as follows. The constant of the rate of conversion for H_2 and that for D_2 at a distance R from the oxygen molecule become

$$k_{oxy}(H_2)=644\times(R_0/R)^{12} \text{ per hour}$$

$$k_{oxy}(D_2)=68.6\times(R_0/R)^{12} \text{ per hour}$$

respectively, insteated of Eq. (4.2) of I and Eq. (4.2) of III (the previous numerical factors were 250 and 35.9, respectively). Therefore we find now that the distance, at which the conversion rate due to an oxygen molecule and the conversion rate due to the mutual interaction of hydrogen molecules become equal to each other, is $R=2.95R_0$ and $3.74R_0$,

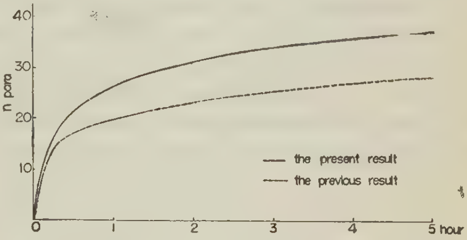

Fig. 1. Number of para-molecules produced around an oxygen molecule as a function of time, for 75% initial ortho-concentration.

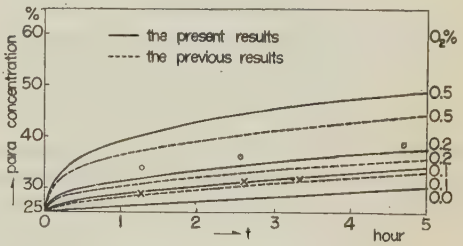

Fig. 2. Increase of the average concentration of para-molecules as a function of time for various values of the molar oxygen concentration and 75% initial ortho-concentration. ⊙ and × represent experimental values obtained at Tōhoku University.

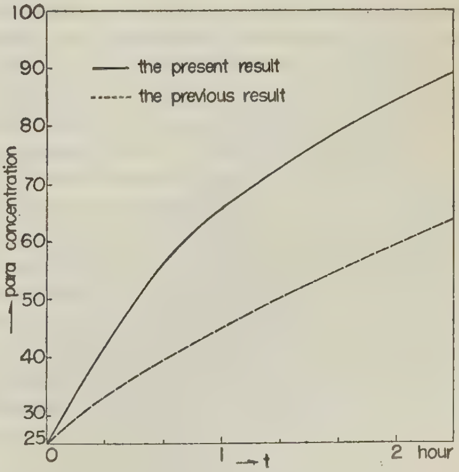

Fig. 3. The average concentration of para-molecules in normal hydrogen as a function of time for a molar oxygen concentration of $\alpha=0.01\%$.

respectively (instead of the previous vulues $2.70R_0$ and $3.54R_0$). In paper I, we have calculated the number of para-H_2 molecules produced around an oxygen molecule and the increase in average concentration of the para-H_2 molecules as function of time (Fig. 1 and Fig. 2 of I) for the case where there is no self-diffusion. In paper II, we have given the increase in para concentration for the case where there is a rapid self-diffusion (Fig. 1). These results have to be modified as in Figs. 1, 2 and 3 of this paper. We give the results only for the case of 75% ortho-hydrogen.

The writers are indebted to Professor K. Husimi for calling our attention to the possibility of the directional change of the oxygen spin moment.

Localized Electron Model and Thermoelectric Power

By Mikio TSUJI

General Education Department, Kyusyu University, Otsubo-machi, Fukuoka

(Received August 20, 1959)

From his analysis of the results of the measurements of the electrical conductivities and the thermoelectric powers of α–Fe_2O_3 and NiO, Morin[1] has derived a conclusion that the mobilities of the carriers of the crystals have a strong temperature dependency which should be described in terms of activation energies for the transport of the carriers. A mechanism of the jumping of the carriers between adjacent ions with an activation energies has been presented by Yamashita and Kurosawa[2] based on a model of localized electron which is tightly bound to an ionic lattice. Now, Morin has analysed his data by using a formula of the thermoelectric power of usual semiconductor theory neglecting the terms due to the kinetic energy of carriers. In the present note, we shall derive a formula of the thermoelectric power of a crystal in which carriers are tightly bound to ions and the jumping of a carrier from an ion to another need an activation energy, and show that Morin's analysis is not satisfactorily consistent. For simplicity, we use the terms 'electron' and 'hole'. For example, in α–Fe_2O_3, 'electron' means Fe^{2+} ion and 'hole' means Fe^{4+} ion. If there are an electric field E_x and a temperature gradient $\partial T/\partial x$ along x-axis in crystal, the current densities due to the electrons j_e and hole, j_h are given by

$$\left.\begin{aligned} j_e&=-eD_e\left(-\frac{\partial n_e}{\partial x}-\frac{en_e}{kT}E_x-\frac{Q_e{}^*n_e}{kT^2}\frac{\partial T}{\partial x}\right),\\ j_h&=eD_h\left(-\frac{\partial n_h}{\partial x}+\frac{en_h}{kT}E_x-\frac{Q_h{}^*n_h}{kT^2}\frac{\partial T}{\partial x}\right),\end{aligned}\right\}\qquad(1)$$

respectively, where D_e and D_h are the diffusion coefficients of the electrons and holes, and n_e and n_h are the carrier densities. $Q_e{}^*$ and $Q_h{}^*$ are given by

$$Q_e{}^*=-k\frac{d\ln W_e}{d(1/T)},\qquad Q_h{}^*=-k\frac{d\ln W_h}{d(1/T)},\qquad(2)$$

where W_e and W_h are the probabilities of the jamping of an electron and a hole from an ion site to adjacent one per unit time and, if we put the lattice constant as a, there are following relations,

$$D_e=a^2W_e,\qquad D_h=a^2W_h\qquad(3)$$

If we neglect a possible temperature dependences of $Q_e{}^*$ and $Q_h{}^*$, we have

$$\left.\begin{aligned} W_e&=\text{const}\times\exp(-Q_e{}^*/kT),\\ W_h&=\text{const}\times\exp(-Q_h{}^*/kT).\end{aligned}\right\}\qquad(4)$$

The carrier densities are given by the Boltzmann distribution,

$$\left.\begin{aligned} n_e&=N\exp\{-(E_1-\zeta)/kT\},\\ n_h&=N\exp\{-(\zeta-E_2)/kT\},\end{aligned}\right\}\qquad(5)$$

where E_1 is the energy of Fe^{2+} ion, E_2 the energy of Fe^{3+} ion, and ζ the chemical potential. Putting (5) into (1), and using the condition $j_e+j_h=0$, we obtain the absolute thermoelectric power S as follows,

$$S=\frac{1}{eT}\frac{\sigma_h(Q_h{}^*+\zeta-E_2)-\sigma_e(Q_e{}^*+E-\zeta)}{\sigma_e+\sigma_h},\qquad(6)$$

where σ_e σ_h are given by

$$\left.\begin{aligned} \sigma_e&=e^2D_en_e/kT=e\mu_en_e,\\ \sigma_h&=e^2D_hn_h/kT=e\mu_hn_h,\end{aligned}\right\}\qquad(7)$$

μ_e and μ_h being the mobilities. The total conductivity is

$$\sigma=\sigma_e+\sigma_h.\qquad(8)$$

Using (3), (4) and (7), we have

$$\frac{\sigma_e}{\sigma_h}=\frac{\mu_e{}^0}{\mu_h{}^0}\exp\left\{\frac{(Q_h{}^*+\zeta-E_2)-(Q_e{}^*+E_1-\zeta)}{kT}\right\},\qquad(9)$$

where $\mu_e{}^0$ and $\mu_h{}^0$ are temperature-independent factors of the mobilities. Comparing our formulas (6) and (9) with Morin's formulas, we see that Morin's $\zeta-E_2$ and $E_1-\zeta$ should be replaced by $\zeta-E_2+Q_h{}^*$ and $E_1-\zeta+Q_e{}^*$ respectively. Thus the values of n_e, n_h, μ_e and μ_h computed by Morin are, in actuality, $n_e\exp(-Q^*/kT)$, $n_h\exp(-Q_h{}^*/kT)$, $\mu_e\exp(Q_e{}^*/kT)=\mu_e{}^0/T$ and $\mu_h\exp(Q_h{}^*/kT)=\mu_h{}^0/T$ respectively. Therefore the 'mobilities' computed by Morin should not have strong temperature dependency of activation energy type. Thus, if our model is accepted, the analysis of Morin may become to be unsatisfactory.

Effect of Re-crystallization on the Temperature Dependence of Photocurrent of Silver Chloride Crystals

By Noriaki ITOH
Department of Electrical Engineering, College of Engineering, Osaka University
and Tokuo SUITA
Department of Nuclear Engineering, College of Engineering, Osaka University

(Received September 4, 1959)

As previously reported, the photocurrent-temperature curve of silver chloride crystals has a sharp maximum at about −80°C[1]. It was also shown that this abrupt change of photocurrent was due to the change of life time of electrons and at the maximum point the life time was estimated to be 5×10^{-6} sec by calculating the Schubweg of electrons from voltage-photocurrent curve. In the decreasing part of photocurrent with increasing temperature, the logarithm of the photocurrent was found to be a linear function of the reciprocal of temperature in Kelvin, and the extrapolation of the curve showed that the life time at room temperature was lower than 10^{-8} sec.

It was also reported by F. C. Brown[2], by J. W. Mitchell[3], by P. Süptitz[4] and by R. S. Van Heyningen and F. C. Brown[5], that the photocurrent of silver chloride crystals depended on the atmosphere in which the crystals were grown. They showed that the specimens made in vacuum or in nitrogen atmosphere has short life time ($< 10^{-8}$ sec) at room temperature, whereas the specimens made in air has longer life time (10^{-6} sec) at room temperature.

These results were unexpected for us, because the crystals used in our measurement were grown in air by the Kyropoulos method. The difference between the methods of crystal preparation of F. C. Brown and J. W. Mitchell and our methods was that we get specimens after recrystallizing raw precipitate of AgCl several times, although they get specimens through only one crystallization from well purified precipitate.

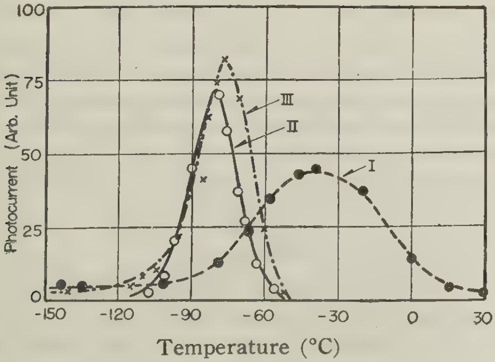

Fig. 1.

In order to clarify whether recrystallization in air shortened the life time of electrons in our specimens at room temperature, we measured the temperature dependence of photocurrent of specimen grown just from precipitate in air, spcimens recrystallized three times in air and also specimens grown in vacuum from precipitate. (Each specimens will be refered to as I, II, and III respectively.) The specimen III was grown by Kyropoulos method in a specially made vacuum cell of 10^{-3} mmHg, into which the cooling pipe was inserted through vacuum seal glass piston. The measuring apparatus was just the same as that reported previously[1].

The results are shown in Fig. 1. The typical peak of photocurrent which had been observed in recrystallized specimens disappeared in specimen I. It should be noted that in the specimen III grown in vacuum from precipitate, photocurrent has the same peak as in specimen II. The life time of specimen I at room temperature is shown to be larger than that of specimen II or III. Recrystallization in air may remove some impurities which make the life time at room temperature higher. The darkenability of specimens I, II and III were also measured and it was found that the specimen I has one third darkenability as the secimen II and III, which is consistent with Brown and Wainfan's results[6].

Qualitative spectrographic analysis of sample I and II was also tried in order to find the difference in impurity content. Some traces of Fe, Ca, Cu, Mg, Mn, Na and Si was detected and it was found that the line of Ca, Cr and Cu in sample II was clearly diminished.

Considering from the facts that the crystal made in vacuum seems to have the same metallic impurity and the effect of metallic impurity on photocurrent is quite different, (see the paper to be published), the disappearance of the peak of photocurrent temperature curve of sample It seems to be due to the effect of oxygen or moisture, which seems to be removed by recrystallization.

The facts that the photocurrent of specimen I do not decrease abruptly from the maximum as the temperature increases and its photographic sensitivity at room temperature is lower seems to be explained if we consider that the oxygen is attached to the sensitivity centers and make them inefficient as suggested by F. Seitz and F. C. Brown[7]. Further experiments on the effect of metallic impurities are now in progress.

We wish to thank to Dr. E. Mizuki and other staffs of Fuji Photofilm Company for supplying silver chloride raw materials and for their valuable discussions. We also thank to Mr. H. Kawaguchi

of Japan Atomic Energy Research Institute for the spectrographic analysis of silver chloride crystals.

Possible Evidence for the Light Induced Plasticity in Germanium

By Makoto Kikuchi
Electrotechnical Laboratory, Tokyo, Japan
and
Mitsuyoshi Saito
Institute of Science and Technology, Waseda University, Tokyo, Japan

(Received August 28, 1959)

It has been reported previously that the surface hardness of germanium illuminated with infrared or ultraviolet light, is much less than that in darkness[1]). Recently, it turned out that when a germanium specimen was bent and fractured under strong illumination, much higher densities of etch pits were revealed on the surface than on the surface of the specimens fractured in darkness[2]).

Here is reported an experimental result which seems to serve as an evidence for the light induced plasticity. Germanium rod specimens were cut from zone-levelled single crystals in the size of 3.2×1.8 ×20 mm. The resistivity of n-type sample ranged from 15 to 17 ohm-cm. The sample was arranged as shown in Fig. 1 and subjected to heavy wedge at the middle point. A razor blade was used as the wedge and the weight of roughly 2 kilogram was applied. An infrared drier lamp was used as the light source, since it had already been found that light of wevelength between 2.0 and 4.0 microns was responsible for the effect being observed.

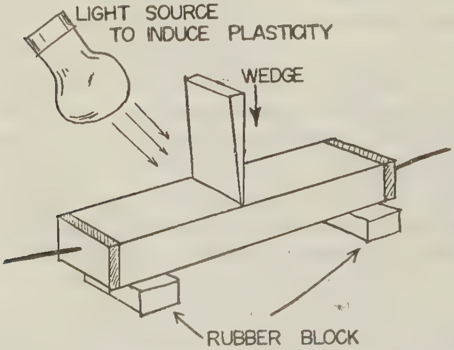

Fig. 1. The arrangement of the sample for room temperature bending under illumination.

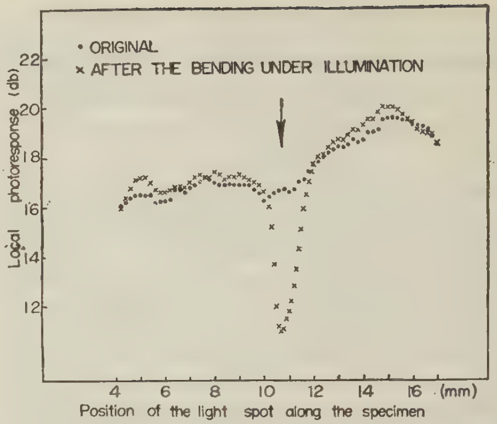

Fig. 2. Photoresponse observed by scanning a small light spot along on the rod specimen. The light is chopped at 225 cps.

The effect of bending under the illumination at room temperature was observed through the change of local photoresponse, snce it is the replica of the change of minority carrier lifetime. Typical result is shown in Fig. 2, where the distribution of photoresponse before and after 1.5 hours' bending are compared. As is shown, the photoresponse is remarkably reduced at the middle of the specimen, where the wedge was pressed.

The temperature rise of the sample caused by the illumination was prevented by applying alcohol on the specimen, so it could be estimated that the temperature did not exceed 90°C. Therefore, it may be concluded that the observed effect is not caused by the thermally induced plastic flow.

The local reduction of the photoresponse shown in Fig. 2 can be explained as the decrease of the hole lifetime caused by the locally produced dislocations and lattice irregularities. In fact, some change was caused by the above mentioned treatment in the surface recombination velocity, but this did not result in such characteristic valley in the curves shown in Fig. 2.

Detailed experimental procedures and results will be presented in the near future.

The Kinetics of Radical Reactions in γ-Irradiated Polyvinyl Chloride

By Kenzi HUKUDA, Jiro ISHII
and Zenêmon MIDUNO

Department of Physics, Faculty of Science, Kyusyu University, Hukuoka, Japan

(Received September 1, 1959)*

The rates of production and extinction of radicals in the γ-irradiated polyvinyl chloride have been investigated by means of the electron spin magnetic resonances at 3 cm wavelength. The pure powder of polyvinyl chloride without any plasticizer was pressed to the form of discs of 2–3 mm thickness and 11 mm diameter under the pressure of about 2000 kg/cm² and the temperature of about 120°C. These discs were irradiated with the medical γ-source of cobalt-60 and the dose rates were measured by the ferrous-ferric dosimetry. The samples were irradiated and preserved in glass tubes in which the atomospheric pressure was about 10^{-3}mmHg and placed in the air only during the ESR measurements. The two hyperfine lines ($m_I = \pm 1/2$) of divalent manganese diluted in MgO crystals served both as g-markers and as intensity standards of the electron spin resonances.

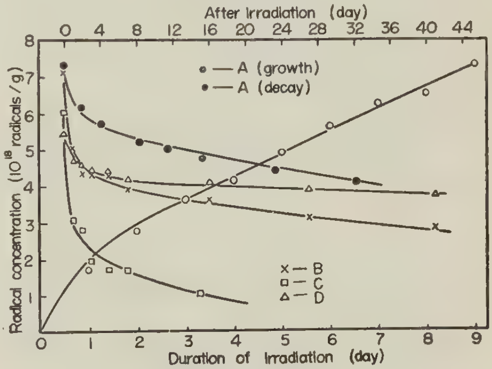

Fig. 1. Time dependences of radical concentrations during and after irradiations of γ-ray. The lines are drawn with the equations (1) and (2).

Table I.

Sample	λ_1 $\left(\frac{1}{\text{day}}\right)$	λ_2 $\left(\frac{\text{g}}{\text{radicals. day}}\right)$	v_{10} $\left(\frac{\text{radicals}}{\text{g}}\right)$	v_{20} $\left(\frac{\text{radicals}}{\text{g}}\right)$
A	0.010	0.62×10^{-18}	5.6×10^{18}	1.7×10^{18}
B	0.010	0.62×10^{-18}	4.0×10^{18}	3.1×10^{18}
C	0.060	1.0×10^{-18}	2.3×10^{18}	3.7×10^{18}
D	0.002	0.50×10^{-18}	4.0×10^{18}	1.4×10^{18}

Fig. 1 shows the measured concentrations of radicals produced in the sample A during the irradiation and also shows the decrease of radical concentrations in the samples A, B, C and D after irradiations. The sample A was irradiated at the dose rate of about 3×10^5 roentgen/day and the temperature of 30°C and after the irradiation it was preserved at the same temperature. The samples B, C and D were all irradiated at 15°C and then preserved at 30 °C, 51°C and 15°C respectively. The dose rate for the sample B was about 7×10^5 r/day and the samples C and D were irradiated at lower dose rate while they were not measured. These results cannot be explained by the ordinary nth order reaction equations such as

$$\frac{dv}{dt}=a-\lambda v^n$$

for radical growth and

$$\frac{dv}{dt}=-\lambda v^n$$

for radical decay, where v, a and λ are the radical concentration, the radical production rate and the radical reaction constant respectively. For instance, if we assume the above equations, the values of n must be about 7 and 3 respectively for radical decays of the samples A and B at the same tempeture of 30°C and for the radical growth of the sample A it must be smaller than unity. Accordingly we assume the existence of two groups of radicals with different reaction mechanisms one of which is of first-order and the other is of second-order and also assume that there is no interaction between the two groups. Then during the irradiation the representation for v becomes,

$$v=\frac{a_1}{\lambda_1}(1-e^{-\lambda_1 t})+\sqrt{\frac{a_2}{\lambda_2}}\tanh(\sqrt{a_2\lambda_2}\,t) \qquad (1)$$

after the irradiation,

$$v=v_{10}e^{-\lambda_1 t}+\frac{v_{20}}{1+v_{20}\lambda_2 t} \qquad (2)$$

---

* The original manuscript was first received two and half months ago, but unfortunately was misplaced in the office of Kyusyu Branch of the Society. At our request, the authors kindly undertook to resubmit the manuscript. We wish to express our deep regret for the dely in the publication of this note. (Editorial Committee)

where v_{10} and v_{20} are the radical concentrations of the two groups when the irradiation is ceased. The curves of Fig. 1 are drawn by the above equations with the numerical values of Table I for λ_1, λ_2, v_{10} and v_{20} and with 0.65×10^{18} radicals. g^{-1}. day^{-1} and 1.8×10^{18} radicals. g^{-1}. day^{-1} for a_1 and a_2 of the sample A.

From these results the activation energies for λ_1 and λ_2 are estimated to be 18 kcal/mol and 4 kcal/mol respectively and the ratio of the numbers of radicals which belong to the two groups must vary with the temperature. Above interpretation is of course not unique one, but it seems to be plausible that there are more than two groups with different reaction mechanisms. The assumption of the two groups, however, has been indicated to give considerably good approximation to the measured variations of the radical concentrations.

The authors wish to express their thanks to Prof. M. Takayanagi, Mr. Y. Ishida and Mr. T. Aramaki for their helpful advice and discussions.

Measurement of Galvanomagnetic Tensors of Bismuth Single Crystals at Low Temperatures

By Shoichi Mase

Department of General Education, Nagoya University

and Sei-ichi Tanuma

Research Institute for Iron, Steel and Other Metals, Tôhoku University

(Received August 31, 1959)

The galvanomagnetic effects of bismuth single crystals at low temperatures have been extensively studied. Recent report for the longitudinal effect by Babiskin[1] has particularly attracted our attention. His experimental result seems not to be in accordance with the approximate theory of galvanomagnetic effect in a strong magnetic field such as $\omega\tau>1$, which predicts that the field dependent part of the longitudinal resistivity tensor is only a small correction due to the quantum effect, so far as the intensity of the magnetic field being within the quantum limit.

The authors measured the tensors of three single crystals with different orientations at 4.2°K and in the magnetic field up to about 10,000 Oersted. A large single crystal from which above three samples were cut out was grown using repeatedly zone-refined sample from Tanadac bismuth having five nine purity. We chose one of the binary axes and the trigonal axis as x- and z-axis respectively. Symmetric and antisymmetric tensors, $\rho^s_{ik}(\boldsymbol{H})$ and $\rho^a_{ik}(\boldsymbol{H})$, are defined as

$$E_i=\sum_k\rho^s_{ik}(H)J_k+\sum_{k(\neq i)}\rho^a_{ik}(\boldsymbol{H})J_k\,,$$

$$\rho^{s,a}_{ik}(\boldsymbol{H})=\rho^{s,a}_{ki}(-\boldsymbol{H})\,.$$

Figs. 1–2 are the representative results of our

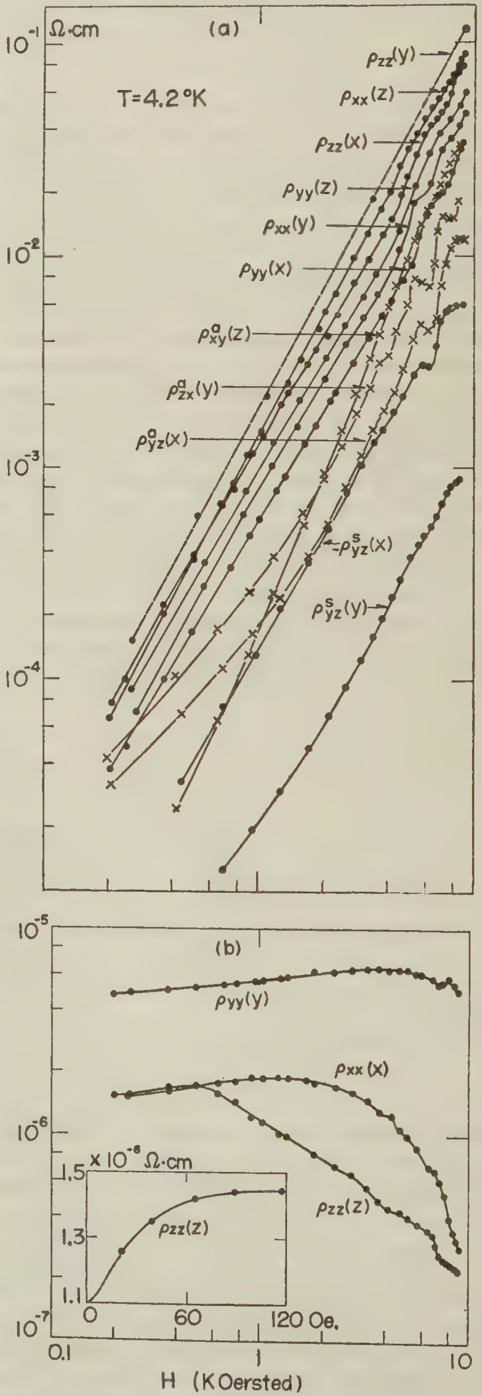

Fig. 1. Symmetric and antisymmetric tensors *versus* H curves.

measurements. Some curves in Figs. 1–2 are qualitatively in accordance with those by the several authors[2]. As one can see clearly from Fig. 2, the longitudinal tensors are conspicuously smaller than the transverse tensors and very slight misalignment of relative direction of the magnetic field or the potential probes and the sample can cause a drastic increase in the magnitude of the longitudinal tensor with the magnetic field due to the transverse component. The negative magneto-resistance shown in Fig. 1 (b) may be due to physical imperfections such as slip boundaries or due to other undesirable effects[3]. Unfortunately there was an evidence that some part of the anisotropy of the tensors shown in Fig. 1 (a) is attributed to the same causes. (It is, however, very difficult in bismuth with very long mean free path to get rid of such spurious effect). The magnitude of each longitudinal tensor in presence of the lowest field (except one run for $\rho_{zz}(z)$) is considerably larger than the respective value in zero field ($\rho^0_{xx}=1.12\times10^{-6}\,\Omega\text{cm}$, $\rho^0_{yy}=1.48\times10^{-6}\,\Omega\text{cm}$ and $\rho^0_{zz}=1.10\times10^{-6}\,\Omega\text{cm}$). This is due to the fact that at 4.2°K the condition $\omega\tau>1$ is necessary satisfied even in presence of the lowest field and the solution is in saturation region of usual solution of the Boltzmann equation (applicable to the case $\omega\tau<1$). It is illustrated in second run for $\rho_{zz}(z)$ (the inset in Fig. 1 (b)). The detail will be published elsewhere.

The authors express their sincere thanks to Prof. K. Ariyama and Prof. T. Fukuroi for their kind encouragements and discussions.

A Note on the Drag of a Screen at Low Reynolds Number

By P. G. MORGAN
Department of Engineering, University of Manchester, England

(Received September 21, 1959)

The work recently reported by Sawada[1] on the drag of a lattice of parallel circular cylinders at low Reynolds numbers shows considerable ingenuity in the manufacture of the lattice. This method of carrying out tests has been used previously, and a criticism is given below.

The overall size of the lattice is 6 cm. × 6 cm. while the cross section of the tower itself is 50 cm. × 50 cm., If we consider the lattice to be stationary and the air moving past it, some air flows through the lattice while the remainder flows around it; the proportions depend upon the resistance of the lattice, and the calculations for a wire gauze screen have been given by Taylor and Davies[2]. Experiments carried out by the author on wire gauzes falling through glycerine, in order to examine the flow resistance at low Reynolds numbers, show that there is a marked difference in the drag of a given wire gauze screen, depending upon the ratio

$$\frac{\text{area of screen}}{\text{area of the duct through which the screen moves}}$$

For wire gauze screens of small open area ratio i.e. high solidity, the differences in resistance are some 20%.

Considerable difficulty has been experienced in our work in keeping the plane of the screen horizontal in free fall experiments; this has been overcome for the screens of higher resistance by fitting a light framework, similar to that shown by Sawada, and measuring the force required to pull the screen upwards with a constant velocity.

Photoneutron Cross Sections for Ag^{107}, Mo^{92} and Zr^{90}

By Naoshi MUTSURO, Yuji OHNUKI, Kazuo SATO
and Motoharu KIMURA

Department of Physics, Tohoku University Sendai, Japan

(Received August 1, 1959)

Photoneutron cross sections and the yield curves were taken by the residual activity method for Ag^{107}, Mo^{92} and Zr^{90}. Threshold energy were obtained as 9.35±0.1 MeV, 9.15±0.1 MeV, 12.38±0.1 MeV and 12.3 ±0.1 Mev for $Ag^{107,109}$, Mo^{92} and Zr^{90} respectively. The energy for the maximum cross section was obtained as 14.5 MeV for Ag^{107}, 16.5 MeV for Mo^{92} and 17 MeV for Zr^{90}. The giant resonance widths were measured about 5.3 MeV, 2.7 MeV and 2.9 MeV respectively. Intrinsic quadrupole moment determined from above data was $(1.9\pm0.7)\times10^{-24}\,\mathrm{cm}^2$ for Ag^{107}.

§ 1. Introduction

The measurement of photoneutron cross section curves have been made by many authors for ten years, and the systematics of (γ, n) reactions were framed by a few authors[1),2)]. On the other hand, the widths of giant resonance show large fluctuation from nucleus to nucleus, and general tendency of the fluctuation was as follows; resonance widths for colsed shell nuclei are appreciably narrower than those of nuclei situated between closed shells.

O kamoto[3)] and Danos[4)] explained those tendency by the nuclear deformation, which is the extension of the hydrodynamical model for the nuclear photoeffect which leads to two giant resonance energies associated with each axis of a deformed nuclei.

Recently Fuller[5)] et al. obtained the cross section curves for Ta^{181}, Tb^{159}, and other elements by good energy resolution experiment, and showed that the giant resonance for Ta^{181} and Tb^{159} was clearly split into two peaks, but Carver[6)] et al. did not observe such splitting for Ta^{181} and also in our laboratory we did not obtain such splitting[7)]. It is the object of our present works to check the above effect for the medium weight nuclei, and we measured the cross section curves for Mo^{92} and Zr^{90} which are closed shell nuclei and for Ag^{107}, which is situated between two closed shells of $N=50$ and $N=82$.

§ 2. Experimental Procedure

The activation curves of photoneutron yield were taken by the Tohoku University 25 MeV betatron bremsstrahlung γ rays. The energy calibration of betatron was made by the use of threshold energy of the reaction $Cu^{63}(\gamma, n)Cu^{62}$, $Fe^{54}(\gamma, n)Fe^{53}$ and $C^{12}(\gamma, n)C^{11}$ and its energy are 10.8 MeV[8)], 13.8 MeV[9)] and 18.7 MeV[10)] respectively. The energy calibration curve is presented in Fig. 1.

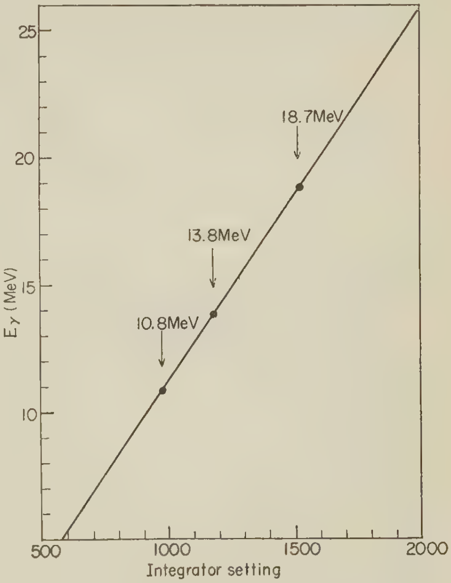

Fig. 1. Energy calibration curve.

During this work, we checked betatron energy frequently by the above threshold energy, and we found that the energy of the betatron were constant within ±10 KeV.

The basic experiment consists of irradiation of a number of samples at various betatron energy, and the yield curves were taken by residual activity measurements.

In the case of $Ag^{107}(\gamma, n)Ag^{106}$ reaction, by using natural silver, two different kinds of activity were formed, one of which is from $Ag^{109}(\gamma, n)Ag^{108}$ and another from $Ag^{107}(\gamma, n)Ag^{106}$ reaction, half-lives of Ag^{108} and Ag^{106} being 2.4 min. and 24 min. respectively.

In order to detect 24 min. β^+ activity from Ag^{106}, Ag sample was irradiated in the γ ray beam for 20 min. and after waiting for 20 min. to cool off the 2.4 min. activity to 1/500, counts were taken for 10 min. by G–M or scintillation counter set to the annihilation peak.

The Ag sample were 3 cm×3 cm×0.15 cm in shape and irradiated at 1.5 m from the betatron target one after another. In the case of Mo^{92}, natural Mo which is shaped 3 cm×3 cm and 0.2 mm thick was irradiated for 15 min. at the same position of the case of Ag^{107}, and after waiting for 2 min. counted for 10 min. by scintillation counter set to the annihilation peak. Counting efficiency of scintillation counter was regularly checked by counting rate of Na^{22}, which was placed at the standard position with respect to the scintillation crystal, the variation of counting efficiency was constant within statistical error during these works. In the case of Zr^{90}, natural Zr shaped 2 cm×2 cm and 0.3 cm thick was irradiated for 2 min. at the same position and after waiting for 2 min. measured for 2 min. by scintillation counter. In order to detect isomeric state of Zr^{89}, the 0.588 MeV γ ray, the half-life of which is 4.4 min., was measured by scintillation counter set to this energy.

During above irradiation, care was taken to hold the dose rate from betatron constant, because average photon flux incident on the

$Ag^{109}(\gamma n)Ag^{108}$	9.15±0.1	9.14±0.05	9.12	14)

sample in a given irradiation dose of Q is Q/t_R, where t_R is the irradiation time, and recorded number of counts were corrected to unit dose rate and to saturation activity by multiplying each reading by $t_R/1-\exp(-\lambda t_R)$.

γ ray dose was measured by means of Victoreen Radocon chamber, which is located at the center of Lucite of 11.7 cm cube. All the samples were irradiated just behind the Radocon chamber. The over all apparatus for each irradiation was presented in Fig. 2.

§ 3. Experimental Results and Discussion

Fig. 3 represents activation curves near threshold of each element. The threshold energy of each element is shown in Table I, the 1st column is reactions, the 2nd contains the threshold energy measured in present work, 3rd those by previous[8),11)-13)] data and 4th represents Q-values calculated from mass data.

In the case of Ag and Zr^{90}, the present data are in agreement with previous ones within experimental error. Threshold energy of Mo^{92} has not been observed previously. There were large deviations in energy calculated from mass data in the case of Mo^{92} and Zr^{90}, this is the general tendency in the case of closed shell nuclei. The activation curves were represented in Fig. 4. Absolute neutron yields were normalized by $Cu^{63}(\gamma, n)Cu^{62}$ yields which was measured by Saskatchewan group[14)] in absolute scale. $Zr^{90}(\gamma, n)Zr^{89*}$ neutron yield

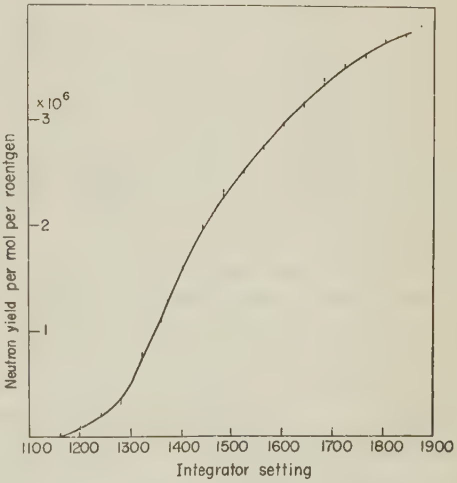

Fig. 4-2. Activation curve for $Mo^{92}(\gamma, n)Mo^{91}$.

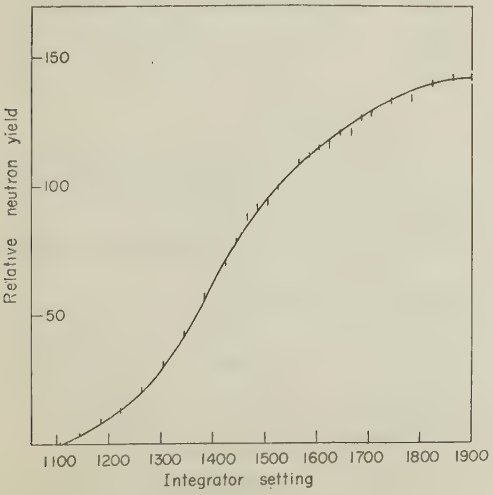

Fig. 4-1. Activation curve for $Zr^{90}(\gamma, n)Zr^{89m}$.

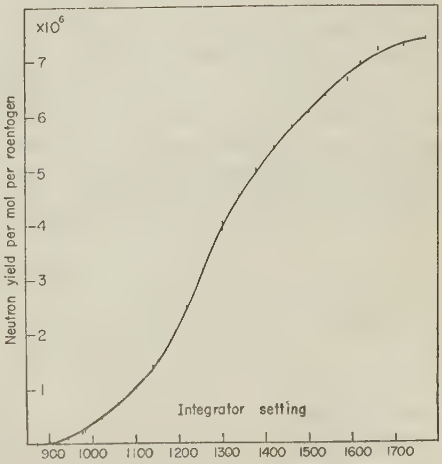

Fig. 4-3. Activation curve for $Ag^{107}(\gamma, n)Ag^{106}$.

represents the relative value. The cross section curves were deduced from activation curves of Fig. 4 by means of photon difference method[14].

Cross section curves of each element are shown in Fig. 5.

As the shape of cross section curve depends sensitively upon a little variations of activation curve, we made three activation curves independently from each successive activation points. These three curves then yield then three cross section curves. The three γ ray resonance energies and the widths at half-maximum thus obtained fall within ±0.5 MeV and ±0.3 MeV respectively. In the case of neutron closed shell nuclei Zr^{90} and Mo^{92}, giant resonance widths show about 2~3 MeV, and $E_{\max}$ about 16.5 MeV for both. Above 18 MeV, cross sections are almost constant to 23 MeV and its value is comparatively large as seen in Fig. 5. This scheme may be explained by the comparatively large contribution of direct process to total cross section in this energy region. In order to check above effect more precisely, it is desirable to measure angular distribution of neutrons from $Y^{90}(\gamma, n)$ reaction in this energy region.

Maximum cross section was measured as 190 mb in $Mo^{92}(\gamma, n)Mo^{91}$ reaction. In the case of Ag^{107}, the width of giant resonance was about 5.3 MeV which was factor of 2 larger than for Zr^{90} and Mo^{92}. $E_{\max}$ of Ag^{107} was about 14.0 MeV, and the cross section is measured as 240 mb at this energy. A small peak was found near threshold in contrast to Mo^{92} case, which is supposed to be $E2$ absorption by the surface oscillation.

All the data concerning the cross sections for each element are represented in Table II, in which the 5th column shows the calculated values of sum rule. In the case of Mo^{92}, the measured σ_{int} deviates largely from the sum rule. But in this case, (γ, p) cross section was anormally large[15] in these mass number region, and if we add this to (γ, n) cross section, integrated cross section will agree fairly good to the sum rule. In the case of Ag^{107},

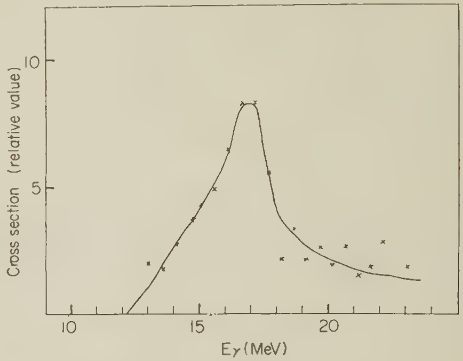

Fig. 5–1. Cross section curve for $Zr^{90}(\gamma, n)Zr^{89*}$.

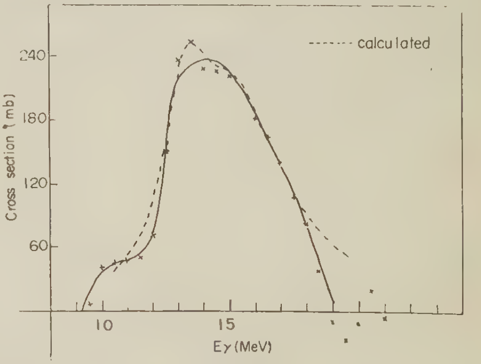

Fig. 5–3. Cross section curve for $Ag^{107}(\gamma, n)Ag^{106}$.

Table II. Summary of cross section measurement.

Reaction	$E_{\max}$ (MeV)	$\sigma_{\max}$ (mb)	Γ (MeV)	σ_{int}	* $\int_0^\infty \sigma dE$
$Zr^{90}(\gamma n)Zr^{89m}$	16.8		2.9		
$Mo^{92}(\gamma n)Mo^{91}$	16.0	190	2.7	1.48 MeV–b	1.92
$Ag^{107}(\gamma n)Ag^{106}$	14.0	240	5.3	2.48 MeV–b	2.21

* We assume $x=0.5$.

present data agree with the sum rule.

The giant resonance of Ag^{107} has large width compared to Mo^{92} and Zr^{90} case. Let us assume that, as Danos[4] has predicted, this giant resonance is split into two resonances which can not be resolved on account of their broadness, and that each resonance shape is of Lorentz type. Then we can express the (γ, n) cross section in the following way as Fuller[5] et al. have done.

$$\sigma(\gamma, n)=\frac{\sigma_a}{1+[(E^2-E_a{}^2)/E\Gamma_a]^2}+\frac{\sigma_b}{1+[(E^2-E_b{}^2)/E\Gamma_b]^2} \tag{1}$$

where E_a, E_b represent two resonance energy. Γ_a, Γ_b are full widths of two resonances lines at half maxima. σ_a and σ_b were adjusted by observed maximum cross section value, and the most suitable values of E_a, E_b, Γ_a and Γ_b which give the best fit to observed cross section curve are given by

$$\left.\begin{array}{ll} E_a=13.3\,\text{MeV} & \Gamma_a=2\,\text{MeV} \\ E_b=15.3\,\text{MeV} & \Gamma_b=4.5\,\text{MeV} \end{array}\right\} \tag{2}$$

$\Gamma_a=2.0$ MeV, $\Gamma_b=4.5$ MeV seems reasonable if we compare with those of Mo^{92} and Zr^{90}. The cross section curve by above parameters was shown by the dotted line in Fig. 6. According to the calculation of Danos, who treated a nucleus as spheroidal shape, the ratio of two resonance energy was represented by

$$E_a/E_b=0.911a/b-0.089 \tag{3}$$

where b and a are the length of minor and major axis of spheroid.

Substituting $E_a=13.3$ MeV, $E_b=15.3$MeV into eq. (3), we get:

$$a/b=1.164\,. \tag{4}$$

On the other hand the intrinsic quadrupole-moment is given by:

$$Q_0=\frac{2}{5}Zr_0{}^2A^{2/3}\left[\left(\frac{a}{b}\right)^2-1\right]\Big/\left[\frac{a}{b}\right]^{2/3} \tag{5}$$

substituting (4) into (5) and taking $r_0=1.20\times10^{-13}$ cm we get

$$Q_0=(1.9\pm0.7)\times10^{-24}\,\text{cm}^2 \tag{6}$$

This result agrees very well to the value, $Q_0=1.7$ or $1.9\times10^{-24}\,\text{cm}^2$ which was obtained from the Coulomb excitation experiment[16].

Thus we suppose that in the case of Ag^{107}, the giant resonance is perhaps split into two resonances, but we cannot resolve by their broadness.

Acknowledgement

The authors are indebted to Professor M. Miwa and Dr. K. Okamoto for valuable discussion. They are also ought to say thanks Mr. K. Kageyama and Mr. T. Inoue for operating the betatron.

Search for the "Anomalous" Scattering of Mu-Mesons (On the Apparatus using a Delayed Coincidence Method)

By Takashi KITAMURA

Institute of Polytechnics, Osaka City University, Osaka

(Received May 22, 1959)

As a result of the discussion about the experimental results on the anomalous scattering of mu-mesons so-far obtained, we came to the conclusion that their apparatuses have two principal deficiency in reaching a definite information: uncertainties in determining the identity and momenta of mu-mesons.

Hence, we have a plan to complete the experiment by using an arrangement of Wilson cloud chamber and G. M. counters which is capable of selecting only mu-mesons, their momenta being determined with a thick absorber within a narrow range of $\left(1^{+0.15}_{-0.20}\right)$ GeV/C and a delayed coincidence method to separate mu-mesons from the other particles. In this paper, moreover, we estimated the possibility to trigger this arrangement with other particles than mu-mesons and found the contribution to be quite negligible.

§ 1. Introduction

It has been believed[1] that mu-meson behaves in many respects as an heavy electron whose mass is about 207 times larger than that of the electron; its interaction with matter is caused mainly through the electromagnetic field in addition to a very weak Fermi type interaction. In the first stage, the idea that the spin of mu-meson should be half-integer was presumed from experimental informations in which the conclusion rested on the assumed identification of the light neutral particles in $\pi-\mu$ decay, μ^--capture and $\mu-e$ decay with the neutrino of β-decay. The analysis of cosmic ray bursts experiment also showed[2] that the spin of mu-meson was smaller than or equal to unity. However, a number of experiments about the scattering of cosmic ray mu-mesons have shown strange results[4)-10)]. This so-called "anomalous" scattering deviates from the scattering distribution predicted by electromagnetic interactions alone. The experimental aspects of the anomalous scattering so far obtained are tabulated in Table. Among these experiments about the mu-meson scattering, all but one performed by Amaldi *et al.*[3] clamied to have observed the anomalous scattering for various momentum regions.

On the other hand, while these researches for the anomalous scattering were being performed, the similarity of the mu-meson to the electron has become almost conclusive by the Columbia experiment[11] that the spin of the mu-meson is half integer and its g-factor is 2.0064 ± 0.0048. Accordingly, we can consider that the mu-meson is the normal Dirac particles as far as its static properties are concerned. In high energy mu-mesons, however, there may occur some anomalies in its dynamic properties which could be revealed at high energies. Moreover, the smallness of the Compton wave length of the high energy mu-meson might faciliate to examine the deviation (if any) of the electromagnetic interaction at small distances from the conventional one. Therefore, the experiment to determine whether the anomalous scattering is real or false, is very significant for the dynamic properties of the mu-meson. As far as possible in avoiding ambiguities which were apparent in the previous observations, we have completed the measurement on the scattering distribution of mu-mesons by using a delayed coincidence method.

The purpose of this paper is to discuss the utility of the experimental arrangement using a delayed coincidence method. We shall critically discuss in § **2** on various theories given up to date which attempted the interpretation on a presence of the anomalous scattering and also in § **3** on the experimental results of mu-meson scattering obtained so-far. On the basis of these discussions we shall show the

Table Recent experiments on the mu-meson scattering.

Lloyd, Rössle and Wolfendale (1957)	method III (sea-level)	1 cm of lead	$5<P<100$ GeV/c			272

* Method I, II and III are various methods of momentum determination: method I means "not measured but inferred from spectrum", method II "estimated from observed scattering" and method III "magnetic curvature".

reason why the delayed-coincidence-apparatus is superior to the previous. Finally, in § 4 and 5, we shall discuss on possibilities that the other particles beside mu-meson might trigger the apparatus.

§ 2. Various Theories Concerning the Anomalous Scattering of Mu-meson

Various attempts have been made in order to explain the observed results showing the anomalous scattering. Firstly, different authors[12),13)] calculated the elastic and the inelastic scattering of mu-meson by nucleus to the first order of Born's approximation using a single particle nuclear model. It was found that these theoretical results are too small to explain the observed distributions at large angles. Secondly, a direction to interpret it in terms of non-Coulomb interactions between fast mu-meson and nucleon was taken as a matter of course[14)]. This attempt, however, was excluded by further observations that the cross section for the anomalous scattering should be proportional to the square of the mass number of material used[8),9)]. Davidson[15)] suggested that the giant nuclear dipole resonance could be responsible for the large angle scattering. Although such a phenomenon was certainly found[16)], the observed cross section was too small to interpret that of the anomalous scattering. Also this event would be caused only by low energy mu-mesons because an existence of the giant resonance is at only γ-rays near 20 MeV, so that Davidson's suggestion couldn't account for the anomalous scattering of high energy mu-mesons which has been observed after publishing of this interpretation. Afterwards, Gatto[17)] studied an influence of correlations between the constituent nucleons on the scattering of mu-meson by a nucleus. Tidman[18)] and Fowler[19)] individually evaluated an influence of the anomalous magnetic moment of mu-meson on the large angle scattering. However, both influences also were too small. It has recently been suggested by Fowler[20)] that the large angle scattering may possibly be interpreted by a mechanism which essentially is the elastic counterpart of the star production by mu-mesons utilizing the result calculated by phase shift analysis about high energy electron scattering of Yennie *et al.*[21)] The reason for the apparent success of this theory is essentially due to the fact that he assumed a large inelastic cross section, that is, 4 mb per lead nucleus for incident mu-mesons having energies greater than 1 GeV to transfer an energy larger than 150 MeV to a nucleus. George and Evans[22)], however, have shown that the observed cross section for 1_p stars and showers by mu-mesons at various depths underground is average $(4.6\pm0.5)\times10^{-30}$ cm^2 /nucleon and the cross section for 0_p stars are only 1/4 of its value. Moreover, it has been suggested by the author and Oda[23)] that a part of the former and greater part of the latter might possibly be attributed to secondary pi-mesons produced by mu-mesons. This suggestion is supported by the latest McDiarmid's experiment[24)] about nuclear disintegrations of mu-mesons. Therefore, the value of 4 mb for the inelastic cross section is too large to be acceptable. Fowler also argued that the cross section of producing stars and showers rises fairly rapidly in energies above 10 GeV and it may become larger than 4 mb. On the contrary, the study of underground hard showers in our laboratory[25)] has shown that secondary high energy pi-mesons produced by mu-mesons increase the apparent cross section for mu-mesons-producing-showers, so that the genuine inelastic cross section for high energy mu-meson showers should be smaller than the observed value. Thus, we have had, up to present, no theory possible to interpret the anomalous scattering of mu-meson.

§ 3. Discussion on the Anomalous Scattering Results to Date

We shall now proceed to examine in detail each of the typical anomalous scattering results shown in Table.

George *et al.*[5)] asserted existence of the anomalous scattering of mu-meson near 200 MeV from their observation with a circular cloud chamber at a depth of 60 meters of water-equivalent (m.w.e.) underground. Generally, Coulomb scattering distribution of mu-meson which should be used for determining the magnitude of anomalous scattering degrees, is very sensitive to the intensity of low energy mu-mesons at that depth. Wolfendale *et at.*[9)], Nishida *et al.*[26)] and the author[27)] independently concluded that the results could not be accepted as evidence of the existence of the anomalous scattering of mu-meson because of an uncertainty in the knowledge of the spectrum of low energy particles traversing the cloud chamber. McDiarmid[8] also concluded that experimental results for mu-mesons of energies of a few hundred MeV were suffered from a difficulty at the experimental arrangement to distinguish between Moliére's (point charged model)[28] and Cooper and Rainwater's (extended charged model)[29] distributions because of very large angles of the mu-mesons scattered. Moreover, the bearing of secondary pi-mesons originated from hard showers of mu-mesons, discribed in the preceding, can have the most influence upon the information about the anomalous scattering at this energy region. In this way, when the anomalous scattering of low energy mu-mesons becomes more and more questionable, the conclusive disproof was obtained by means of a measurement on the pair production of mu-mesons by high energy γ-rays which was performed in 1956 by Masek *et al.*[30] The observed yield was compatible with the theoretical cross section which had been derived by modifying the conventional formula for the pair production of fermions by photons in a Coulomb field for the effect of a finite nuclear size. The energy transferred to nucleus in this measuremeut was between 40 MeV and 200 MeV. Thus, it was definitely concluded that there is little or no anomalies of mu-mesons below the corresponding energy.

In the experiment of McDiarmid[8], a multiplate cloud chamber was used at a depth of 26 m.w.e. underground. The meson momenta were estimated through multiple scattering measurements in six two cm thick lead plates and divided into three groups: group I (150 MeV/C $<p\beta<$ 1000 MeV/C), group II (300 MeV/C $<p\beta<$ 2200 MeV/C) and group III (600 MeV/C $<p\beta<$ 5 GeV/C). He asserted scattering, interpreted as anomalous, was found in Group III. The present author has investigated what energies of mu-meson affected much on the conclusion in this measurement. By using the Cooper and Rainwater theory, $f(p\theta)$, and momentum spectrum of McDiarmid's group III, $S(p)$, the calculated curves of $f(p\theta)\cdot S(p)dp$ at various values of scattering angle θ have been calculated. Those curves are drawn in Fig. 1. From the figure it is clear that the scattering distribution at large angles (larger than 5 degrees) is completely determined by an intensity of mesons in the 0.6~1.5 GeV/C region. This fact indicates that an evaluation of the intensity of mu-mesons having momenta near the threshold in the apparatus used has a great influence on the value of Coulomb scattering distribution and, as a result of it, on the conclusion led by such a measurement.

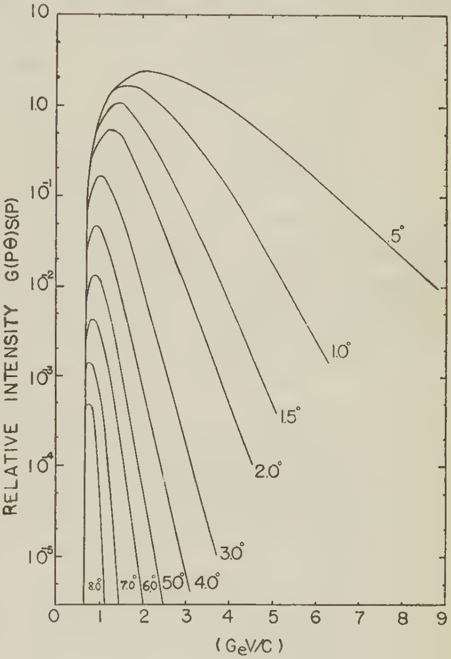

Fig. 1. Function $f(p\theta)\,S(p)\,dp$ at McDiarmid's experiment.

Nevertheless, McDiarmid's experimental result would have a great measuring error in determining momenta of the mesons because of using of the method of multiple scattering measurement as discussed in Olbert's paper[31] which first presented the method. In this connection, the comparison of McDiarmid's experimental points with our Coulomb scattering distribution calculated by the above-described $\int_{\theta_0}^{\infty} d\theta \int_{p_0}^{\infty} f(p\theta)\cdot S(p)dp$, represented no anomalous scattering that quite agreed with a conclusion independently obtained by Nishida *et al.*[26] from their analysis of McDiarmid's result. This fact may be considered that the experimental method of McDiarmid is very hard on giving the definite conclusion. Thereupon, we cannot but agree that McDiarmid's evidence is not conclusive.

In the following, we shall refer to the experiments which bear on the scattering of higher energy mu-mesons, using a magnetic cloud chamber. A main problem associated with this method is in an accurancy of the momentum determinations. In the magnetic cloud chamber, it is usual to measure the residual-value-curvature, ΔC, of tracks of high speed in case of no magnetic field. Corresponding to this curvature there is a "maximum detectable momentum". According to the data given in Wilson's book[32], however, occasional tracks may have large unexpected apparent curvatures; a distortion which produces a curvature of nearly $1.2\,\mathrm{m}^{-1}$ can occur in one of 40 tracks in a cloud chamber which has measured value of $0.16\,\mathrm{m}^{-1}$ for ΔC. In a measurement of the momentum spectrum of mu-mesons in a chamber for which $\Delta C = 0.2\,\mathrm{m}^{-1}$, we found that one track in 50 had a curvature of nearly $1.5\,\mathrm{m}^{-1}$ and among them some distorted tracks were almost completely expressed with only a parabola equation that absolutely cannot be separated from their true curvature values[34]. Experiments in which very rare events are measured, show clear that this sort of distortions can be misleading and for this reason we feel that magnetic cloud chamber measurements of mu-meson scattering must be regarded with caution.

There is further the question of small admixture of protons in the mu-meson "beam". There is some evidence that the elasticity of high energy proton-proton collisions may have[35] a value near 0.7 and the recent data of accelerator shows[36] an unexpected large value of elasticity in collisions of proton-proton near 2 or 3 GeV, so that the absorption mean free path of protons in the atmosphere would be larger than the 200–300 g/cm² previously assumed. This has the effect of increasing

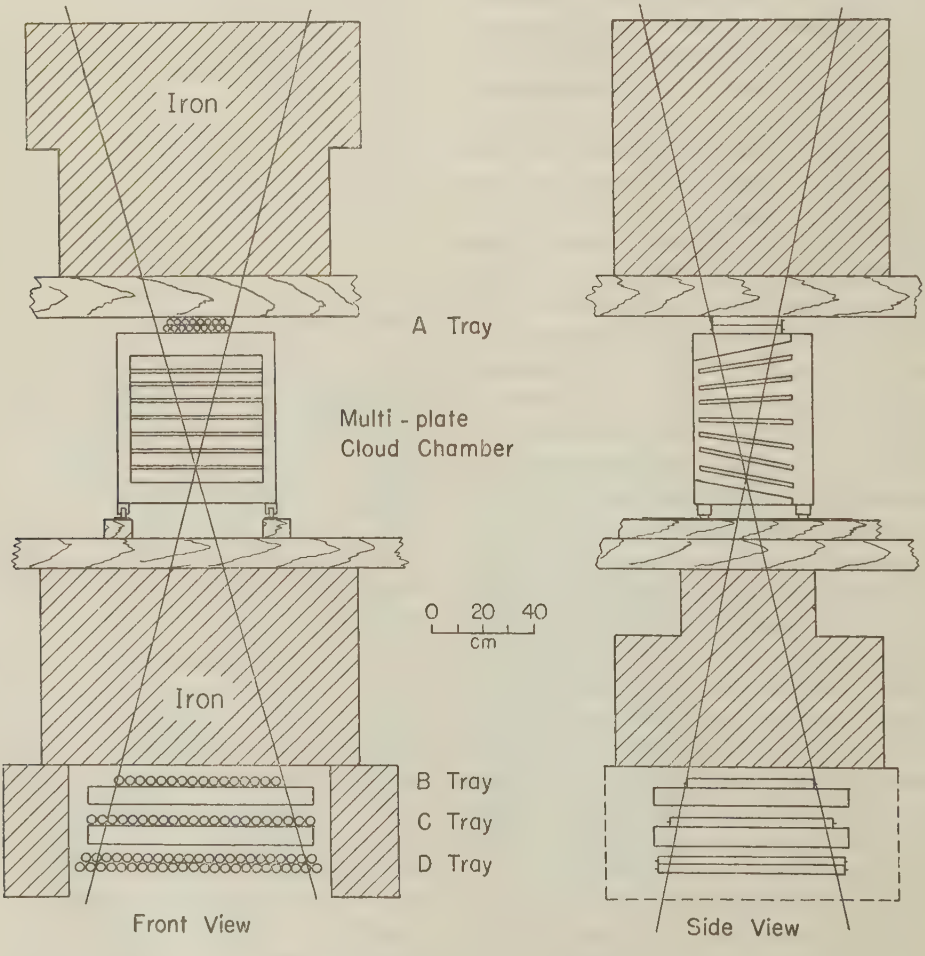

Fig. 2. Arrangement of apparatus.

the proton intensity. A suitable choice of the longer absorption mean free path may bear the proton contamination which is responsible for the anomalous scattering observed by Lloyd *et al.*[9]

Thus, it is hard to draw a very definite conclusion of existense of the anomalous scattering for mu-mesons from the measurements up to date. At the present that its existence in low energy mu-mesons has been excluded by the mu-pairs experiment, it is accordingly the most importance to measure the scattering distribution of moderate energy mu-mesons. Our present experiment was planned with the method capable of selecting only mu-mesons, their momenta being determined with a thick absorber and a delayed coincidence method within a narrow range of $\left(1^{+0.15}_{-0.2}\right)$ GeV/C.

§ 4. Experimental Arrangement

The arrangement is illustrated in Fig. 2. An upper absorber consists of iron block having a density of 7.0 g/cm^3 (its error ±4.5 %) and total thickness of 1.0 metre. It is expected that incident nuclear-active particles from the atmosphere decrease considerably under the iron absorber but incident mu-mesons do not. A cloud chamber has an effective volume $47\times35\times50$ cm^3 and contains seven one cm lead plates. The thickness 75 cm of iron absorber below the chamber serves to define a residual range of particles passing through this absorber corresponded to a momentum of 1 GeV/C. Iron was used for an economical reason because it is almost equal to lead from view point of capability of absorbing nuclear-active particle. After traversing the iron, the mesons stopped and decayed in either of two 8 cm thick carbon slabs. Two rather than just one carbon slab were used to increase the detection efficiency. The triggering method of the present apparatus is $AB-D+(B \text{ or } C \text{ or } D)_{\text{delay}}$. After passing through trays A and B (i.e. through the chamber), such mu-mesons as come to rest in the carbon slab and decay into electron are possible to trigger this arrangement. In the triggering method, the anti-coincidence of D tray with AB coincidence pulses was used for excluding a chance delayed-coincidence between ABD prompt coincidence pulses and pulses in single discharge of tray B, C or D. Each counter in tray B, as well as in trays C and D were hodoscoped for the prompt pulse. Whenever a delayed coincidence occurred, neon bulbs were photographed together with the triggered cloud chamber. In this way the track in the cloud chamber could be checked for their alignment with the struck counters.

§ 5. Other Particles Contributions Beside Mu-meson

It is conceivable that the present apparatus may be triggered by other particles than mu-mesons. We shall evaluate those phenomena using Olbert's production spectrum[37] which is an over-all energy spectrum of secondary pi-mesons produced by nucleon-air nucleus collisions. Difference between the energy distributions of secondary particles in nucleons-iron and air nucleus collisions is represented by (mass number)$^{1/3}$ law. Henceforth, we shall call the above iron absorber as absorber A and the lower iron absorber as absorber B. Let x g/cm^2 and y g/cm^2 represent each one of upward measured distances from each bottom surface of those absorbers A and B, respectively.

[I] Delayed coincidence triggering

A) *Incident nucleons*

We shall treat only vertical incident particles because inclined incident ones are much fewer. By doing this these calculations will be able to be simplified. The possibility that the present apparatus may be triggered by $\pi-\mu-e$ decay event in the process discussed below, is caused by the fact that a lifetime of 10^{-8} sec in $\pi-\mu$ process is quite negligible for the time of 10^{-6} sec in $\mu-e$ process.

a) A pi-meson, having been produced in a penetrating shower in the upper absorber A, traverses the chamber and the absorber B and comes to rest in the carbon and decays to a electron through the $\pi-\mu-e$ process.

The frequency may be expressed in the following form,

$$\int_0^{700(\mathrm{Fe})} \exp\left\{-\frac{1030(\mathrm{air})}{\lambda_{\mathrm{abs}}(\mathrm{air})}\right\} \exp\left\{-\frac{700(\mathrm{Fe})-x(\mathrm{Fe})}{\lambda_{\mathrm{abs}}(\mathrm{Fe})}\right\} G(x(\mathrm{Fe})+79(\mathrm{pb})+525(\mathrm{Fe});\ 1030(\mathrm{air}))$$
$$\times \exp\left\{-\frac{x(\mathrm{Fe})525(\mathrm{Fe})}{\lambda_{\mathrm{col}}(\mathrm{Fe})}\right\} \exp\left\{-\frac{79(\mathrm{pb})}{\lambda_{\mathrm{col}}(\mathrm{pb})}\right\} \exp\left\{-\frac{\mu}{p\tau}(x(\mathrm{Fe})+525(\mathrm{Fe})+79(\mathrm{pb}))\right\} dx \quad [\mathrm{cm}^2\,\mathrm{sec}^{-1}\,\mathrm{sr}^{-1}]\,.$$

All lengths are measured in units of g/cm². (air) symbol refers to thickness of air, (Fe) to thickness of iron and so on. p attributes to a momentum of a secondary pi-meson, μ to its rest energy and τ to its mean lifetime. The first term in the integrand represents a feature of the nucleonic component decreasing as an approximately exponential function with an absorption mean free path in air, $\lambda_{\mathrm{abs}}(\mathrm{air})$, from the top of atmosphere to sea-level (1030 g/cm² air). Function $\exp\left(-\frac{1030}{\lambda_{\mathrm{abs}}}\right)\cdot G$ (range; 1030) bases on the Olbert's assumption that meson-producing component is absorbed exponentially throughout the atmosphere with an effective absorption mean free path. The second term shows the probability that the incident nucleons being absorbed with the absorption mean free path λ in absorber A may survive to a producing point x g/cm². The third term is a value of Olbert's production spectrum at a range $(x(\mathrm{Fe})+525(\mathrm{Fe})+79(\mathrm{pb}))$ g/cm², namely, an intensity of pi-mesons having the residual range which corresponds to total thickness of remaining layers in absorber A, absorber B and lead plates in the chamber. These pi-mesons come to rest just within the carbon layer. So this intensity must be given by a integrated value over a thickness of the carbon layer. The fourth and fifth terms show the probability that these pi-mesons having the above range do not interact with matter during passing the passage of their range. We should use a collision mean free path instead of an absorption mean free path in those terms because the pi-mesons would lose almost all of their energy on account of their low energy even in nuclear interactions within the layers which are to be passed. The sixth term expresses the survival probability of pi-mesons that the pi-mesons don't decay to mu-mesons in performing their passing range.

By comparing a calculated numerical result of the above equation and an intensity of mu-mesons having 1 GeV/C to be measured under absorber A, $(3\times10^{-6})\times$(thickness of carbon layer) $[\mathrm{cm}^{-2}\,\mathrm{sec}^{-1}\,\mathrm{sr}^{-1}]$[38], we can get an order of the contribution in this case. The ratio, using the values of $\lambda_{\mathrm{abs}}(\mathrm{Air})=125$ g/cm² air, $\lambda_{\mathrm{abs}}(\mathrm{Fe})=200$ g/cm² iron, $\lambda_{\mathrm{col}}(\mathrm{Fe})=130$ g/cm² iron and $\lambda_{\mathrm{col}}(\mathrm{pb})=160$ g/cm² lead, was calculated to be 5.0×10^{-7}.

b) A pi-meson, produced as in *a*) above, decays from within the lower absorber, the mu-meson travelling on to decay in the carbon.

With a similar treatment in case *a*) this intensity will be express as follows.

$$\int_0^{700(\mathrm{Fe})} \exp\left(-\frac{1030(\mathrm{air})}{\lambda_{\mathrm{abs}}(\mathrm{air})}\right) \exp\left(-\frac{700(\mathrm{Fe})-x(\mathrm{Fe})}{\lambda_{\mathrm{abs}}(\mathrm{Fe})}\right) \int_0^{525(\mathrm{Fe})} G(x(\mathrm{Fe})+79(\mathrm{pb})+(525-y)(y))$$
$$\times \exp\left(-\frac{x(\mathrm{Fe})}{\lambda_{\mathrm{col}}(\mathrm{Fe})}\right) \exp\left(-\frac{79(\mathrm{pb})}{\lambda_{\mathrm{col}}(\mathrm{pb})}\right) \left\{1-\exp\left(-\frac{\mu}{p\tau}y(\mathrm{Fe})\right)\right\} dxdy \quad [\mathrm{cm}^{-2}\,\mathrm{sec}^{-1}\,\mathrm{sr}^{-1}]\,.$$

The last term represents the probability that incident pi-mesons decay into mu-mesons through $\pi-\mu$ process within the absorber B. The remaining terms have the same physical meanings as adopted in *a*). In using the same mean free path values, we obtained 1.5×10^{-6} as a ratio of this calculated result to the intensity of the mu-mesons.

c) A proton incident from the atmosphere, traverses the upper iron absorber A to produce a pi-meson which goes on to decay in the carbon.

This intensity will be

$$\frac{1}{2}\int_0^{525(\mathrm{Fe})} \exp\left(-\frac{1030(\mathrm{air})}{\lambda_{\mathrm{abs}}(\mathrm{air})}\right) \exp\left(-\frac{700(\mathrm{Fe})}{\lambda_{\mathrm{abs}}(\mathrm{Fe})}\right) \exp\left(-\frac{79(\mathrm{pb})}{\lambda_{\mathrm{col}}(\mathrm{pb})}\right) G(y(\mathrm{Fe}))$$
$$\times \exp\left(-\frac{525(\mathrm{Fe})-y(\mathrm{Fe})}{\lambda_{\mathrm{abs}}(\mathrm{Fe})}\right) \exp\left(-\frac{y(\mathrm{Fe})}{\lambda_{\mathrm{col}}}\right) \exp\left(-\frac{\mu}{p\tau}y(\mathrm{Fe})\right) dy \quad [\mathrm{cm}^{-2}\,\mathrm{sec}^{-1}\,\mathrm{sr}^{-1}]\,.$$

The factor outside the integral is due to the view that only proton flux in nucleonic component is favourable to this case. We may use collision mean free path at the third term because an occurance of any interactions of the incident particles within lead plates in a chamber will be able to be noticed with the chamber photographs.

The ratio between this calculated result and the mu-mesons intensity was found to be 4.0×10^{-6}.

d) A proton incident from the atmosphere traverses the upper iron absorber and cloud chamber as in *c*) above, and produces a π meson which decays within the lower absorber, the mu-meson traveling on to decay in the carbon.

An intensity of this event was estimated with a similar treatment and the ratio to the mu-meson was 1.0×10^{-6}.

In order to distinguish the Cooper and Rainwater theory for finite nucleus from the Moliére theory for point nucleus, it is necessary to get data of about 5000 traversals as estimated from these differential scattering probability. The data would be got with about 1000 particles of mu-mesons scattered in five plates in middle of the chamber as their scattering phenomena in the top and bottom plates might be rejected because of the distortions of those tracks there. Therefore, thinking of the number of mu-mesons to be measured, the present result that a total intensity of the above-described events caused by nucleons and pi-mesons have been led to a rate of 7.0×10^{-6} per the mu-meson intensity, suggests that their contributions to the apparatus would be quite negligible for the mu-mesons even if actual mean free path values for absorption and collision were longer than those values adopted in the above calculations. Also, bearing in mind that almost all of the above-discussed events producing pi-mesons just capable of triggering the present apparatus are accompanied with the other secondary particles of energies which have a possibility of passing across *D* tray, we can say it is nearly impossible to trigger the apparatus for these events by virture of an action of anti-coincidence of *D* tray. In practice, on our measuring results of about 1000 particles by means of this equipment, we have observed none of such cloud chamber photographs which had other coinciding secondary particles than mu-mesons triggering the apparatus (hard showers in absorber A), or had a triggering mu-meson and a lightening of many neon bulbs in a hodoscope *B*-tray (hard showers in absorber *B*). This fact seems to give support to the view that our above conclusion on the events caused by nucleons gives correct evaluations.

B) *Incident pi-mesons*

From the preceding results, the similar events arised from incident pi-mesons from the atmosphere instead of incident nucleons are known to be quite ignored because the pi-meson intensity at sea-level is assumed to be only few percent of the nucleon's one.

C) *Incident mu-mesons*

a) Nuclear showers of mesons

Although it is much less likely, a pi-meson having been produced in a nuclear shower of mu-mesons in the absorber *A*, may possibly produce a triggering of the apparatus. So long as we use the semi-classical procedure of Williams and Weizsäcker[39] as a cross-section for production of pi-mesons by fast mu-mesons, a ratio of the intensity of the pi-mesons to that of the mu-meson triggering the apparatus was no more than a degree of 2.0×10^{-5}. In addition, most of the event is impossible to trigger the apparatus by virture of the action of anti-coincidence in *D* tray because of the narrowness of angles between the pi-mesons produced and the parent mu-mesons.

b) Nuclear disintegration initiated by mu-mesons

This is a low energy star produced by mu-mesons which may be very nearly regarded as an elastic process. If the recoiling nucleons have not enough energy to penetrate a thickness of one cm of lead plates in the cloud chamber, such a event seems to be a scattering phenomenon.

An angle of scatter of an incident mu-meson of energy E_μ in this event is given from the conservation of energy and momentum by approximate elastic process treatment. This expression is as follows;

$$\theta = \sqrt{\frac{2m_pC^2E_p}{E_\mu{}^2 - E_\mu E_p}}$$

where m_pC^2 is a rest mass energy of proton and E_p is an energy of recoiling nucleons.

On the other hand, the cross section for a production of the event with energy E_p released by a fast mu-meson of energy E_μ has been expressed by the Williams and Weizsäcker expression[39),

$$\sigma(E_\mu, E_p)=\left(\frac{2\alpha\sigma_{h\nu}}{\pi}\right)\frac{dE_p}{E_p}\ln\left(\frac{E_\mu}{E_p}\right)$$

where α is a fine structure constant and $\sigma_{h\nu}$ is the cross-section for the production of stars by photons. Now, we can put a value of 1 GeV in E_μ of this expression because energies of measured mu-mesons have been taken as the value. The angular distribution of mu-mesons scattered with this event is obtained from the above two equations. As shown in Fig. 3, the differential scattering probability near 7 degrees was evaluated to be of the order of 10^{-6} per degree which was very smaller compared to the Cooper and Rainwater theory.

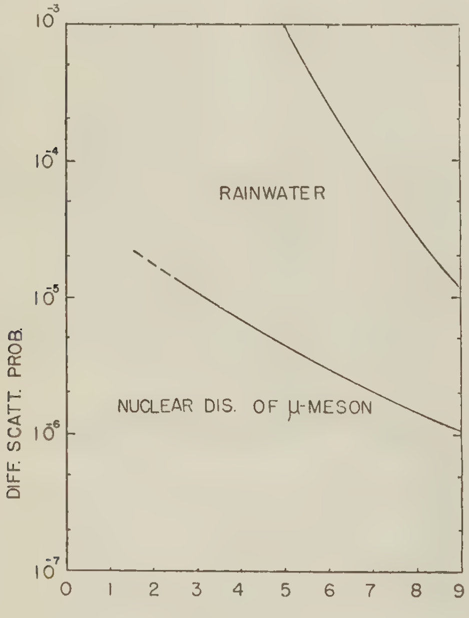

Fig. 3. Contribution of nuclear disintegrations of mu-meson.

[II] Prompt coincidence triggering

In order to clarify a significance of delayed coincidence method, it is better we make also an observation with a prompt coincidence method *ABD* which selects all of particles penetrating through the absorber and the apparatus. When using this method, it is also possible that the counter system may be triggered by a nucleonic component. From Mylori and Wilson's data[40), a ratio between intensities at sea-level of protons having larger than 1 GeV/C and of mu-mesons of the same momentum is assumed to be of 10^{-3} order. Taking an assumption that the proton flux attenuates with an absorption mean free path of 200–300 g/cm² of iron in penetrating absorbers *A* and *B*, the ratio between proton and mu-meson flux to trigger the prompt coincidence-arrangement may decrease to a value smaller than 10^{-4}. Taking into account an existence of an elasticity in nucleon-nucleus collisions, however, we cannot assert that this value is so small as the contribution of these proton does not disturb the observation with the prompt coincidence.

By using the above-discussed apparatus, we have observed the scattering distributions of mu-mesons having momenta of $\left(1^{+0.15}_{-0.20}\right)$ GeV/C determined with the delayed coincidence and having larger momenta than 1 GeV/C with the prompt coincidence. From the observations, we excluded the possibility that the anomalous scattering of mu-meson is in existence at the moderate energies[41).

Acknowledgements

The author is indebted to Professor Y. Watase and Dr. S. Fukui (Osaka University) for many stimulating discussion and valuable suggestions. It is a pleasure to acknowledge the invaluable contributions made by Messers. H. Nishimura and M. Teranaka who assisted in the numerical calculations, equipment setup and experimental runs throughout the course of this work.

Temperature Dependence of Surface Voltage of Silver Bromide

By Sanemi SONOIKE and Hisawo WAKABAYASI
Faculty of Engineering, Chuo University, Tokyo

(Received July 27, 1959)

The temperature dependence of surface voltage of silver bromide crystals has been studied. The change in the surface voltage is due to the change in the ionic space charge voltage between silver metal and silver bromide. Near and on free surface, silver ions and electrons move, and their surface levels change under the condition that their change cancels the voltage change due to the ionic space charge of this side. The curve of surface voltage vs temperature consists of two straight lines, one of which refers to the impurity region, the other refers to the intrinsic region. The more Cd the sample contains, the higher temperature the knee point moves to. The formation energy of Frenkel defect and other quantities were obtained.

§ 1. Introduction

One of us has observed the electron diffraction patterns of silver bromide monocrystal surfaces in the temperature region from room temperature to about 300°C, and found that when the specimens were illuminated by the light from the heater of the furnace, in which they were set, metallic silver precipitated on their surfaces,[1] the amount of which was larger in the impurity region than in the intrinsic region.

If the difference of surface structure between two regions was characteristic to silver bromide, we would be able to observe the surface change in dark with silver bromide. So we intend to find the temperature dependence of the surface voltage of silver bromide monocrystal in dark, which contains known amounts of impurities. In our experiments, cadmium was used as the impurity.

§ 2. Apparatus

Specimens were made from melt in the air, cut by Ti-saw, and lapped and etched by HBr. After these treatments, they were rinsed for about twenty minutes. One side of a silver bromide monocrystal is free, and the other side is coated by silver metal, which were developed by usual development process. The samples are 1 mm thick.

The arrangement around the sample is shown in Fig. 1. The free surface was placed against the reed of a vibrating reed electrometer, which is made of semi-transparent glass coated with platinum. The coated surface of the sample is in contact with a platinum plate, which is the other electrode of the electrometer and is grounded. The sample can be heated by the heater placed under the platinum plate, and is insulated from it by mica plates. The heater is made of platinum. By controlling the heater current the sample can be heated at any arbitrary temperature between room temperature and the melting point of silver bromide. The temperature of the crystal was measured by a copper-constantan thermocouple, which is welded on a silver plate placed on the platinum plate.

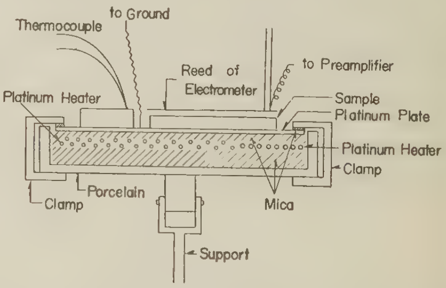

Fig. 1. Schematic arrangement of crystal, electrodes and heater.

The above parts are placed in a bell jar together with the preamplifier, and the system was evacuated to 10^{-4} mm Hg. The bell jar is shielded from electric disturbance and also screened from light. The block diagram of the apparatus is shown in Fig. 2.

For the experiment in the lower temperature region, the platinum heater was replaced by a copper rod, the end of which was immersed in liquid oxygen. By heat conduction of the rod, the temperature of the sample could be made to fall to about 130°C below zero. By immersing the rod in glycerine bath with heater, the sample could be heated to 120°C. But this apparatus was used only for the preliminary test in the lower temperature region.

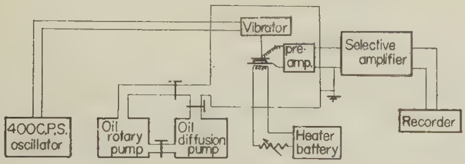

Fig. 2. Block diagram of complete apparatus.

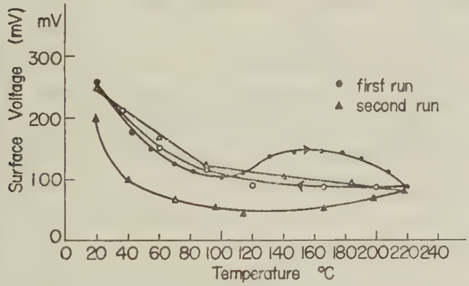

Fig. 3. The temperature dependence of the surface voltage of a silver bromide crystal. After heating the crystal, it cooled along the same path.

§ 3. Experimental Results

In the preliminary test, the upper electrode of the electrometer was contaminated at higher temperatures by evaporated material from the crystal surface and the temperature region was restricted to be below 220°C.

The change of the surface voltage of silver bromide containing 0.01 Mol.–% of cadmium bromide is shown in Fig. 3. In the first run, its surface voltage decreased until the temperature of the crystal was elevated to about 100°C, and increased thereafter. It remained nearly constant in the temperature region from 140°C to 180°C. In higher temperature region, it again decreased. After keeping the crystal at about 220°C for an hour, we gradually cooled it. Then its surface voltage changed along another path, and increased a little down to about 100°C. Below 100°C, the surface voltage increased more steeply, and below 80°C took nearly the same path as in heating. So in the curve of surface voltage versus temperature, we found a knee point near 100°C. The elevation of surface voltage in the first run was not observed in the case of silver chloride samples. Silver bromide is soluble in hydrobromic acid, and silver chloride is not soluble in hydrochloric acid. Each acid was used in the last stage of etching. We might suppose that the elevation was due to the evaporation of bromine. The behavior in the first run may show the character of etching.

In the second run, we could not find the increase of surface voltage between 100°C and 140°C. In heating, the voltage change followed different paths from run to run, but nearly the same path was taken in cooling. So the latter path was used to calculate various figures for the crystal.

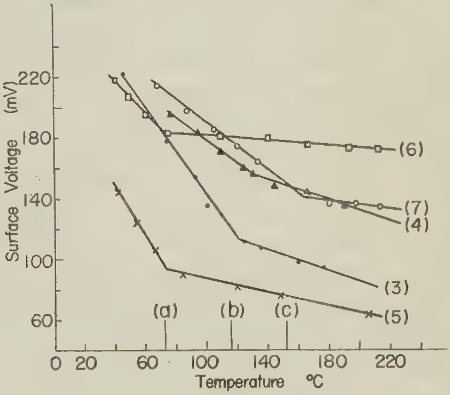

Fig. 4. The temperature dependence of the surface voltage of silver bromide crystals. The associated number indicates the corresponding one in the paper. (a) is the calculated knee point temperature for crystal 5 and 6, (b) is that for crystal 3 and 4, and (c) is that for crystal 7.

The experimental results are shown in Fig. 4. Each voltage was measured after the crystal was kept half an hour at each temperature. Crystal 3 and 4 contain 0.01 Mol.–% of cadmium bromide, and crystal 7 contains 0.05 Mol.–% of cadmium bromide. Crystal 5 and 6 contained no intended impurities, but they were estimated to contain 0.001 Mol.–% of divalent cation impurities, according to the results of our experiment and the ionic conductivity experiment. The amount of the impurity ingredient—cadmium bromide—was weighed before doping. We did not analyse chemically the amounts of impurities solved in the silver bromide crystals.

From Fig. 4, the curve of surface voltage versus temperature may be represented by two straight lines. One is in the temperature region from room temperature to the knee point temperature, which corresponds to surface voltage change in the impurity region and the other is in the higher temperature region than the knee point, which corresponds to surface voltage change in the intrinsic region.

It is easily seen that the more impurities the crystal contains, the higher temperature the knee point moves to. We could expect that in the intrinsic region, all lines would overlap one another because the behavior in this region must be independent of the amounts of impurities. But it is not our case. It is hard to measure the absolute surface voltage, and we cannot expect their overlappings, but their parallelism among them. Besides, they were frequently not parallel, as will be accounted by our interpretation in the next paragraph.

The behavior of surface voltage of silver bromide crystal in the temperature region from room temperature to 140°C below zero is utterly different by the pre-treatment. After heating the sample from room temperature and keeping it at 120°C, its temperature was made to fall. Below room temperature, surface voltage versus temperature curve continued to follow the line determined by the experiments at higher temperatures. At temperatures from −20°C to −40°C, the curve becomes flatter. But by illuminating the crystal with light shorter than 400 mμ the path again followed the extrapolated line, though its gradient was less steep below 0°C. In the temperature region from −100°C to −120°C, there appeared no change of surface voltage.

When we cooled the crystal from room temperature without heating it, the surface voltage of silver bromide increased with a gentler slope than after heating it, and it changed a little from −50°C to −120°C. The surface voltage versus temperature curve obtained for crystal 4 is shown in Fig. 5. Whether the sample at low temperature attains to thermal equilibrium in our observation time is doubtful.

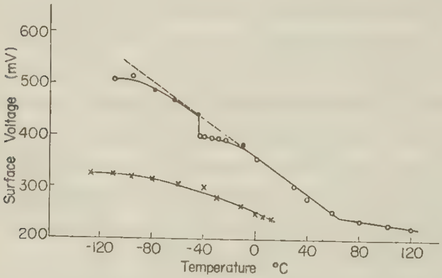

Fig. 5. The temperature dependence of the surface voltage of silver bromide crystal 4 in the temperature region from room temperature to 120°C below zero.

§ 4. Interpretation

In order to interprete these curves in Fig. 4, we shall propose the following mechanism. According to Lehovec,[2] there is an ionic space charge layer between the surface and the bulk in an ionic crystal. In our case, the one surface is coated by silver metal. The work required for taking away a silver ion from silver metal to infinity is $-E$ ev. (E is negative.) Silver bromide is of Frenkel defect type, and a silver ion occupies a normal lattice site or an interstitial site. By $-W$ ev, we represent the work required for taking away a silver ion from an interstitiai site of silver bromide to infinity, and $-U$ ev stands for the work required for taking away a silver ion from a normal lattice site to infinity. E, U, and W are not equal. When silver bromide is in contact with silver metal, silver ions move and an ionic space charge layer will be established. We measure voltage in silver bromide, taking the voltage of silver metal for zero. The voltage in the crystal is denoted by V. The schematic diagram of E, U, W and V with other quantities which will appear later, is shown in Fig. 6.

The number per unit volume of silver ions at interstitial sites of the crystal $-n_{Ag\cdot^{+}}-$ and that of silver vacancies $-n_{Ag\square^{-}}-$ will be determined by E, U, W and V. From the

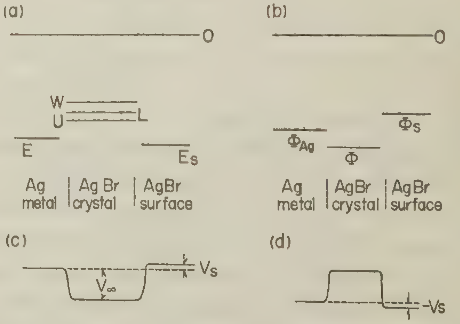

Fig. 6. Energy level diagram for silver ion and electron (a) Energy levels for silver ion (b) Energy level for electron (c) Potential for silver ion (d) Potential for electron.

equilibrium equation, we have the following equations

$$n_{Ag\cdot^{+}}=N_1\exp\{-(W-E+eV)/kT\} \qquad (1)$$

$$n_{Ag\square^{-}}=N_2\exp\{-(E-U-eV)/kT\} \qquad (2)$$

where we denote the number of interstitial sites available to a silver ion per unit volume by N_1, and the number of normal silver ion lattice sites per unit volume by N_2. N_1/N_2 is 2 in this case. k is Boltzmann constant, e is the charge of proton and T is the temperature of the crystal in absolute unit.

In the interior of the silver bromide monocrystal, the charge must be neutral, where voltage V is constant and its value is denoted by V_∞. The charge neutrality in the interior will be established with cadmium impurity, which increases silver ion vacancies. Then we have

$$n_{Ag\square^{-}}=n_{Ag\cdot^{+}}+cN_2 \qquad (3)$$

where cN_2 is the number of Cd^{++} at lattice sites in place of silver ions per unit volume and c is Mol.-% of cadmium ions dissolved in the crystal. From the equations (1), (2) and (3), we obtain

$$\left.\begin{aligned} eV_\infty &= E-U+kT\ln\left\{\frac{c}{2}+\sqrt{\left(\frac{c}{2}\right)^2+\frac{N_1}{N_2}\exp-\frac{W-U}{kT}}\right\} \\ &= E-L \end{aligned}\right\} \qquad (4)$$

$-L$ ev is the work required for taking away a silver ion from the interior of silver bromide crystal to infinity. If we could measure V_∞, V_∞ versus temperature curve would have a knee point, where

$$c^2=\frac{N_1}{N_2}\exp\left(-\frac{W-U}{kT}\right) \qquad (5)$$

It is not this voltage, but surface voltage that we can measure.

On the free surface of the crystal, we may make the following assumptions. There is the surface level of silver ions on the free surface, which corresponds to the work required for taking away a silver ion from the surface to infinity. We denote it by $-E_s$ ev. So we obtain the equation on the free surface similar to the equation (4). It is

$$\left.\begin{aligned} e(V_\infty-V_s) &= E_s-U+kT\ln\left\{\frac{c}{2}+\sqrt{\left(\frac{c}{2}\right)^2+\frac{N_1}{N_2}\exp-\frac{W-U}{kT}}\right\} \\ eV_s &= E-E_s \end{aligned}\right\} \qquad (6)$$

where V_s is the surface voltage of the crystal referred to the silver metal.

The dependence of surface voltage of the crystal on temperature will be determined by E_s because E is almost independent of temperature. In order to explain our results, we must suppose that E_s varies in a wide range and its change shows a knee point at some temperature. It is unreasonable to suppose that E_s changes abruptly at some temperature which is different according to the amount of cadmium impurities in the bulk.

It was shown in the former experiment that surface state of silver bromide crystal changed as its temperature rose and metallic silver precipitated on its surface. It may be natural to conjecture that electrons could contribute to the surface change on the free surface. On the other surface, silver ions only move in the boundary between silver and silver bromide, for silver bromide is an ionic crystal and the diffusion of electron may be neglected in our observation times. On the free surface both silver ions and electrons may contribute to equilibrium and there may be some factors that hinder the contribution of electrons. They may be removed by such procedure as illuminating the surface with shorter waves than 400 mμ. We denote the work required for taking away an electron in silver bromide crystal to infinity by $-\phi$ eV, and that from its surface by $-\phi_s$ eV.

The voltage induced by electrons for equilibrium between free surface and silver bromide crystal is $(\phi_s-\phi)/e$, and that by silver ions is $(L-E_s)/e$. There does exist only one voltage, so that they must be equal. We have

$$L-E_s=\phi_s-\phi \qquad (7)$$

The equation (7) would not always be consistent, if E_s, ϕ_s, and ϕ were all nearly constant. There was change of surface state. It would be preferable that E_s could change. Then the equation will become consistent. We have

$$\begin{aligned} eV_s &= E-E_s \\ &= eV_\infty+\phi_s-\phi \end{aligned}$$

The dependence of V_s on temperature is entirely determined by V_∞, if $\phi_s-\phi$ is constant. We can measure V_s, and it is equivalent to measuring V_∞ which is the voltage established by the ionic space charge layer near the silver coated surface. Then the curve of surface voltage versus temperature may have a knee point which can be controlled by the amounts of cadmium. In the above argument, the number of electrons which move to and from the free surface is supposed to be small and not to affect the charge neutrality condition.

In the intrinsic region, where the contribution of the impurities is negligible, we have the equation for V_s as follows

$$eV_s=E-\frac{U+W}{2}+\frac{kT}{2}\ln\frac{N_1}{N_2}+\phi_s-\phi \qquad (8)$$

The curve of surface voltage versus temperature seems to be a line with the same slope for all crystals because the factors except $\phi_s-\phi$ are determined by the bulk characters and $\phi_s-\phi$ is assumed to be constant. In reality, there are some discrepancies from one crystal to another. So we assume that $\phi_s-\phi$ is not constant and has a term proportional to change of E_s. That is:

$$\phi_s-\phi=(\phi_s-\phi)_1-\alpha kT\ln\left\{\frac{c}{2}+\sqrt{\left(\frac{c}{2}\right)^2+\frac{N_1}{N_2}\exp-\frac{W-U}{kT}}\right\} \qquad (9)$$

$$eV_s=eV_\infty+(\phi_s-\phi)_1-\alpha kT\ln\left\{\frac{c}{2}+\sqrt{\left(\frac{c}{2}\right)^2+\frac{N_1}{N_2}\exp-\frac{W-U}{kT}}\right\} \qquad (10)$$

where $(\phi_s-\phi)_1$ is the term of $\phi_s-\phi$ which is independent of E_s, and α is a constant, which has different values from sample to sample. α is determined mainly by surface condition of the sample. We attribute the difference of the slope between the samples to α.

Neglecting the dependence of $W-U$ on temperature, we get a value as a knee point temperature, which is higher than the observed one. We must consider the dependence of each level on temperature, and may assume that the dependence of each level on temperature is linear. We have

$$E=E_0-kT\ln A_1 \qquad (11a)$$

$$(\phi_s-\phi)_1=(\phi_s-\phi)_{10}-kT\ln A_2 \qquad (11b)$$

$$W=W_0-kT\ln B_1 \qquad (11c)$$

$$U=U_0-kT\ln B_2 \qquad (11d)$$

where each character with suffix 0 represents respectively the energy level at 0°K of the energy level denoted by each character.

The expression for eV_s is:

$$\begin{aligned} eV_s=E_0-U_0+(\phi_s-\phi)_{10}-kT\ln\frac{A_1A_2}{B_2} \\ +(1-\alpha)kT\ln\left\{\frac{c}{2}+\sqrt{\left(\frac{c}{2}\right)^2+\frac{N_2B_2}{N_1B_1}\exp-\frac{W_0-U_0}{kT}}\right\} \end{aligned} \qquad (12)$$

In the impurity region, we have:

$$eV_{s1}=E_0-U_0+(\phi_s-\phi)_{10}-kT\ln\frac{A_1A_2}{B_2c^{1-\alpha}} \qquad (13)$$

where V_{s1} is the surface voltage in the impurity region, and the term $\exp-(W_0-U_0)/kT$ is neglected.

In the intrinsic region, we have

$$eV_{s2}=E_0-\frac{U_0+W_0}{2}+(\phi_s-\phi)_{10}+\frac{\alpha}{2}(W_0-U_0)$$
$$-kT\ln\frac{A_1A_2}{B_2}\left(\frac{N_2B_2}{N_1B_1}\right)^{(1-\alpha)/2} \qquad (14)$$

where V_{s2} is the surface voltage of silver bromide in the intrinsic region, and the concentration of impurity is neglected in the logarithm term.

The dependence of surface voltage on temperature in each region is represented by a straight line. Extrapolating these lines to 0°K, we obtain:

$$eV_{s1}-eV_{s2}=\frac{W_0-U_0}{2}\times(1-\alpha) \qquad (15)$$

The value of $V_{s1}-V_{s2}$ at 0°K is determined experimentally, while W_0-V_0 obtained by Teltow[4] is 1.27 eV. The value of α which we obtained are shown in Table I.

Table I.

Sample Number	Molar Percent of Impurity	$2\times(eV_{s1}-eV_{s2})$	α	N_1B_1/N_2B_2	Knee Point Temperature expe.	Knee Point Temperature calc.
3	$1.\times10^{-4}$	1.00 eV	0.21	3.9×10^8	392°K	393°K
4	1.	0.36_5	0.71	0.7	400	393
5	0.1	1.02	0.20	4.2	344	342
6	0.1	0.76	0.40	4.2	344	342
7	5.	0.62	0.51	0.7	442	440

The difference of the slopes of two lines in the two region is

$$\varDelta G=k\ln\left(\frac{N_1B_1}{N_2B_2c^2}\right)^{(1-\alpha)/2} \qquad (16)$$

$\varDelta G$ is calculated from the experimental data. We can find N_1B_1/N_2B_2 which must be nearly constant, for it involves only the intrinsic factors of silver bromide crystal not affected by its surface state. α is sensitive to surface condition and its value are different from sample to sample. If the experimentally determined value of N_1B_1/N_2B_2 are nearly constant, we may conclude that our assumptions are reasonable.

We have the following table.

We can easily see that N_1B_1/N_2B_2 is constant for the samples which were cut from the crystal containing the same amounts of impurities. Furthermore, the discrepancy between the samples is little except for crystal 7. Crystal 7 seemed to be strained in being lapped.

The knee point temperatures were calculated by using the values of the impurity concentration c and N_1B_1/N_2B_2 obtained from Fig. 7. There is also good agreement between their experimental and calculated values.

Under the condition that B_1/B_2 is 0.65×10^8, the formation energy of Frenkel defect E_F is dependent on temperature as follows:

$$E_F=W-U=W_0-U_0-kT\ln\frac{B_1}{B_2}$$
$$=1.27-1.6\times10^{-3}T \qquad (19)$$

The equation (19) shows that B_1/B_2 is larger than one. Rough evaluation of B_1 and B_2 can be made as follows. In the equation (12), there are two terms involving the temperature T. If we plot the curve of the term involving the impurity concentration c, the curve has a minimum near the knee point temperature, while the curve obtained experimentally has a slightly negative slope in the high temperature side of the knee point. If, as a very rough approximation, the sum of two terms dependent on temperature is assumed to be zero in the intrinsic region of silver bromide crystal, and if it is further assumed that α is zero, then we have

$$A_1A_2/B_2=(N_1B_1/N_2B_2)^{1/2}$$

whence, substituting $N_1B_1/N_2B_2=1.3\times10^8$,

$$A_1A_2/B_2\fallingdotseq10^4$$

The value of A_1 for silver is nearly equal to one. We assume that A_2 might vary from 1 to 10^{-3}. Then B_2 must vary inside the region from 10^{-2} to 10^{-7}. From the above relation, B_1 must vary from 10^6 to 10. As the temperature rises higher, it becomes easier to take away a silver ion from a normal lattice site, and the work required to take away a silver ion from an interstitial site increases. The level of U elevates, and that of W drops, as the temperature of the silver bromide crystal rises. The difference between the lattice site and the interstitial site tends to disappear by thermal motion of the lattice.

The knee point temperature T_k is determined by the equation (5),

$$c^2=\frac{N_1B_1}{N_2B_2}\exp\{-(W_0-U_0)/kT\} \qquad (5)$$

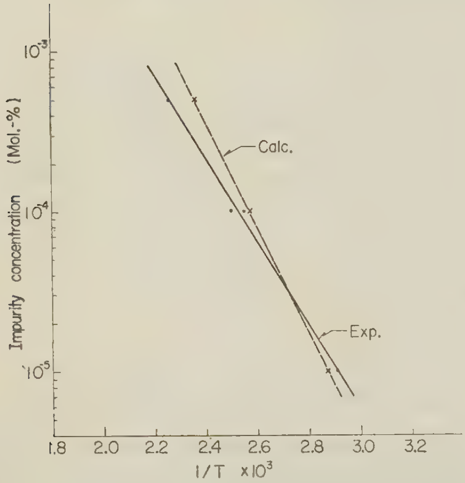

Fig. 7. The curve of the logarithm of the impurity concentration versus the reciprocal of the absolute temperature. From the slope of the line, we have $E_F{}^0=1.03$ eV and $N_1B_1/N_2B_2 = 1.3\times10^8$.

The curve of $\ln c$ versus the reciprocal of the absolute temperature is a straight line. The experimental result is shown in Fig. 7. The dotted line is the calculated one under the condition that $E_F{}^0$ is Teltow's 1.27 eV, and N_1B_1/N_2B_2 is 3×10^8. The formation energy of Frenkel defect, $E_F{}^0$, can be determined from the slope of the line. The value 1.03 eV is obtained, and the value 1.3×10^8 is obtained for N_1B_1/N_2B_2.

The value of α differs from sample to sample, though the samples are cut from the same crystal. But the knee point temperatures of the samples supposed to contain the same amount of cadmium coincide with each other. Therefore, $E_F{}^0$ is experimentally determined without trouble over α. The discrepancy between 1.27 eV and 1.03 eV may be removed by improvement. Improvement may be obtained by the following ways:

1) more accurate measurement of the temperature of the samples
2) better and uniform treatment of surfaces
3) exact knowledge about the amounts of impurities

Lidiard[5] calculated that the association of silver vacancies and cation impurities is virtually complete at room temperature. Surface voltage of silver bromide would not change at temperatures near and below 0°C because the impurities do not contribute to its change. We found its change at further lower temperatures. Whether the flatness of the surface voltage change below room temperature is caused by complex pairs, or by the absorption on the surface cannot decided in the present stage. But it seems that silver ions may move hardly below -100°C, and complex pairs which decrease the concentration of effectively dissoluble cadmium may contribute to the change of surface voltage. This problem might be solved by the experiments in the wider range of temperature from liquid oxygen temperature to 220°C. The result will appear later.

Acknowledgements

The authors wish to thank Dr. T. Ninomiya for numerous helpful conversations throughout the course of this work. The authors are also grateful to Professor H. Takahasi for helpful suggestions and criticism to the manuscript. Sincere appreciation is extended to Mr. K. Akimoto and Mr. S. Oyama for their encouragement. To Mr. H. Motoi, the authors wish to their sincere gratitude for his continual efficient and untiring assistance. The present investigation has been partly supported by the Special Research Grant from Chuo University.

Study on Precipitation Phenomena during Aging of Aluminium-Silver Alloy in Thin Evaporated Films*

By Yasushige FUKANO** and Shiro OGAWA
The Research Institute for Iron, Steel and Other Metals
Tohoku University, Sendai

(Received April 14, 1959)

Precipitation phenomena during aging have been observed on aluminium-20 wt. per cent silver alloy in thin evaporated films by electron micryscopy and electron diffraction. A super-saturated solid solution has successfully been obtained in thin films by a new quenching method. In a preprecipitation stage aggregates composed of random clusters have been found in electron micrographs, no appreciable diffraction effect having been perceived. In a true precipitation stage precipitates have been found in electron micrographs to change from a needle-like to a three dimensional shape with increasing aging, the axial ratio obtained from diffraction patterns changing from 1.63_3 to 1.59 passing 1.61_2. It is a merit of the present study that a hexagonal precipitate with the ideal axial ratio has been detected in the course of aging. Except this point, the results obtained confirm generally those reported by X-ray studies. So called "equal-thickness interference fringes" have been found in images of precipitates aged at 250°C.

§ 1. Introduction

The precipitation process of age-hardened alloys such as aluminium-copper, aluminium-silver etc. will be elucidated in more detail, if both morphology and crystal structures of precipitates are examined on one and the same specimen without using replicas. For this purpose the direct observation on thin films by means of electron microscopy together with electron diffraction is most adequate[1]. Evidence for structural transitions in alloys will directly be obtained by this method, and therefore various changes of physical and mechanical properties of alloys accompanying aging will fully be explained.

In order to realize the direct observation of aging two types of specimen preparation are available, that is to say, one is thin-sectioning of bulk alloys by electropolishing or chemical etching and the other is vacuum evaporation. The latter method was adopted in the present experiment because of its easiness and simplicity. This method has been tried by some investigators[2)-5)] but without success, for they could not get a supersaturated solid solution, by quenching of thin films, from which the observation on the aging process should be started. In the present study a quenching unit for evaporated alloy films was prepared with a new idea. This apparatus enabled us to quench thin films successfully, and the direct observation on the aging process of aluminium-20 wt. per cent silver alloy could be carried out by electron microscopy and electron diffraction. The description of the quenching unit and the quenching method and of results obtained will be given in § 2 and § 3, respectively.

§ 2. Experimental Method

1. *Quenching unit*

The most necessary condition for quenching of thin films is to keep the cooling speed at least in the same order of magnitude as that of water quenching of bulk material. Moreover, the following must be avoided.

(1) Formation of oxides or other compounds.
(2) Contamination by organic compounds such as grease.
(3) Breakdown of films.

It seems to be the best way, therefore, that alloy films are quenched without being exposed to air, immediately after the solution treatment has been done in vacuum or in inert gas. Bulk materials are usually quenched by putting directly into liquid refrigerant, say, cold water, but it is clear that this method is inadequate to thin films. Winkelmann tried quenching of films by sudden fall of a heated specimen onto a cooled metal plate in vacuum. According to him, thermal radiation from the specimen suddenly placed in surroundings of low temperature might quickly decrease the specimen temperature. But, at the same time, a considerable quantity of heat must be given to the film by a film supporter the cooling speed of which is far smaller than that of the former because of its large heat capacity. Thus, the cooling speed of the film is thought to be maintained almost in the same order of magnitude as that of the supporter. This point is considered as a main source from which he could not get a supersaturated solid solution.

---

* A short note concerning the present work has been published in Acta Cryst. **9** (1956) 971.

** Now at Department of General Education, Nagoya University.

If a film heated in vacuum can quickly be contacted with some inert gas of large accommodation coefficient, a considerably large cooling speed must be obtained without formation of any harmful compound. Under such an idea a quenching unit as shown in Fig. 1 was prepared. It permitted the most effective heat exchange between films and inert gas and enabled the specimen temperature to be instantaneously decreased below room temperature. The unit consists of a heating chamber, *A*, a nozzle part, *B*, from *c* in which gas is jetted into the heating chamber, and a cooling chamber *C*, in which the cooling of a specimen film as well as well as of inert gas is completed. *A* is made of a transparent quartz tube 8 mm in diameter and 0.7 mm in wall thickness on which a heating coil of nickrom wire, *a*, is tightly wound. The specimen is placed at the central part of the quartz tube without being put in any container. The specimen temperature can be measured by a thermocouple of Pt-PtRh, *b*. But, as the high accuracy of temperature measurement was not necessary for quenching, the thermocouple was removed on the actual procedure, in order that it might not interfere with a jet of gas, and the quenching temperature was then estimated by the coil current. The cooling tube, *e*, in *C* is made of hard glass 10 mm in diameter and 0.5 mm in wall thickness and is beforehand cooled by liquid nitrogen contained in a Dewar's vessel *d*. In *e* is contained a helical winding of thin platinum or silver wire to promote heat exchange between inert gas and the specimen. *g* in *B* is a gas reservoir into which gas is filled to 2 atmospheric pressure through a valve, *h*, before quenching. Carbon dioxide gas was selected as an innert gas suitable for the present experiment, owing to its large accommodation coefficient. The dissociation of this gas does not thermally proceed below 2000°C, that is to say, the reaction $2CO_2 \rightleftarrows 2CO+O_2$ does not actually take place. The dissociated volume is about 2 per cent at 2000°C. The specimen film was heated above 500°C for $1\sim2$ hours in vacuum of 10^{-5} mmHg to obtain a homogeneous solid solution and then was quenching.

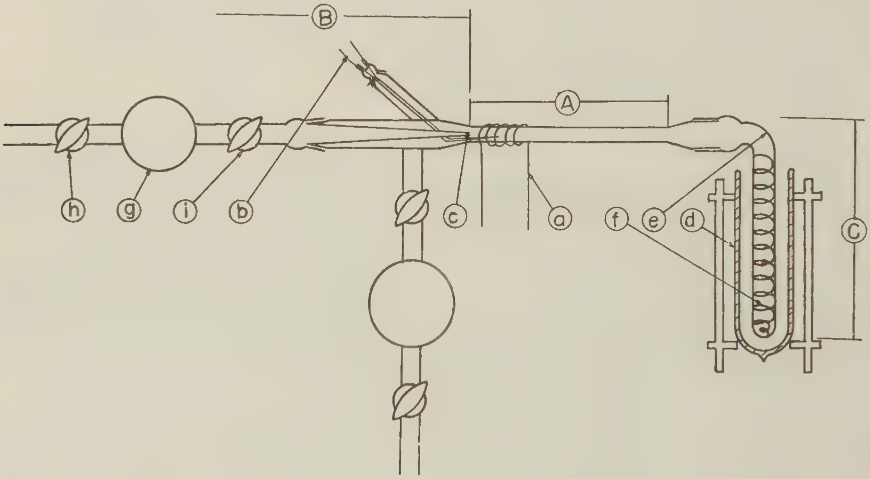

Fig. 1. Schematic diagram of the quenching unit.

2. *Quenching method and heat treatment for aging*

The quenching procedure is carried out in the following order:

(1) The valve, *i*, is opened and the gas is jetted into *A* through *c*.
(2) Cold water is poured onto *A*.
(3) The electric current through *a* is switched off.

These three operations must be done almost simultaneously. The object of the operation (2) is firstly to prevent carbon dioxide gas from temperature increase due to heat exchange with the inside wall of *A* and secondly to avoid blowing-off of *C* due to thermal expansion of the gas filled in *A*. The specimen film is instantaneously blown away by the jetted gas and is fallen down onto the bottom of *e*. At the same time, as soon as the gas reaches the cooling tube, it transforms instantaneously to dry ice by giving heat to *f* and *e*. The process may be analysed in the following way; the gas jetted from the nozzle forms a narrow stream, without filling *A*, and brings the film away to the cooling chamber, carrying it on the tip of its stream. In this moment the tip may get little heat from the inside of *A* because of a sufficiently short length of the heating coil. In order that the above procedure may completely be finished, the distance between the nozzle tip and the film, and the size of the heating coil may have to be finely adjusted. The breakdown of some films is unavoidable owing to the abrupt transport, but about two-thirds of the total number of the tried films could be subjected to the successive aging experiments without being broken down. This comparatively little damage may depend upon a flying manner of a film, that is to say, this is apt to blown away with its surface parallel to the flying direction. After the quenching was finished, the unit was again highly evacuated, dry ice formed being gradually sublimated, and then the film was exposed to air. The time actually required from the finish of the quenching till the observation by electron diffraction or electron microscopy is estimated at least 2 hours.

Heat-treatments for aging were done in high vacuum as follows;

(1) When the heating temperature was below 200°C, films were placed at the bottom of *e* which was immersed into hot water or an oil bath.
(2) When the temperature is above 200°C, they were placed at *A*.

3. *Preparation of specimens*

Specimens used in the present study were single-crystalline evaporated films of aluminium-20 wt. per cent silver. The two component metals were simultaneously evaporated onto cleavage surfaces of rocksalt, which were maintained at about 450°C after having been heated up to 500°C, from two wires of aluminium and silver laid in a small tungsten filament 0.2 mm in diameter. Evaporated quantities were so adjusted that the desired composition and the desired thickness, 800 ~1000Å, might be obtained. Both of the composition and the thickness were, however, considerably different from the expected values because of uncertain evaporated quantity of aluminium. This metal is soluble in tungsten and hence some quantity of it always remains unevaporated. To obtain a composition as close to the desired one as possible, a planned quantity of aluminium was somewhat increased by experience. Uncertainty of the distance between the filament and the substrates, caused by a not negligible extent of the evaporation sourse, may also give rise to some error in the composition and the thickness. Films evaporated onto pieces of rocksalt were freed from the substrates by immersion into distilled water and mounted on nickel plates 3 mm in diameter and less than 0.1 mm in thickness with small holes 0.1~0.3 mm in diameter, covered by thin collodion films. Films prepared in this way were well orientated, their surfaces being parallel with (001) plane. Electron micrographs showed, however, clear subgrains having probably twisted boundaries with the axis of rotation lying in the film plane, as suggested by diffraction spots without arcing and visible over a wide angular extent.

4. *Temperature rise in films by irradiation of electron beam*

Specimen films were examined first by electron diffraction and then by electron microscopy after quenching and after every aging. The electron microscope was made by Hitachi Company (HU-7), the operating voltage being 50 KV, and electron micrographs were taken on photographic plates at a magnification of 10,000×. This microscope, however, did not permit to take diffraction patterns at the same specimen position as that in case of microscopy, and hence diffraction experiments had to be done in an independent diffraction camera. Owing to a large film thickness, microscopic images on the fluorescent screen were often too dark to be observed in detail unless the irradiation was more intensified than usual. This increased intensity, however, gave rise to true precipitation in a super-saturated solid solution during observation. The precipitates much resembled those formed in an early stage of 165°C aging, but further progress of the precipitation did not occur even after observation for about one hour. The acceleration of precipitation by irradiation could naturally be avoided by decreasing the intensity at the cost of readiness of observation. When a specimen was subjected to the repeated quenches and the prolonged observation in the electron microscope, the increase of its contamination made the electron image darker and the minute observation more difficult. Nevertheless, the images with marked contrast in themselves in true precipitation stages suffered scarcely serious interference.

5. *Determination of the axial ratio of hexagonal precipitates*

The axial ratio, c/a, of hexagonal precipitates was determined from diffraction spots $(0\bar{1}11)$, $(0\bar{1}12)$ and $(10\bar{1}3)$, which were caused by lattice planes nearly perpendicular to the film plane, as follows:

$$\left(\frac{c}{a}\right)^2=\frac{l_1^2A-l_2^2}{4/3\cdot(1-A)},$$

where,

$$A=\frac{d_{h_1k_1i_1l_1}}{d_{h_2k_2i_2l_2}}=\left(\frac{R_2}{R_1}\right)^2 \qquad (1)$$

where R_1 or R_2 is a distance between (000) spot and $(h_1k_1l_1)$ or $(h_2k_2l_2)$ spot on the diffraction pattern. The accuracy of measurements of R_2 and R_1 was somewhat decreased due to radial elongation of the hexagonal spots, but the change in the axial ratio with aging could be determined at an error of about ±0.01. When hexagonal spots $(10\bar{1}0)$ $(10\bar{1}1)$ were fortunately observed by tilting the specimen to the electron beam, the following equation was used:

$$\left(\frac{c}{a}\right)^2=\frac{1}{4/3\cdot(A-1)},$$

where

$$A=\left(\frac{d_{10\bar{1}0}}{d_{10\bar{1}1}}\right)^2=\left(\frac{R_{10\bar{1}0}}{R_{10\bar{1}1}}\right)^2 \qquad (2)$$

Mean values of results from the above two methods were used as the axial ratio of precipitates. Individual values of c and a were not determined.

§ 3. Experimental results

Six specimens were examined by electron microscopy and electron diffraction throughout various aging stages after quenching, and the results obtained are classified into the following two; (1) low temperature aging in which true precipitation does not yet take place and (2) high temperature aging in which true precipitation already proceeds. It was done in the first place to examine whether the quenching caused a supersaturated solid solution or not, and the first aging state was detected by this procedure. In the second aging state shape, size, distribution and the axial ratio of precipitates of hexagonal phase were studied, depending on aging temperature.

1. *Low temperature aging*

Photos. 1 and 2 show a typical electron micrograph and a typical diffraction pattern, respectively, taken from a specimen aged at room temperature for two hours after quenching. In the former, complex aggregates composed of minute dark spots are seen, e.g., in *A* or *B*. These aggregates always exist in specimens aged at temperature below 100°C and are believed to consist of small clusters of silver atoms. This point will be discussed in § 4. The electron diffraction patterns seem to be scarcely influenced by the presence of aggregates. Sharp diffraction spots due to the face-centered single phase are accompanied by no appreciable extra scattering, except a comparatively strong background scattering which is markedly reduced in high temperature aging. A small elastic strain of the matrix lattice due to the occurrence of small clusters may be responsible for this phenomenon. Although shape and size of individual clusters forming an aggregate could not definitely be determined in the present observation, it may roughly be said from random shapes and

random sizes of aggregates that each individual cluster is not precipitated on any definite lattice plane and that its shape resembles a sphere, say, about 100Å in diameter.

2. *High temperature aging*

(i) Aging below 200°C

True precipitation was confirmed neither to occur at room temperature aging even after one month nor to occur at 100°C aging even after two hours, but it was found to begin at 165°C after 20 minutes. Needle-like or narrow wedge-like precipitates were grown along [110] and $[1\bar{1}0]$ directions lying in the film plane, (001), originating chiefly from sub-grain boundaries or from lattice imperfections such as small holes inside sub-grains, as shown in Photo. 3. These precipitates began to appear with increasing aging time also at places where there were no apparent imperfection inside sub-grains. Electron diffraction patterns corresponding to this precipitation stage exhibited streaks emerging from diffraction spots of the face-centered cubic matrix, as shown in Photo. 4. The streaks appear to be extended along [110] and $[1\bar{1}0]$ directions in the projection to (001) reciprocal plane. On these streaks diffraction spots due to the hexagonal lattice appeared by further aging at higher temperatures and increased their intensity with aging. This fact seems

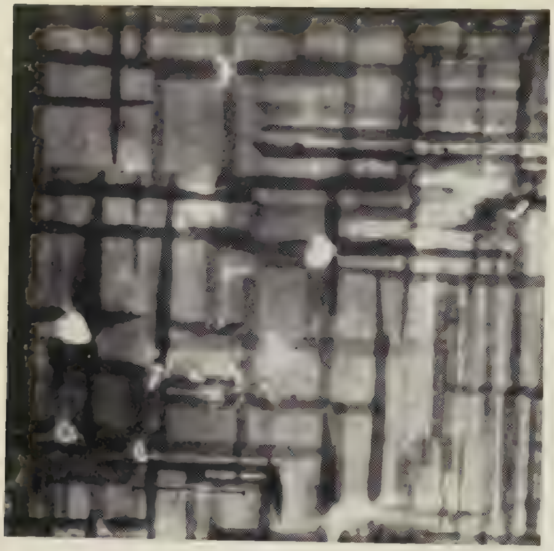

Photo. 5. Electron micrograph taken from a specimen aged at 200°C for 2 hours. This micrograph reproduces the same field as that in Photo. 3, showing the growth of precipitates.

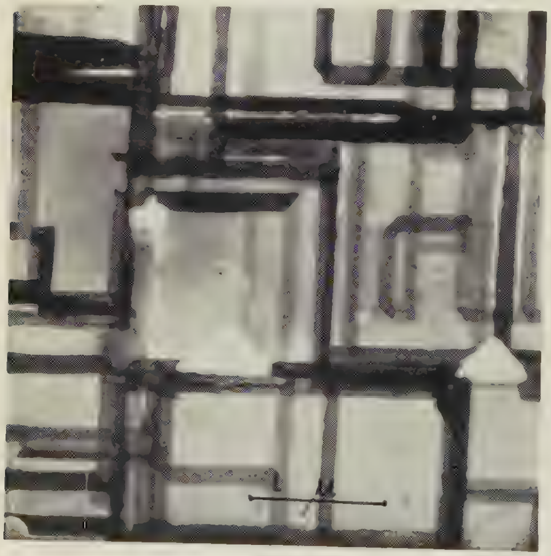

Photo. 6. Electron micrograph taken from a specimen aged at 250°C for 10 hours. Fine parallel striations are seen inside images of some precipitates.

to suggest that the streaks are extended actually along ⟨111⟩ directions in reciprocal space. That is to say, lamellae causing the streaks may be parallel with {111} planes. For the visibleness of ⟨111⟩ streaks on diffraction patterns of normal incidence the rotation of crystallites forming sub-grains and the bending of films may be responsible.

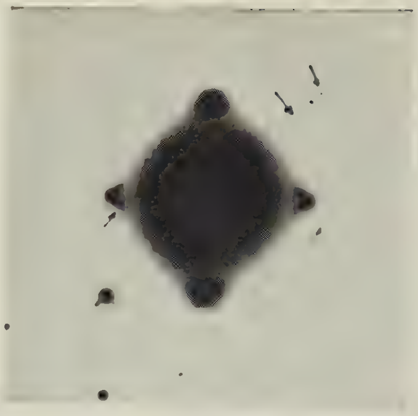

Photo. 7. Electron diffraction pattern corresponding to Photo. 6. The arrows indicate the diffraction spots due to the hexagonal phase.

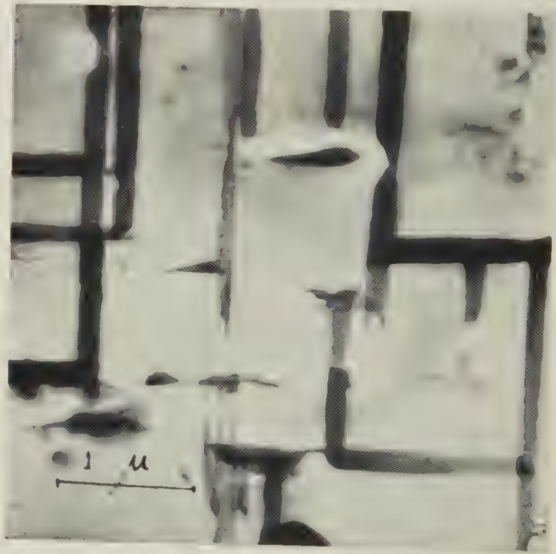

Photo. 8. Electron micrograph taken from a specimen aged at 400°C for 3 hours.

The following view will be held about the earliest stage of precipitation: The needle-like or narrow wedge-like precipitates are very thin lamellae which are formed coherently on the matrix {111} planes and grown preferentially along [110] or $[1\bar{1}0]$ direction. Their thickness may be estimated from the length of the streaks to be at most a few atomic layers, but their width on the {111} planes may be 100Å in the order of magnitude. This view is supported also by the fact that the above precipitates are further developed to plate-like precipitates with their planes parallel to the matrix {111} planes, as shown in Photo 5.

(ii) Aging above 200°C

The thin and narrow precipitates bellow 200°C gradually grow up with aging above 200°C to three-dimensional plates bounded by two {111} planes of the matrix and two film surfaces. Photo. 5, 6, 7 and 8 show electron micrographs and a diffraction pattern in this precipitation stage. The distribution density of precipitates attains maximum after aging at 200°C for 2∼4 hours and decreases with further increase of aging temperature and time. The orientation relationship between precipitates and the matrix can be determined from diffraction pattterns as follows:

$$(111)_{\mathrm{matrix}}//(0001)_{\mathrm{hexagonal}}\ ,$$
$$[110]_{\mathrm{matrix}}//[11\bar{2}0]_{\mathrm{hexagonal}}\ .$$

The thickness of the precipitates along their c axis reaches maximum after 250°C aging. The precipitates exhibit a fairly good habit below this temperature, but above 300°C they begin to dissolve again into the matrix, which causes both ends of their rod to be deformed to a V shape and, at the same time, causes their thickness to be diminished. Behavior of diffraction spots from hexagonal precipitates with increasing temperature just corresponds to the changes of electron micrographs; that is to say, their intensity reaches maximum after 200°C aging and their sharpness increases until 250°C aging. Above the latter temperature the intensity of the diffraction spots from hexagonal precipitates is decreased in spite of the unchanged sharpness of the spots. It is remarkable that the axial ratio of the precipitates changes with aging from 1.63_3 to 1.59. The axial ratio of an ideally close-packed hexagonal lattice, 1.633, was found in the precipitates formed after aging at 200°C for 4 hours (Photo. 5). The measured value was $1.63_3 \pm 0.007$. It decreases to $1.61_2 \pm 0.005$ by 250°C aging and this value exactly corresponds to γ' phase. On further aging above 300°C the axial ratio changes to 1.59 ± 0.01 which nearly coincides with that of γ phase, 1.588.

§ 4. Discussion and Conclusion

It is the essential point of the present paper to confirm to what extent the direct observation throughout the whole aging process can be effectively carried out by electron microscopy and electron diffraction in an aluminium-silver alloy, using thin alloy films quenched by the method described in § 2. There have been many X-ray studies on the aging process of aluminium-silver alloys. According to them, the process can be classified into preprecipitation and true precipitation which are responsible, respectively, for low temperature age-hardening and high temperature age-hardening. The results of the present study will be discussed in the light of these X-ray studies, as follows.

As-quenched or low temperature aged (below 100°C) specimens do not exhibit in their electron micrographs any sign of true precipitation except at some of sub-grain boundaries where something looking like precipitates is seen, as indicated by the arrows in Photo. 1. There are only aggregates consisting of random distribution of minute dark spots inside sub-grains. It was impossible due to a low resolving power of the present electron microscope and due to a considerable thickness of the films to obtain a distinct information about individual shape and size of dark spots. According to Guinier *et al*6) and Gerold7), the formation of silver-rich spherical small clusters was concluded by X-ray small angle scattering in low temperature aging of super-saturated solid solution of aluminium-silver. Gerold10) showed only clusters with a radius more than 50Å to be responsible for low temperature age-hardening. According to him, a scattering angle, $2\theta_{\max}$, corresponding to maximum intensity of small angle scattering for spherical clusters with a radius of gyration, R, is proportional to $\lambda/2\pi R$. Owing to a very short wave-length of fast electron used in diffraction experiments, however, it is not too much to say that detecting small clusters by small angle scattering around the diffraction spot of Oth order, that is, around the direct spot is made impossible by a high halation in electron diffraction. The effect from clusters may be observed in general also around any diffraction spot of hth order, if they are coherent with the matrix lattice. There is actually seen tolerable diffuse scattering, but a similar one is visible also in diffraction pattern of single-crystalline evaporated films of pure metal. Therefore, true diffuse scattering caused by clusters cannot be distinguishable, being masked by the above scattering, even if it exists. If a culster were a stringlet or a platelet of minute size with its axis or plane of growth parallel to a special lattice plane of the matrix, a diffraction effect suggested by Geisler and Hill⁸⁾—a plane or a rod passing through a reciprocal lattice point—would emerge from diffraction spots including the direct spot. Any diffraction pattern, however, does not exhibit even a sign of the effect. That is to say, clusters may be spherical. The present electron-microscopic observations suggests that their radius is about 100Å.

The locally dense distribution of clusters is thought of as caused by annihilation of silver-laden dislocations inside sub-grains⁹⁾ and by condensation of silver atoms along dislocation loops due to migration of lattice vacancies. The arrows in *B* in Photo. 1 indicate the condensation of silver clusters along single dislocation loops. The existence of something looking like large precipitates along sub-grain boundaries in Photo. 1 resembles the fact found by Heidenreich⁹⁾ in lead-silver alloys. He tried to explain this phenomenon by mass transport of solute atoms by dislocations into grain boundaries. In the present evaporated films sub-grains may be considered to be more loosely connected with one another than in bulk crystals, and this may lead to quick growth of precipitates along sub-grain boundaries under strain-free condition. The thinner the films, the stronger this tendency will become. The fact²⁾,³⁾,⁵⁾ that evaporated films less than 500Å thick with patch-like structure gave always diffraction spots due to hexagonal precipitates in their diffraction patterns even immediately after quenching might be caused partly by the enhanced preferential precipitation at their loosely connected sub-grain boundaries, although the marked precipitation owes its origin largely to an incomplete quenching. A trial to examine whether diffraction spots arising from precipitates appeared immediately after the quenching by the present method or not was done in case of thinner films less than 500Å thick, but did not succeed, as they were all broken owing to the thinness. Generally speaking, the inside of sub-grains will remain super-saturated under an adequate quenching, if the sub-grain size is sufficiently large. On the other hand, a greater part of solute atoms will be diffused out into sub-grain boundaries and a depletion of the atoms inside sub-grains will form two phases in equilibrium with precipitates at boundaries, if the sub-grain size is considerably small and a quenching is inadequate.

X-ray studies on true precipitation, especially on its early stage, was fully done by Köster *et al*¹⁰⁾. Hardy and Heal¹¹⁾ tried to express the development of true precipitation in terms of the following process, chiefly based on the results of Köster *et al*:

Stacking faults in the matrix
  → lamellae of γ' phase
  → three dimensional γ' phase → γ phase

The present results obtained on thin films above 165°C can be expressed in the following way:

Stacking faults in the matrix
  → needle-like or narrow wedge-like γ'' precipitates → lamellae of γ'' precipitates
  → three dimensional γ'' precipitates
  → γ' phase → γ phase

The precipitates denoted by γ'' mean those having the axial ratio of 1.633 characteristic of an ideal hexagonal close-packed lattice.

The face-centred cubic lattice of the matrix is thought of as a sequence of (111) plane,⋯⋯ ABCABCABC⋯⋯. Solute atoms may be diffused into stacking faults such as⋯ABCAC-ABC⋯ formed in the lattice, and thus extremely thin embryos of precipitates are formed, the ideal axial ratio, 1.633, being held. Among possible growing directions of embryos lying on (111) plane, $[\bar{1}10]$, $[\bar{1}01]$ and $[01\bar{1}]$ directions on this plane may be most favorable, because the best coherency can be obtained on the plane and the atomic registry is easiest to be held along the closest-packed directions, ⟨110⟩. The work necessary to add solute atoms to ends of growing embryos is least along these directions. The occurrence of strain field at embryo's ends favors atoms to be diffused here, and the longitudinal growth is still more accelerated, which leads to a needle-like or narrow wedge-like shape.

The axial ratio, 1.633, still persists until the beginning of three-dimensional growth. Thus, γ'' precipitates behave below 200°C as if they were most stable. However, they may be unable to increase so much their thickness that the axial ratio, 1.633, may be recognized by X-rays. This will make the difference between the X-ray results and the present results on the precipitation process, with that it is scarcely possible to distinguish between γ' lamellae and γ'' lamellae only from the streak on a diffraction pattern. Any precipitate with the ideal axial ratio has not so far been reported by X-ray studies. On the other hand, such a precipitate with the ideal axial ratio or with an axial ratio close to it has been found by Götsche⁵⁾ and Watanabe⁴⁾ in evaporated films by means of electron diffraction. It was detected from the beginning in the formation of their evaporated films, but not in the course of precipitation from a super-saturated solid solution. Its detection in thin films, however, may reasonably be understood just in the light of the present study.

As shown in Photo. 6, fine striations were sometimes seen inside images of precipitates. Such striations are often originated from stacking faults formed in face-centred cubic lattices,¹²⁾ as a result of dynamical interaction of electrons with faulted lattices, but the precipitation stage in which the present striations appeared was a considerably developed one, as seen from the diffraction pattern and the micrograph, and hence it is improbable that stacking faults caused them to occur. The striations are believed to be so-called "equal-thickness interference fringe" produced by dynamical interaction of electrons with the crystal lattice in a wedge-shaped part formed by precipitation, as often found in an image of a crystal with a regular habit such as magnesium oxide.¹³⁾⁻¹⁵⁾ Fig. 2 explains how the fringe can be produced by the intensity variation of electron beam along the incident direction in the wedge-shaped part of the precipitate lattice, A, if the responsible Bragg reflection occurs here. The fringe can be caused, however, also by the dynamical interference in the wedge-shaped part of the matrix lattice, B, in the same way, if the responsible Bragg reflection occurs here. The calculation shows that the spacing of the observed fringe may be obtained by either of the two explanations, and therefore, it can not be determined at present which lattice is responsible for the observed fringe. This point will be answered in a future report.

Dielectric Properties of Mixed Crystals of Barium-Strontium Titanate

By Shunkichi KISAKA, Seiji IKEGAMI and Hiromu SASAKI

Radio Department, Matsushita Electric Industrial Co., Ltd. Kadoma, Osaka

(Received April 15, 1959)

Mixed crystals of (Ba-Sr)TiO_3 containing up to about 10 mole per cent of Sr were grown in the same triangular plate shape as $BaTiO_3$ single crystals, and dielectric measurements were performed thereon. Up to 2.25 mole per cent Sr, the dielectric constant *vs* temperature (ε-T) curve near the cubic-tetragonal transition temperature maintains the same form as that of pure $BaTiO_3$, the peak value rising with increasing Sr content. Above 5.64 mole per cent Sr, however, the ε-T curve has a rounded peak and the peak value drops remarkably. The temperature of maximum dielectric constant decreases with increasing Sr content at a constant rate of 2.9°C per mole per cent in spite of this change. The Curie-Weiss temperature also drops with increasing Sr content at nearly the same rate, the difference between these two temperatures being held at about 20°C. The Curie constant also seems to decrease slightly with increasing Sr content. A comparison between the effect of replacing Ba with Sr and the effect of hydrostatic pressure on the transition temperature and the lattice constant suggests that the transition temperature depends mainly on the lattice constant of the tetragonal c-axis.

§ 1. Introduction

Many investigations[1)–6)] concerning the ceramics of (Ba-Sr)TiO_3 solid solution have been made in order to improve the dielectric and the piezoelectric properties of $BaTiO_3$ ceramics, or for other purposes. On the other hand, Remeika's method[7)] for growing $BaTiO_3$ single crystals in which potassium fluoride (KF) is used as a solvent and by which good plate-like crystals are obtained, has extensively and rapidly advanced the fundamental studies on $BaTiO_3$. In the course of our studies on ferroelectric crystals, preparations of mixed crystals with varying strontium (Sr) content from zero up to 10 mole per cent have been tried out by Remeika's method. As a result, the mixed crystals containing Sr of about 10 mole per cent were still found to be able to grow in the same triangular plate shape as does the pure $BaTiO_3$. Reports on the crystal containing Sr of more than 10 mole per cent can be found indeed, but these are all on the "chunky" crystals, and there seems to have been no known case that plate-like crystals have been grown at 10 mole per cent Sr.

In this paper, the results of the dielectric measurements on our single crystals are reported, and compared with those on ceramics of (Ba-Sr)TiO_3 solid solution. The effect of substitution of Sr for barium (Ba) on the transition character is also compared with the influence of hydrostatic pressure on that of $BaTiO_3$ single crystal.

§ 2. Preparation of Crystals

Crystals have been grown by Remeika's method from the solution of 30 grams of mixture in a desired ratio of each powder of $BaTiO_3$ and $SrTiO_3$ in the solvent of 70 grams of KF[8)], using the compositions of solute and solvent as shown in Table I. When the Sr content in solute is increased above 8 mole per cent, crystals having the shape of trian-

gular plates (plate-like crystals) tend to decrease in number, but even in the case of BS–6 (Table I), which contains 10 mole per cent Sr, plate-like crystals having one side of more than 10 mm length could still be grown in pairs. So-called "chunky" crystals also grew at the same time. Chemical and X-ray analyses have been performed on both forms of crystals, but only the plate-like crystals have been used in the measurement of the dielectric properties.

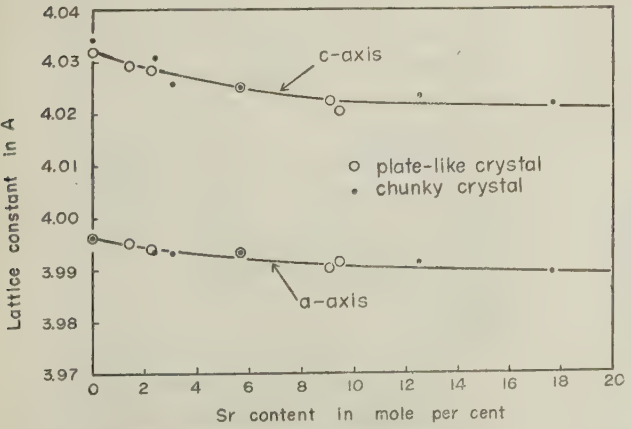

Fig. 1. The variation of lattice constant against Sr content.

§ 3. Chemical and X-ray Analyses

Molar percentage of Sr contained in crystals grown, according to the results of chemical analyses, are shown in Table II. Content of Sr in plate-like crystals is in general smaller than that in the original solute. But in chunky crystals, much more Sr was sometimes found therein than in the solute. Therefore, Sr content in the crystal could not be estimated from that in the solute. On the other hand, content of undesirable elements was found to be very little (less than 0.1 per cent in total), and the spectroscopic analyses, too, showed only faint traces of these impurities.

Moreover, lattice constants of plate-like and chunky crystals were measured by X-ray spectrometer at room temperature (30±2°C). These results are shown in Table III.

Fig. 1 shows the lattice constants of the tetragonal axes of these crystals plotted against Sr content obtained by chemical analyses. Both lattice constants decrease at the same rate with increasing Sr content. This figure will be used to obtain a relation between the Curie temperature and the lattice constant.

§ 4. Dielectric Properties

Only plate-like crystals have been used in measurements of the dielectric properties, since our chunky crystals had small sizes and irregular shapes. Measurements were performed mainly on the dielectric constant-temperature characteristics near the cubic-tetragonal transition temperature. From these measurements, the transition temperature, thermal hysteresis, and discontinuity were obtained as function of Sr content, and the Curie-Weiss temperature and the Curie constant were obtained either graphically or by calculations. Three to five crystals were selected from each group for these measurements.

(1) Method of Measurement of the Dielectric Constant-Temperature Characteristics.

Silver electrodes with guard rings

were evaporated on each crystal in vacuum. Diameter of the guarded electrode is 1.5 to 1.9 mm, the inner diameter of the guard electrode 2.2 to 2.8 mm, and the outer diameter of the guard electrode and the diameter of unguarded electrode are about 4.5 mm. Thickness of crystals is 0.065 to 0.44 mm. Fig. 2 shows the block diagram of the circuit for measuring the electric capacity-temperature characteristics. As shown there, the temperature of the crystal was measured by an iron-constantan thermocouple attached to the guard electrode, its output being fed to the X-axis input terminals of the X-Y recorder. A D.C. voltage proportional to the electric capacity of the specimen was fed to the Y-axis input terminals of the recorder. Thus the dielectric constant-temperature characteristics were automatically recorded by changing slowly the temperature of the specimens.

(2) Results of Measurements and Calculations.

In Fig. 3 is shown the most representative among the dielectric constant-temperature curves of the crystals of each group near the transition temperature. These curves actually show thermal hysteresis at the transition temperature (shown in the curve of BS-3 as an example), and the differences between the temperature of maximum dielectric contant in rising temperature and that in falling temperature are 2 to 4°C. Curves in Fig. 3 show only for decreasing temperature, except for BS-3 which shows both heating and cooling curves.

As is seen in Fig. 3, the characteristic curves for the specimens of BS-2 and BS-3 have similar shapes to that of BS-1 (pure $BaTiO_3$), that is, these curves drop discontinuously at the transition temperature, and the maximum value of the dielectric constant increases with increasing Sr content. But in the specimens BS-4, BS-5 and BS-6, containing more Sr, the discontinuity at the transition temperature disappears and the maximum value also drops, showing an obvious difference from the former. Therefore, it may be said that there is a limit in Sr content below which the transition character of crystal is very little influenced by the substitution of Sr for Ba, but above which it is considerably done. So far as our

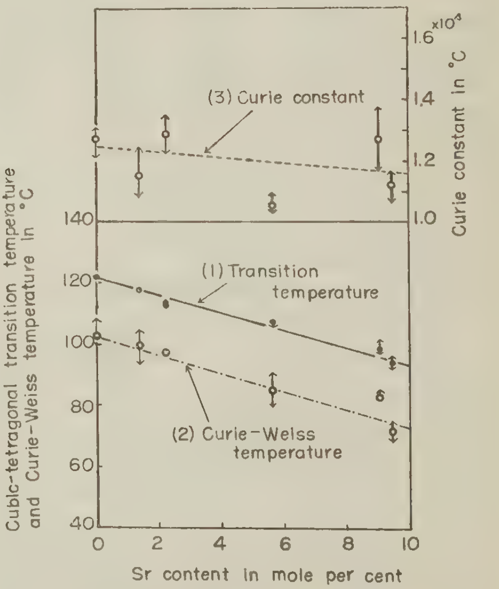

Fig. 4. Variations of the transition temperature, the Curie-Weiss temperature, and the Curie constant with increasing Sr content.

crystals are concerned, this limiting point must lie within 2.25 to 5.64 mole per cent. In the previous reports on ceramics or single crystals of (Ba-Sr)TiO_3 solid solution, this transition from discontinuous to rounded curve have been little noticed because of large rate of change of Sr content in preparation of specimens.

The transition temperature, defined as the temperature of maximum dielectric constant for decreasing temperature, decreases linearly with increasing Sr content, as shown in the curve (1) in Fig. 4. The arrows accompanying each point show the range of the measured values. The rate is estimated as 2.9°C per mole per cent within the range examined.

The average values of the Curie-Weiss temperature and the Curie constant, obtained from the reciprocal dielectric constant *vs.* temperature curve, are shown, respectively, in curves (2) and (3) of Fig. 4. The Curie-Weiss temperature also decreases with increasing Sr content, but in the range of our measurements, the difference between the transition and the Curie-Weiss temperature remained nearly constant independent of Sr content.

The Curie constant also seems to decrease slightly with increasing Sr content, but the values measured show a wide range of variation even among crystals of the same group, so that no definite conclusion can be drawn.

§ 5. Discussion

From the change of the shape of the dielectric constant-temperature curve and the shift of the transition temperature with Sr content mentioned above, it will be concluded that:

(a) Up to about 10 mole per cent Sr, essential character of the transition in the dielectric properties is scarcely influenced.

(b) The substitution of Ba by Sr take place in the form of a homogeneous solid solution up to 2.25 mole per cent.

(c) For Sr content of above 5.64 mole per cent, the crystal is supposed to be in the state of inhomogeneous solid solution, although no localization of constituents could be detected by our X-ray analyses, and because of this inhomogeneity, the dielectric behavior is averaged over a whole crystal, and consequently the dielectric constant-temperature curve has a rounded peak.

In our case, the transition from the homogeneous to the inhomogeneous solid solution occurred somewhere between 2.25 and 5.64 mole per cent Sr. However, it may be possible for this transition to shift to more Sr content by changing some of the conditions in the preparation of crystal.

The shift of the cubic-tetragonal transition temperature in ceramics containing Sr more than 10 mole per cent has been reported by many workers with, however, widely varying results, for instance, S. Sawada *et al*[1]. gave 2.9, D. F. Rushman *et al.*[2] 3.0, W. Jackson *et al.*[3] 3.9, and W. B. Westphal[4] 1.8°C per mole per cent.

The measurements on chunky crystals gave a decrease of Curie temperature of about 3.4[9] and 2.0[10] °C per mole per cent. In general, composition of crystal is different from that of solute, so that it is probable that these results on chunky crystals need to be corrected for Sr content. Though our measurements on the plate-like crystals are not of wide range, it is plausible that the rate of the shift of the transition temperature in (Br-Sr)TiO_3 system is 2.9°C per mole per cent.

Merz[11] observed the influence of hydrostatic pressure upon the transition temperature in $BaTiO_3$ single crystal and compared it with the effect of (Ba-Sr)TiO_3 solid solution. Namely, on the basis of the fact that the application of hydrostatic pressure and the replacement of Ba by Sr in $BaTiO_3$ had likewise the effects of both decreasing the lattice constant and lowering the transition temperature, he calculated the change of the transition temperature with lattice constant for each case, and obtained 3.3×10^3°C Å^{-1} from hydrostatic pressure and of 2.8×10^3°C Å^{-1} from ceramics of solid solution, in quite a good agreement with each other in spite of its simple treatment.

Let us now make similar calculations from a slightly different aspect. Using the results on our crystals (Fig. 1 and 4), the changes of the transition temperature are evaluated against the rates of decrease of:

(a) lattice constant a

(b) lattice constant c

(c) volume a^2c

Similar evaluations are made for the result of hydrostatic pressure, using the elastic compliances s^E of $BaTiO_3$ single crystal by Berlincourt *et al.*[12]. The results are shown in Table IV. As shown therein, both results show good agreement only for the rate of change with respect to the c-axis. This would possibly suggest that the transition temperature depends mainly upon the lattice constant c, but not upon a.

Table IV. Rate of decrease of the transition temperature with change of the lattice constant. a, c and v indicate the lenght of a- and c-axis and the volume of a unit cell respectively, and θ is the transition temperature.

	Rate (°C)	
	substitution by Sr	hydrostatic pressure
$\Delta\theta/(\Delta a/a)$	2.06×10^4	12.45×10^4
$\Delta\theta/(\Delta c/c)$	1.19 〃	1.10 〃
$\Delta\theta/(\Delta v/v)$	0.55 〃	0.93 〃

Merz also reported a slight increase of the peak value of the dielectric constant by hydrostatic pressure, which is similar to our results for $(Ba\text{-}Sr)TiO_3$ mixed crystals with Sr content of up to 2.25 mole per cent. This is a further confirmation of the analogy between the effect of hydrostatic pressure and that of Sr content.

The difference between the transition and the Curie-Weiss temperture, obtained from measurements on many crystals ranging from pure specimens of $BaTiO_3$ to the specimens containing about 10 mole per cent Sr is 20°C. The values obtained by Drougard *et al.*[13] and other workers are about 10°C, only a half of ours. Reason for this discrepancy is not clear.

The Curie constant of pure $BaTiO_3$ single crystal (BS–1 in our case) is 1.27×10^4°C (C.G.S.) in average, in fairly good agreement with that by Merz[14] (1.35×10^4) and by Drougard *et al.*[13] (1.38×10^4°C). It decreases slightly with increasing Sr content, but confirmation of this tendency should await further study, perhaps after growing the plate-like crystals containing more Sr if at all possible.

§ 5. Summary

(1) Mixed crystals of $(Ba\text{-}Sr)TiO_3$ containing Sr up to about 10 mole per cent have been grown in the same triangular shape as the crystal of $BaTiO_3$.

(2) Thermal hysteresis is generally 2 to 4°C.

(3) Below 2.25 mole per cent of Sr, the dielectric constant-temperature curve holds the same shape as that of pure $BaTiO_3$ near the cubic-tetragonal trasition, having a discontinuity, and the maximum of the dielectric constant increases with increasing Sr content. Above 5.64 mole per cent of Sr, the peak is rounded and the maximum value drops remarkably.

(4) The transition temperature decreases linearly at a rate of 2.9°C per mole per cent with increasing Sr content, in spite of the change of shape of the characteristic curve.

(5) The Curie-Weiss temperature also drops at nearly the same rate as the transition temperature, and the difference between these two temperatures is about 20°C.

(6) The Curie constant seems to decrease slightly with increasing Sr content.

(7) The transition temperature depends mainly on tetragonal c-axis.

Acknowledgement

The authors wish to express their sincere thanks to Dr. T. Suita, Dr. R. Kiriyama, and especially Dr. K. Yosida of Osaka University for their valuable suggestions. They are also indebted to Mr. C. Okazaki, Mr. S. Mori and Mr. F. Kanamaru in this Laboratory for their X-ray analyses, and to Mr. M. Itaya and Mr. N. Masaki for their help in the experiments.

Exciton Structures in Alkali Halides

By Yukio OSAKA

Physical Institute, Tohoku University, Sendai

(Received July 20, 1959)

Exciton structures in alkali-halides are analyzed according to the p^5d configurations based on the "transfer" model for exciton. The ratio of intensity of the absorption peak which is estimated from the p^5d configuration are calculated for some values of parameters. Qualitative comparison with the experimental facts are also given.

§ 1. Introduction

Recentry, the complicated structures of exciton in alkali-halides are found by the experiment on the optical absorption at lower temperatures. We shall investigate this structure from the view of atomic spectroscopy. Peterson(1) analyzed the ratio of intensity between the peaks corresponding to the doublet splitting. He used the atomic data of rare gas which is of isoelectronic configuration with the atoms constituting the crystal concerned. Recent experiments have revealed the many absorption peaks which do not correspond to the doublet splitting. Overhauser(2) calculated the number of absorption peaks which is predicted from the "transfer" model for the exciton. When we analyze the experimentally observed structure of exciton absorption, we need the number of absorption peaks and the ratio of intensity among these peaks which are estimated theoretically. We shall investigate the absorption peaks which do not correspond to the doublet splitting, by introducing the higher p^5d configuration. Although our treatment is carried out using the method of atomic spectroscopy, our analysis is based on the "transfer" model for the exciton.

§ 2. Exciton Structure

As mentioned above, experiments have shown that there appear the absorption peaks which have a splitting nearly equal to the doublet splitting in halogen atom and whose intensities are nearly equal. This experimental fact suggests that in exciton states which have an effect on the optical absorption, the spin-orbit interaction of a hole is larger than the exchange interaction between a hole and an electron. Peterson(1) estimated the ratio of the intensities of the lines corresponding to this splitting, by using the data of atomic spectra in rare gas. This treatment is implicitly based on the assumption that the optical absorption of an exciton is the atomic excitation in halogen ions. We shall assume that the spin orbit interaction of the hole is larger than the exchange interaction between the hole and the electron and investigate the absorption peaks which do not corresponds to the doublet splitting.

We introduce the higher p^5d configuration which is allowed in the optical transition from the ground state p^6. In cubic crystals, d orbits split in $d\varepsilon$ level and $d\gamma$ level. This splitting is large when crystalline electric field is large in case of the atomic d level in solids. In case of an exciton, another effect determine predominantly the splitting between $d\varepsilon$ and $d\gamma$. This effect occurs in the "transfer" model for an exciton. If the energy of empty

p orbit on the alkali-ion is much higher than that of empty s orbit, the electron on the halide-ion transfers only to s orbit on the alkali-ion. In such a case, the L.C.A.O. wave function constructed only from the transferred s orbit includes the wave function having the $d\gamma$ character in the crystals of NaCl-type structure and $d\varepsilon$ in the crystal of CsCl-type structure, as Overhauser[2)] showed. Therefore, the main factor determining the splitting between $d\varepsilon$ and $d\gamma$ is the difference of energy between s-orbit and p-orbit on the alkali-ion. The effect of crystalline fields for the electron is smaller in the "transferred" model for an exciton, because the largest contribution to the crystalline field arises from the next-nearest ions and the crystalline field is cubic. But the approximation which takes into account the s-orbit only as Overhauser did does not seems to hold in the alkali-halide crystal. In the first approximation, the wave function of the electron in the exciton states is similar to that of the trapped electron in case of the F-center. The experimental and theoretical investigations[3)] for the F-center showed that the ground-state wave function of the F-center is constituted by the s-orbit and p-orbit in nearly equal proportion. It seems to be reasonable that similar situation exists in the exciton states. Therefore, we assume that the energy of $d\varepsilon$ level and $d\gamma$ level are nearly equal, that is, we can use the approximately degenerate d level. But, this "d level" mainly makes up the electron transferred orbit rather than the orbit of intra-atomic excitation. Therefore, the following treatment is based on the "transferred" model for the exciton. On the "excitation" model for the exciton, we cannot neglect the effect of the crystalline electric field even approximately.

The ground state S_0 has the p^6 configuration. According to the selection rule, the pure states to which the optical transition is allowed are ${}^1P_1(p^5s)$ and ${}^1P_1(p^5d)$, leaving the higher configurations out of account.

At first, we neglect the exchange interaction between the electron and the hole and consider, in addition to the Coulomb interaction between them, only the spin orbit interaction of the hole. Diagonal energy for the electrostatic energy is given in the following.

$$\left.\begin{aligned} &{}^1P_1(p^5s)\,,\quad {}^3P_1(p^5s)=-F_0 \\ &{}^1P_1(p^5d)\,,\quad {}^3P_1(p^5d)=-F_0'-7F_2'+\varDelta \\ &\qquad\qquad\quad\; {}^3D_1(p^5d)=-F_0'+7F_2'+\varDelta\,, \end{aligned}\right\} \quad (1)$$

where $\varDelta$ denotes the difference of energy between s-function and d-function for the electron and F_0, F_0' and F_2' are derived from the following F^0, $F^{0\prime}$, $F^{2\prime}$ in the same way as T.A.S.[8)], they are all positive quantities. Where

$$F^0=\iint P_s^2(r_1)Q_p^2(r_2)\alpha^0(r_1r_2)\,d\tau_1\,d\tau_2$$

$$F^{0\prime}=\iint P_d^2(r_1)Q_p^2(r_2)\alpha^0(r_1r_2)\,d\tau_1\,d\tau_2$$

$$F^{2\prime}=\iint P_d^2(r_1)Q_p^2(r_2)\alpha^2(r_1r_2)\,d\tau_1\,d\tau_2\,.$$

$P(r_1)$ denotes the radial part of the wave function multiplied by radius for the electron and $Q(r_2)$ denotes the one for the hole. $\alpha^k(r_1r_2)$ is given by

$$\alpha^k(r_1r_2)=\begin{cases} r_1^k/r_2^{k+1} & r_1<r_2 \\ r_2^k/r_1^{k+1} & r_2>r_1 \end{cases}$$

and

$$F_2'=F^{2\prime}/35\,.$$

From these value, we get the following matrix of energy for the five atomic terms.

$$\left.\begin{array}{cccccc} & {}^1P_1(p^5s) & {}^3P_1(p^{53}) & {}^1P_1(p^5d) & {}^3P_1(p^5d) & {}^3D_1(p^5d) \\ {}^1P_1(p^5s) & -F_02 & 2\sqrt{2}\,\lambda & A & 0 & 0 \\ {}^3P_1(p^5s) & 2\sqrt{2}\,\lambda & -F_0+2\lambda & 0 & A & 0 \\ {}^1P_1(p^5d) & A & 0 & \varDelta-F_0'-7F_2' & \sqrt{2}\,\lambda & \sqrt{6}\,\lambda \\ {}^3P_1(p^5d) & 0 & A & \sqrt{2}\,\lambda & \varDelta-F_0'-7F_2'-\lambda & \sqrt{3}\,\lambda \\ {}^3D_1(p^5d) & 0 & 0 & \sqrt{6}\,\lambda & \sqrt{3}\,\lambda & \varDelta-F_0'+7F_2'+\lambda\,. \end{array}\right\} \quad (2)$$

λ is the constant determined by the spin orbit coupling. If we consider the (p^5s) configuration, the doublet splitting ξ is related to λ by

$$\lambda=\xi/6\,.$$

A is the nondiagonal coulomb interaction between ${}^{1,3}P_1(sp^5)$ and ${}^{1,3}P_1(dp^5)$. This term has been calculated making use of the formula given by Racah[4]. The non-vanishing term is the term including the following $F^{1''}$ because of symmetry.

$$F^{1''}=\iint P_s(r_1)P_d(r_1)\alpha^1(r_1r_2)Q_p{}^2(r_2)\,d\tau_1\,d\tau_2\,.$$

But the multiplicative factor for $F_1{}^{1''}$ is shown to be zero, using the formula of Racah[4]. Then, matrix (2) is reduced into two parts. The part for the (p^5d) configuration is

$$\Delta-F_0'-7F_2'+\begin{pmatrix} 0 & \sqrt{2}\lambda & \sqrt{6}\lambda \\ \sqrt{2}\lambda & -\lambda & \sqrt{3}\lambda \\ \sqrt{6}\lambda & \sqrt{3}\lambda & \lambda+14F_2' \end{pmatrix}. \tag{3}$$

The part for the (p^5s) configuration is

$$-F_0+\begin{pmatrix} 0 & 2\sqrt{2}\lambda \\ 2\sqrt{2}\lambda & 2\lambda \end{pmatrix}. \tag{4}$$

We shall calculate the energy and the wave function given by the matrix (3). In order to solve matrix (3), we transform it by the orthogonal transformation matrix T.

$$T=\begin{pmatrix} 1/\sqrt{3} & 1/\sqrt{6} & -1/\sqrt{2} \\ 1/\sqrt{3} & -\sqrt{2/3} & 0 \\ 1/\sqrt{3} & 1/\sqrt{6} & 1/\sqrt{2} \end{pmatrix}.$$

Then, matrix (3) transforms into the following matrix.

$$\lambda\begin{pmatrix} -2+\dfrac{\alpha}{2} & 0 & -\dfrac{\alpha}{2} \\ 0 & -2 & 0 \\ -\dfrac{\alpha}{2} & 0 & 4+\dfrac{\alpha}{2} \end{pmatrix}.$$

where

$$\alpha\equiv 14F_2'/\lambda\,.$$

From this matrix, we obtain the eigenvalue and the eigenfunction of (3) as follows.

eigenvalue	eigenfunction	
-2λ,	$\dfrac{1}{\sqrt{3}}{}^1P_1-\sqrt{\dfrac{2}{3}}{}^3P_1$,	(5a)
$\lambda\dfrac{(2+\alpha)+\sqrt{\alpha^2+36}}{2}$,	$\cos\theta\left(\dfrac{1}{\sqrt{3}}{}^1P_1+\dfrac{1}{\sqrt{6}}{}^3P_1-\dfrac{1}{\sqrt{2}}{}^3D_1\right)$ $-\sin\theta\left(\dfrac{1}{\sqrt{3}}{}^1P_1+\dfrac{1}{\sqrt{6}}{}^3P_1+\dfrac{1}{\sqrt{2}}{}^3D_1\right)$,	(5b)
$\lambda\dfrac{(2+\alpha)-\sqrt{\alpha^2+36}}{2}$,	$\sin\theta\left(\dfrac{1}{\sqrt{3}}{}^1P_1+\dfrac{1}{\sqrt{6}}{}^3P_1-\dfrac{1}{\sqrt{2}}{}^3D_1\right)$ $+\cos\theta\left(\dfrac{1}{\sqrt{3}}{}^1P_1+\dfrac{1}{\sqrt{6}}{}^3P_1+\dfrac{1}{\sqrt{2}}{}^3D_1\right)$,	(5c)

where

$$\mathrm{coo}\,\theta=\sqrt{\frac{1}{2}+\frac{3}{\sqrt{\alpha^2+36}}}\,,\qquad \sin\theta=\sqrt{\frac{1}{2}-\frac{3}{\sqrt{\alpha^2+36}}}\,, \tag{6}$$

Since the ground state is the $S_0(p^6)$ configuration, the ratio of intensity arising from the transitions to the above levels is given by

$$1:(\cos\theta-\sin\theta)^2:(\cos\theta+\sin\theta)^2\,. \qquad (7)$$

The difference of energy among these levels and the ratio of intensity are calculated for some values of α. In Fig. 1, we plot this result. The line due to the transition to the level which is mainly constructed by the $^3D_1$ term is omitted, because the intensity of this level must be very weak. Since we do not know the difference between the average energy of the p^5s configuration and that of the p^5d configuration, we slide Fig. 1 as compared with the observed doublet splitting and compare this expected ratio of intensity and the positions of the lines with the observed peaks which do not correspond to the doublet splitting. Martienssen's[6] experiment for CsI and Teegarden's[7] experiment for KI are qualitatively similar to the case $\alpha \gtrsim 10$ and the case $\alpha \lesssim 5$, respectively. But the expected ratio of intensity is larger than the experimental value in case of KI.

Next, we shall take into account the effect of exchange interaction between the electron and the hole. The energy of p^5d configuration including the exchange interaction is given by Condon-Shortley[8]. This result is as follows;

$$^3D_1=-F_0'+7F_2'$$
$$^3P_1=-F_0'-7F_2'$$
$$^1P_1=-F_0'-7F_2'+20G_1'$$

G_1' is the energy of exchange corresponding to F_1'. From this we obtain the matrix of energy for the p^5d configuration as follows:

$$\Delta-F_0'-7F_2'+\lambda\begin{pmatrix} \gamma & \sqrt{2} & \sqrt{6} \\ \sqrt{2} & -1 & \sqrt{3} \\ \sqrt{6} & \sqrt{3} & 1+\alpha \end{pmatrix},$$

where

$$\gamma\equiv 20G_1'/\lambda\,.$$

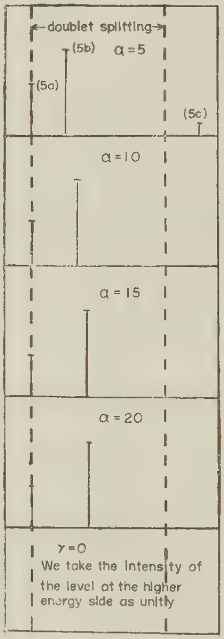
Transforming this matrix by the above orthogonal transformation matrix T, we get

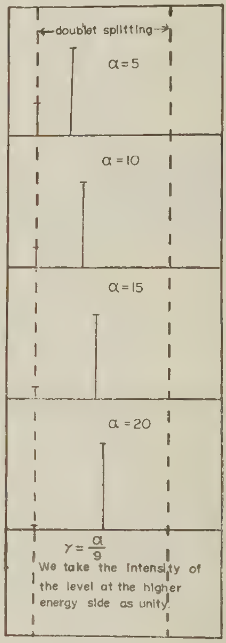
$$\lambda\begin{array}{c} \begin{array}{ccc} \quad {}^3P_1 \quad & \quad {}^3D_1 \quad & \quad {}^1P_1 \quad \end{array} \\ \begin{pmatrix} -2+\frac{1}{3}(\alpha+\gamma) & -\frac{\alpha}{2}+\frac{\gamma}{3} & \frac{\gamma}{3} \\ -\frac{\alpha}{2}+\frac{\gamma}{3} & 4+\frac{\alpha}{2}+\frac{\gamma}{3} & \frac{\gamma}{3} \\ \frac{\gamma}{3} & \frac{\gamma}{3} & -2+\frac{\gamma}{3} \end{pmatrix} \end{array}. \qquad (9)$$

For $\gamma \ll \alpha$, we can omit the nondiagonal term $\gamma/3$ in the first approximation.

The parts of the matrix for the $^3P_1$ and $^3D_1$ configuration is written

$$\begin{pmatrix} -2+\frac{\alpha}{3}+\frac{\gamma}{3} & -\frac{\alpha}{2}+\frac{\gamma}{3} \\ -\frac{\alpha}{2}+\frac{\gamma}{3} & 4+\frac{\alpha}{2}+\frac{\gamma}{3} \end{pmatrix}$$
$$=\frac{\gamma}{3}+\begin{pmatrix} -2+\frac{\alpha}{2} & -\frac{\alpha}{2}+\frac{\gamma}{3} \\ -\frac{\alpha}{2}+\frac{\gamma}{3} & 4+\frac{\alpha}{2} \end{pmatrix}.$$





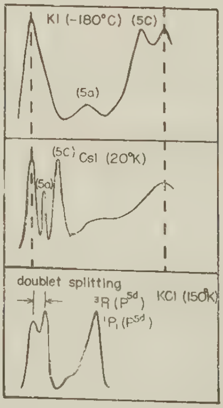


Fig. 1. Case of omitting the exchange interaction.

Fig. 2. Exciton absorption.

Fig. 3. Case of taking into account the exchange interaction.

Since the difference of the energy between the $^3P_1$ level and $^3D_1$ level is large, we omit $\gamma/3$ in the nondiagonal part of the above matrix. Then, we take as the unperturbed states the state of which the energy is determined by the matrix

$$\frac{\gamma}{3}+\begin{pmatrix} -2+\frac{\alpha}{2} & -\frac{\alpha}{2} \\ -\frac{\alpha}{2} & 4+\frac{\alpha}{2} \end{pmatrix} \quad \text{and} \quad -2+\frac{\gamma}{3}\,.$$

If the effect of the nondiagonal term $\gamma/3$ is taken into account as the perturbation between those states, we obtain the following results. The energy difference of the peaks which were shown in Fig. 1, is now modified to

$$\lambda\left(\frac{(2+\alpha)-\sqrt{\alpha^2+36}}{2}+2+\frac{2\gamma}{3}B\right),$$

where

$$B\equiv\gamma/3\bigg/\frac{(2+\alpha)-\sqrt{\alpha^2+36}}{2}+2\,.$$

The ratio of intensities of these peaks is

$$(1-B(\cos\theta+\sin\theta))^2 : ((\cos\theta+\sin\theta)+A)^2\,.$$

The results are shown in Fig. 3, where the parameter γ is set to the value $\alpha/9$.

The fact that the ratio of the intensity of the peaks decreases than in the case where the exchange interaction is omitted, is qualitatively similar to the experimental result of KI. Therefore, we can assign the peaks in KI and CsI to the perks due to the p^5d configuration as is shown in Fig. 2.

§ 3. Discussions

According to the experiment by Teegarden[7], the main feature of the absorption spectrum on KI and NaI is nearly similar. The exciton structures in Hartman's[9] experiment for NaCl and KCl are sketched in Fig. 2. The discussion in the preceeding section suggests that the experiment for NaCl and KCl may be the case $14F_2'\gg\xi\gg 20G_1'$. When $\alpha=14F_2'/\lambda$ is large, the doublet splitting in the p^5d configuration is at most half of that in the p^5s configuration. Therefore, the peak in the higher energy side seems to be the doublet splitting corresponding to the p^5d configuration, whose splitting is too small to be observed at present. From this speculation and the discussion in the preceeding section, it is expected that the parameters F_2', G_1' and ξ have the following relations in each crystals.

In KI (and similar iodide)

$$14F_2'\sim\frac{15}{6}\xi\,,\qquad 20G_1'\sim\frac{14F_2'}{9}\,.$$

In CsI

$$14F_2'\sim\frac{5}{6}\xi\,,\qquad 20G_1'\ll\frac{14F_2'}{9}\,.$$

In NaCl (and KCl)

$$14F_2'\gg\xi\gg G_1'\,.$$

we shall compare these relations with the atomic data of rare gas which has the isoelectronic configuration to the halide ions of the crystal. The intra-atomic excitation of the $2p^53d$ configuration in NeI has the following values according to T.A.S.[8].

F_2'	G_1'	$\xi/1.5$	$\xi/1.5$ (ionic)
15.50	2.98	530.11	521 (unite cm^{-1})

(ionic) denotes the doublet splitting of neon in the ionic configuration. This quantity corresponds to the doublet splitting in the neutral halide of the exciton. The ration F_2'/ξ for the exciton, which is predicted by our analysis, is larger than that of the data in neon. Since the transferred orbit in the alkali-ion has a smaller energy than the intra-atomic excitation in the halogen ion, this fact is understood. The larger values of F_2'/ξ for the exciton are understood. The tendency that F_2' decreases when the energy becomes larger, is confirmed experimentally by the fact that, in Neon I, the values of F_2' are 15.50, 6.60, 3.62 (cm^{-1}), respectively, in case of the excitation p^53d, p^54d, p^55d.

Experimentally, the intensities of the components of the doublet in the exciton which corresponds to that of the neutral halogen atom are nearly equal. These lines are due to the p^5s cofiguration. In case of the atomic spectrum of rare gas, the intensities in KrI are nearly equal. In this case, $G_1\sim 0.150\xi$. where G_1 is the quantity in the p^5s configuration corresponding to G_1' in the p^5d configuration. Therefore, this ratio between G_1 and ξ in the p^5s configuration seems to be reasonable in the p^5s configuration of an exciton. Taking the above estimated value of G_1', the ration $G_1'/G_1\sim 0.10$ in case of KI. In Neon I, in the p^53d configuration $G_1'/\xi\sim 0.4\times10^{-2}$ and in the p^53s configuration $G_1/\xi\sim 2$. From these values $G_1'/G_1\sim 0.2\times10^{-2}$.

Therefore, the value G_1'/G_1 in the exciton of KI is larger than that of the atomic excitation in rare gas. Taking a view-point of the "transfer" model the wave functions in the $p^5 3s$ configuration and in the $p^5 3d$ configuration are not radically different as in the case of the intra-atomic excitation. Then, the large value G_1'/G_1 in the exciton can be understood on the "transfer" model for the exciton.

In our analysis, the difference of the absorption curve in KI and CsI is attributed to that of the magnitude of F_2'/ξ. This difference of F_2'/ξ may be due to that of the transferred orbit or the crystal structure.

Finally, we discuss the approximation neglecting the crystalline electric field for the transferred orbit, which comes from the next-nearest neighbour and the more distant neighbour. According to Bethe[10], the energy difference between $d\varepsilon$ orbit and $d\gamma$ orbit is given by

$$E(d\gamma)-E(d\varepsilon)=\frac{10}{21}D\langle r^4\rangle_{\text{av}}$$

where $\langle r^4\rangle_{\text{av}}$ denotes the average by the transferred orbit and

$$D=-(7e/8)\sum_j{}'(l_j/R_j^9)(5Z_j^4-R_j^4)$$

and l_j, R_j and Z_j are the charge, the distance from the origin and the Z-coordinate of the j-th ion, respectively. If the summation over the nearest neighbours and the more distant neighbours of D is expressed by D' and that over the next-nearest neighbour and the more distant neighbours is expressed by D'', we obtain

$$D'=-3.580e^2/a^5\ ,\quad D''=-0.080e^2/a^5$$

for the crystal of NaCl-type,

$$D'=+9.323e^2/a^5\ ,\quad D''=+2.936e^2/a^5$$

for the crystal of CsCl-type,

where a is the lattice constant.

In our model, D'' determines the effect of the crystalline electric field. From the above value of D'' we can neglect this effect for the crystal of NaCl type, because the overestimation in which we put $a^4=\langle r^4\rangle$ yields about-0.02 e.V., for the $E(d\varepsilon)-E(d\gamma)$, using the typical value of a. However, since the value D'' for the crystal of CsCl type is comparable with D', it seems that the crystalline electric field may have some effect on the absorption curve in CsI even on the "transferred" model for the exciton.

The author wish to express his cordinal thanks to his colleagues of the Physical Institute. Tôhoku University, for stimulating discussions. The present work was partially financed by the Scientific Research Fund of the Ministry of Education.

Acoustoelectric Effect in Metals

By Nobuo MIKOSHIBA

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received July 27, 1959)

A classical Boltzmann theory is given of the acoustoelectric effect in monovalent metals, using Pippard's approach to the ultrasonic absorption by conduction electrons. Weinreich's phenomenological relation between the acoustoelectric effect and the ultrasonic absorption holds in all frequency ranges for both longitudinal and transverse ultrasonic waves. For longitudinal waves in the intermediate and high frequency ranges, the result is essentially identical with that derived from the quantum-mechanical calculation. The order of magnitude of the acoustoelectric effect in the low frequency range is smaller than Parmenter's result but larger than that obtained by Weinreich-Holstein's approach. A phenomenological theory is developed of the acoustoelectric effect due to electron transfer mechanism in polyvalent metals, the method of which can be applied also to many-valley semiconductors.

§ 1. Introduction

The theories of the acoustoelectric effect in metals have been developed by Parmenter[1] (hereafter denoted by P1), Van den Beukel[2] and the present author[3] in the *intermediate* and *high* frequency ranges, and by Parmenter[4] (hereafter denoted by P2), Weinreich[5] and Holstein[6] in the *low* frequency range. In the previous paper, we discussed that P1 seems deficient for several reasons and Van den Beukel's method may be applicable to real metals. In a recent paper, however, Weinreich et al.[7] have asserted that Van den Beukel's method cannot be correct because it neglects the effect of the space charge caused by ultrasonic waves. On the other hand, P2 and Weinreich-Holstein's approach lead to mutually conflicting results in the low frequency range.

The main object of this paper is to give a reasonable method for the calculation of the acoustoelectric effect in monovalent metals and to discuss Weinreich et al.'s assertion, P2 and Weinreich-Holstein's approach. We shall use the classical Boltzmann equation developed by Pippard[8] and Steinberg[9], of the ultrasonic absorption by conduction electrons, in which the effects of the space charge and the internal electric field are correctly taken into account. The important informations obtained in our theory are as follows:

1) Weinreich's phenomenological relation[10] between the acoustoelectric effect and the ultrasonic absorption holds in *all* frequency ranges for both longitudinal and transverse ultrasonic waves. Then the present author's argument[3] in the previous paper must be revised, which states that the other relation may exist in the low frequency range.

2) For longitudinal waves in the intermediate and high frequency ranges, the result is essentially identical with that derived from the quantum-mechanical calculation (Van den Beukel's method). Then we can conclude that Van den Beukel's method is suitable for the intermediate and high frequency ranges, and involves implicitly the effect of the space charge in the electron-phonon coupling constant.

3) For longitudinal waves in the low frequency range, the obtained result is smaller than that of P2 but larger than that obtained by Weinreich-Holstein's approach.

In § 2, we shall give a brief review of Pippard's theory in some modified form for later uses. In § 3 we shall calculate the acoustoelectric effect in monovalent metals. Comments on P2 and Weinreich-Holstein's approach are given in § 4.

In § 5, a phenomenological theory is developed of the acoustoelectric effect and the ultrasonic absorption due to electron transfer mechanism in polyvalent metals. This theory is also applicable to many-valley semiconductors in the low frequency range. In fact, this theory leads to Weinreich's formula[7] for n-Ge.

§ 2. Ultrasonic Absorption by Conduction Electrons

The Boltzmann equation of conduction electrons under the influence of acoustic waves[9] is given by

$$\frac{\partial f}{\partial t}+(\boldsymbol{v}\cdot\nabla)f+\frac{e}{m}(\boldsymbol{\varepsilon}\cdot\nabla_v)f=-\frac{f-f_0(|\boldsymbol{v}-\boldsymbol{u}|)}{\tau}\,, \qquad (2.1)$$

where $\boldsymbol{v}$ and $\boldsymbol{u}$ are the velocity of an electron and of lattice ions respectively, $\boldsymbol{\varepsilon}$ the internal electric field, τ the relaxation time and $f_0(|\boldsymbol{v}-\boldsymbol{u}|)$ the local equilibrium distribution function. The solution of (2.1) is approximated by

$$f=f_0(|\boldsymbol{v}-\boldsymbol{u}|)-\Psi(\boldsymbol{v})\cdot\partial f_0/\partial v\,, \qquad (2.2)$$

where $\Psi(\boldsymbol{v})$ has the physical meaning of the drift velocity, relative to the local equilibrium, of the electron with the velocity $\boldsymbol{v}$ (hereafter called electron $\boldsymbol{v}$) caused by acoustic waves. Unknown quantities $\boldsymbol{\varepsilon}$, n (nonequilibrium number density of electrons) and j (local current density) are determined by 1) the current expression by f, 2) Maxwell's equation and 3) the equation of continuity.

The absorption coefficient of acoustic waves is written as

$$A=2W/\rho V|u|^2\,, \qquad (2.3)$$

where ρ is the density of metals, V the sound velocity and W the absorbed energy by electrons per unit time and volume. W is given by the expression

$$W=\frac{1}{2}\,\mathrm{Re}\left[\sum_v\frac{E(v)}{\tau(v)}\cdot f'^*(v)\right] \qquad (2.4)$$

where $E(\boldsymbol{v})$ is the excess energy of the electron $\boldsymbol{v}$ from the local equilibrium value and $f'(\boldsymbol{v})$ is the deviation of f from the local equilibrium distribution. It is easily seen that

$$E(\boldsymbol{v})=m\boldsymbol{v}\Psi(\boldsymbol{v})\,,\quad f'(\boldsymbol{v})=-\Psi(\boldsymbol{v})\cdot\partial f_0/\partial v\,. \qquad (2.5)$$

In this connection, we can see that the electron $\boldsymbol{v}$ exerts the force

$$X'(\boldsymbol{v})=-m\boldsymbol{v}\Psi(\boldsymbol{v})/V\tau(\boldsymbol{v}) \qquad (2.6)$$

on acoustic waves, because the acoustic energy density $\frac{1}{2}\rho|u|^2$ suffers the energy loss $m\boldsymbol{v}\Psi(\boldsymbol{v})$ from the electron $\boldsymbol{v}$ in a distance $V\tau(\boldsymbol{v})$.

Inserting (2.4) and (2.5) into (2.3), we get Pippard's formula

$$A=\frac{3Nm}{4\pi\tau\rho V|u|^2}\int_0^\pi\int_0^{2\pi}|\Psi(\boldsymbol{v}_0)|^2\sin\theta d\theta d\phi\,, \qquad (2.7)$$

where we used the identity

$$\sum_v=\frac{2m^3}{h^3}\int v^2dv\sin\theta d\theta d\phi\,,$$

and N and $\boldsymbol{v}_0$ are the equilibrium number density and the Fermi velocity of electrons respectively.

§ 3. Acoustoelectric Effect in Monovalent Metals

The acoustoelectric effect F is defined as the *dc* electric field caused by acoustic waves under the open circuit condition. This definition is equivalent to that eF is the average *dc* force on electrons exerted by acoustic waves[7]. If we denote $X(\boldsymbol{v})$ as the force exerted by acoustic waves on the electron $\boldsymbol{v}$, we get

$$eF=\frac{1}{2N}\,\mathrm{Re}\,[\sum_v X(\boldsymbol{v})\cdot f'^*(\boldsymbol{v})]\,. \qquad (3.1)$$

From (2.6) we see

$$X(\boldsymbol{v})=-X'(\boldsymbol{v})=m\boldsymbol{v}\Psi(\boldsymbol{v})/V\tau(\boldsymbol{v})\,, \qquad (3.2)$$

using the principle of reaction. Then the formula

$$F=\frac{3m\gamma}{4\pi\tau\rho eV^2|u|^2}\int_0^\pi\int_0^{2\pi}|\Psi(\boldsymbol{v}_0)|^2\sin\theta d\theta d\phi \qquad (3.3)$$

is obtained, where $\gamma=\frac{1}{2}\rho|u|^2V$ is the acoustic energy flow density. Comparing (3.3) with (2.7), Weinreich's phenomenological relation

$$A=(NeV/\gamma)F \qquad (3.4)$$

is proved in general.

Making use of the calculation of A by Pippard, we get the following expressions in various cases:

1) Longitudinal Waves:

$$F=\frac{4mv_0{}^2\tau\omega^2}{15\rho eV^4}\cdot\gamma \quad \text{(low frequency range)}\,, \qquad (3.5)$$

$$F=\frac{\pi mv_0\omega}{6\rho eV^3}\cdot\gamma \quad \text{(intermediate and high frequency range)}\,. \qquad (3.6)$$

2) Transverse Waves:

$$F=\frac{mv_0{}^2\tau\omega^2}{5\rho eV^4}\cdot\gamma \quad \text{(low frequency range)}\,, \qquad (3.7)$$

$$F=\frac{4mv_0\omega}{3\pi\rho eV^3}\cdot\gamma \quad \text{(intermediate frequency range)}\,, \qquad (3.8)$$

$$F=\frac{m}{\rho eV^2\tau}\cdot\gamma \quad \text{(high frequency range)}\,, \qquad (3.9)$$

where ω is the angular frequency of waves.

The formula (3.6) is essentially the same as that derived from the quantum-mechanical calculation[2),3)], since the electron-phonon coupling constant has the order of magnitude of the Fermi energy. This fact implies that Van den Beukel's method involves the effect of the internal electric field in the electron-phonon coupling constant[11)].

It will be worth while to estimate whether the effect in metals can be detected experimentally at present. Since the maximum available frequency[12)] of ultrasonic waves may be $\nu=2.5\times10^9$ cyc/sec, we take, as an example, the purest sample of Cu at low temperatures; $\omega=1.6\times10^{10}$, $v_0=1.6\times10^8$ cm/sec, $\rho=9$ g/cm³, $V=5\times10^5$ cm/sec. Then, from (3.6) for longitudinal waves.

$$F\simeq10^{-8}\gamma\ ,$$

taking the units of F and γ as volt/cm and watt/cm² respectively. Therefore the experimental check may be expected in future.

As will be seen in the next section, we should remark that the formula (3.9) for *transverse* waves in the *high* frequency range is identical with Parmenter's result (4.3) for *longitudinal* waves in the *low* frequency range.

§ 4. Weinreich's and Parmenter's Approaches

Several years ago, Weinreich[5)] and Holstein[6)] calculated the acoustoelectric effect by *longitudinal* waves in the *low* frequency range in simple semiconductors, and got very small effect not detectable in experiments. In a recent paper[7)] (see § 5), Weinreich et al. have derived a correct formula in many-valley semiconductors, but have asserted, on the basis of the previous calculation[5),6)] that in metals the effect may be extremely small in virtue of the Coulomb repulsion between electrons. In fact, the straightforward application[4),6)] of Weinreich-Holstein's method to metals gives the small effect

$$F_1\simeq16\pi^4\left(\frac{\lambda_{FT}}{\lambda}\right)^4\cdot\frac{m}{\rho e\tau V^2}\cdot\gamma \tag{4.1}$$

with

$$\lambda_{FT}\equiv mv_0^2/12\pi Ne^2\ . \tag{4.2}$$

Here λ is the wave length of acoustic waves and λ_{FT} is the quantum analog to the Debye length in Fermi-Thomas model.

In a recent paper, Parmenter[4)] has revised Weinreich-Holstein's approach and got the formula

$$F_2\simeq(m/\rho e\tau V^2)\cdot\gamma \tag{4.3}$$

in both simple semiconductors and metals. In our method, this formula is obtained by setting

$$X_2=mu/\tau \tag{4.4}$$

instead of the force X in (3.2). The ratios of the formula F in (3.5) with F_1 and F_2 are

$$F/F_1=\frac{1}{60\pi^4}\left(\frac{\lambda}{\lambda_{FT}}\right)^4\cdot(ql)^2\ \text{ and }\ F/F_2=\frac{4}{15}(ql)^2\ , \tag{4.5}$$

under the condition of the same acoustic energy flow density, where q is the wave vector of waves and l is the mean free path of electrons. From the facts that $ql<1$ and $(\lambda/\lambda_{FT})^4\gg1$ in the low frequency range, we get the inequality $F_1<F<F_2$.

The physical reason of extremely small effect by Weinreich-Holstein's approach may lie on the neglect of the induced motion of lattice ions or charged impurities, as has been pointed out by Parmenter[4)]. On the other hand, Parmenter's method involves this effect; however, he has overestimated the force exerted by waves on electrons. The force X_2 in (4.4) implies that conduction electrons get the drift velocity u from acoustic waves in the time interval τ. But as will be seen from (2.2), the electrons with the drift velocity u are in local equilibrium and cannot affect the acoustic vibration, or inversely speaking they are exerted no force by waves. In fact, the drift velocity relative to u (i.e. relative to $f_0(|\boldsymbol{v}-\boldsymbol{u}|)$) contributes to Λ and F.

§ 5. Acoustoelectric Effect in Polyvalent Metals

According to Leigh's theory[13)] of the elastic stiffness constants of Al, the constant for the shear stress, c $(=c_{44})$, is written as $c=c_0-c_t$. Here c_0 is the component due to the stress-induced changes of the electrostatic energy, the exchange energy between ion cores and so forth; c_t is the component due to electron tranfer mechanism by the electrons which lie on near the centers of the hexagonal faces of the boundary of the Brillouin zone. The shear stress changes the potential energy of the electrons near the centers of the hexagonal faces antisymmetrically. Then the electrons with higher energy transfer to the lower energy positions in momentum space. This situation is analogous to that of many-valley semiconductors such as n-Ge.

For transverse ultrasonic waves, we consider the relaxation of the component of the elastic energy due to electron transfer mechanism and put

$$c=c_0-c_t/(1+i\omega\tau)\ . \tag{5.1}$$

This procedure is similar with Morse[14] and Kittel's[15] approaches to the ultrasonic absorption in metals. Solving the equation $\rho\cdot(\partial^2 s_x/\partial t^2)=c\cdot(\partial^2 s_x/\partial y^2)$ (s_x is the displacement of lattice ions), we get

$$\Lambda=\frac{c_t}{\rho V^3}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\ , \tag{5.2}$$

where the small dispersion of the sound velocity is neglected.

The acoustoelectric effect due to electron transfer mechanism can be calculated as follows. We take the idea analogous to the deformation potential[16] in semiconductors, i.e. the potential energy of the electrons near the hexagonal faces is simply put as $U=\Xi\cdot(\partial s_x/\partial y)$. Then the force exerted by waves is given by

$$X=-\Xi\cdot\left(\frac{\partial^2 s_x}{\partial y^2}\right)=-i\frac{q^2\Xi}{\omega}u\ . \tag{5.3}$$

Next, the fluctuation of the electron concentration in local equilibrium is determined by the definition of c_t, i.e.,

$$n_{\text{eq}}=-c_t\cdot(\partial s_x/\partial y)^2/U=\frac{c_t}{\Xi V}\cdot u\ . \tag{5.4}$$

Thus, solving the equation of the relaxation, $\partial n/\partial t=-(1/\tau)(n-n_{\text{eq}})$, we get

$$n=\frac{(c_t/V\Xi)}{1+(\omega\tau)^2}\cdot u-\frac{i\omega\tau(c_t/V\Xi)}{1+(\omega\tau)^2}\cdot u\ . \tag{5.5}$$

From (5.3) and (5.5) we obtain the formula

$$F=\frac{1}{2Ne}\cdot\text{Re}\,(n^*X)=\frac{c_t}{\rho NeV^4}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\cdot\gamma\ , \tag{5.6}$$

where N is the total number density of the electrons contributing to electron transfer mechanism.

The results (5.2) and (5.6) satisfy Weinreich's relation (3.4). It should be remarked that the theory developed in this section is only applicable to the low frequency range, because we isolate considerations to a small portion of materials in comparison with λ. For Al, we can take[13]

$$c_0=16.2\times10^{11}\ \text{dynes/cm}^2\ ,$$
$$c_t=13.1\times10^{11}\ \text{dynes/cm}^2$$

at very low temperatures. Then Λ and F due to electron transfer mechanism are of the same order as those derived from the free electron model, (3.7).

We can apply (5.2) and (5.6) to n-Ge. For transverse waves ($s_x\propto\exp(i\omega t-iqy)$), the deformation potentials of the valleys are expressed as $U=\pm(\Xi_u/3)\cdot(\partial s_x/\partial y)$, where Ξ_u is the deformation potential constant for uniaxial shear. Then, from (5.4) and $N+n_{\text{eq}}\propto\exp(-U/kT)$ we get easily

$$c_t=\frac{1}{9}\cdot\frac{N\Xi_u^2}{kT}\ . \tag{5.7}$$

Inserting (5.7) into (5.6), we obtain Weinreich's formula for n-Ge:

$$\left.\begin{aligned}\Lambda&=\frac{N\Xi_u^2}{9\rho V^3kT}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\ ,\\ F&=\frac{\Xi_u^2}{9\rho eV^4kT}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\cdot\gamma\ .\end{aligned}\right\} \tag{5.8}$$

§ 6. Remarks

In the Boltzmann theory developed in § 3, the effects of the space charge and the induced motion of ions could be explicitly taken into account. But these effects are implicitly involved in the phenomenological theory ((5.3), (5.4) and (5.5)), where we assumed that electrons followed nearly perfectly to the ionic displacement and then the appreciable electric potential was not produced. Such assumption in metals can be verified from the following consideration. If the formula in § 5 are applied to free electron model and the use is permissible of Morse's calculation[14] of the change of the electronic elastic energy caused by ultrasonic waves, we can get

$$\left.\begin{aligned}c_t&=\frac{4}{15}Nmv_0^2\quad\text{(longitudinal waves)}\\ &=\frac{1}{5}Nmv_0^2\quad\text{(transverse waves)}\ .\end{aligned}\right\} \tag{6.1}$$

Inserting (6.1) into (5.6), the same formulae as (3.5) and (3.7) are obtained, which were derived from the explicit consideration of the effects of the space charge and the induced motion of ions.

In semiconductors, however, such assumption has never been verified. Although Weinreich et al.[7] showed that the phenomenological theory similar to that in § 5 may be applicable to many-valley semiconductors like *n*-Ge, there are some questions whether the theory are applicable to semiconductors with degenerate energy surfaces like *p*-Ge. If we apply tentatively the formula in § 5 to *p*-Ge, we can get the acoustoelectric effect of the same order of magnitude as that in *n*-Ge, when the carrier concentrations are of the same order. This is because that 1) the piezoresistance[17) for the shear stress and 2) the change of the absorption peaks by the shear stress in cyclotron resonance[18) are of the same order in both *n* and *p*-Ge. Therefore, it is expected in future to study applicability of the theory in § 5 to simple and degenerate semiconductors.

Acknowledgements

The author should express his thanks to G. M. Hatoyama and M. Shibuya for their encouragements. He also is indebted to W. Sasaki for valuable discussions.

Note added in proof.

After this manuscript had been submitted to the editor we have read the paper by E. I. Blount [Phys. Rev. **114** (1959) 418], in which essentially the same results as this manuscript were derived from somewhat different approach.

The X-ray Non-diagram Lines $K\beta'$ of Some Compounds of the Iron Group

By Kenjiro Tsutsumi

Department of Physics, Faculty of Science, Osaka University

(Received August 1, 1959)

The wavelength values and relative intensities of the X-ray non-diagram lines $K\alpha_{3,4}$ of metallic iron and $K\beta'$ of Cr_2O_3, $Cr_2(SO_4)_3 \cdot nH_2O$, MnO_2, $MnSO_4 \cdot 4H_2O$, Fe_2O_3 and $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ were measured by the fluorescent X-ray method using twe different characteristic X-rays. The $K\alpha_{3,4}$ lines did not appear when an iron atom was excited by Ni K rays but were clearly observed when excited by Cu K rays. This was expected from the origin of the $K\alpha_{3,4}$ lines that is supposed to arise from a KL–LL transition. In the case of the $K\beta'$ line no difference was found regardless of whether it was excited by photons of energy lower or higher than $K(Z)+L(Z+1)$ which is necessary to remove simultaneously a K and an L electrons of an atom (Z). Therefore, the author may conclude that the $K\beta'$ line is due not to the double but to the single ionization process and that it can be derived from the difference of the exchange interactions of the states having different total spins ($S+1/2$) and ($S-1/2$), where S is the total spin of the incomplete $3d$ shell and 1/2 is that of the incomplete $3p$ shell in the final state. The energy separations of the $K\beta_1$ and $K\beta'$ lines calculated from the above-mentioned exchange energies nearly agree with those observed in the experiments.

§ 1. Introduction

The X-ray non-diagram line $K\beta'$, or so-called satellite line of the $K\beta_1$ line, has been investigated by many authors[1)-11)], because it has interesting characters different from other non-diagram lines. Such characters may be summarized as follows: (1) the $K\beta'$ line appears on the long wavelength side of the $K\beta_1$ line (parent line), (2) its intensity is large in comparison with other non-diagram lines, and (3) it is distinctly separated from the $K\beta_1$ line only when the substance is a chemical compound having a high magnetic susceptibility. In all the previous investigations only the wavelengths of the $K\beta'$ lines were measured, but the measurements of their intensities were not made. Generally, in the investigations of the X-ray emission spectra -especially of the X-ray emission spectra emitted from compounds- the fluorescent X-ray method has been used, because the substances under investigation have a tendency to decompose or to react chemically with the material of an anticathode by the bombardment of cathode rays. Most of the previous investigations[2)3)8)9)] of the $K\beta'$ lines were carried out by this fluorescence method, but, because the substances under investigation were held on the cathode part in the X-ray tube, they might change chemically by various causes, for instance, temperature rise of their surfaces and reduced pressure in the X-ray tube. In the present experiment this trouble could be avoided by placing the substances outside of the X-ray tube.

On the origin of the $K\beta'$ line many theories have been proposed, and, in order to test the validity of these various theories, measurements of the excitation potentials[13)] of the satellites and their intensities are required. In the present paper these measurements are carried out and a discussion is given of the origin of the $K\beta'$ line.

§ 2. Experiment

Fluorescent X-ray spectra of the non-diagram lines $K\alpha_{3,4}$ from metallic iron and $K\beta'$ from $Cr_2(SO_4)_3 \cdot nH_2O$, Cr_2O_3, MnO_2, $MnSO_4 \cdot 4H_2O$, $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ and Fe_2O_3 were taken with a bent crystal focusing spectrograph of the Johann type by means of the fluorescence method. The diameter of the focal circle was 20 cm and the second order reflection from the (110) plane of a quartz crystal was used. The substances under investigation which emitted the fluorescent spectra were placed on the Rowland circle.

The dispersion on a photographic plate is 7.55 x.u./mm in the region of Fe $K\alpha$, 6.48 x.u./mm in the region of Cr $K\beta$, 7.76 x.u./mm in the region of Mn $K\beta$ and 8.57 x.u./mm in the region of Fe $K\beta$. For the production of the fluorescent spectra, two anticathodes, copper and nickel, were used in the case of iron compounds, nickel and cobalt in the case of the compounds of manganese, and cobalt and iron in the case of the compounds of chromium. Two kinds of fluorescent spectra of each substance were obtained by using the above-mentioned two different anticathodes. The experiment on the $K\alpha_{3,4}$ lines of iron was carried out to confirm the intensity difference which is expected when an iron atom is excited by the radiations from two different anticathodes. From this experiment it can be concluded, as shown in § 4. (i), that the influence of general radiation on the present fluorescent spectra is negligible. The load of X-ray tube was about 40 kV peak and 15 mA, and the time of exposure was varied from 50 to 60 hours in the case of the $K\beta'$ spectra and 150 hours in the case of the $K\alpha_{3,4}$ spectra. All the spectrograms were photographed on Fuji A-1 plates. For the measurements of ralative intensities the auto-calibration single exposure method was chosen with the aid of various thicknesses of aluminum foils.

§ 3. Experimental Results

All of the experimental results are summarized in Table I and II, which give the results on the $K\alpha_{3,4}$ lines and the $K\beta'$ line respectively. In these tables the second column shows the materials which emit the non-diagram lines under investigation. The fourth column shows the anticathodes of the X-ray tube. The fifth column gives the wavelength values of the $K\alpha_1$ line measured by Parratt[18] and the $K\beta_1$ lines measured by Yoshida[8] (Cr_2O_3, $MnSO_4$, MnO_2 and Fe_2O_3) and by Tanaka and Okuno[9] ($Cr_2(SO_4)_3$ and $Fe(SO_4)_2\cdot(NH_4)_2$). The sixth and seventh columns give the $\Delta\lambda$ and Δev of satellites measured from the parent lines respectively.

were smoothed and separated into two components of the parent lines and the non-diagram lines, by assuming that the parent line is symmetrical with respect to the position.

§ 4. Discussion and Conclusion

i) $K\alpha_{3,4}$: The origin of the non-diagram lines $K\alpha_{3,4}$ proposed by Druyvesteyn[13] and supported by Parratt[12] and by Sawada[14] is as follows: the $K_{3,4}$ lines are supposed to arise from a KL–LL transition where KL refers to an atomic state in which one K electron and one L electron are missing. The probability[13][15][16][17] of two (or more) electrons being ejected from an atom by successive impacts of electrons or photons (when an atom is excited by X-rays) is much too low to account for the observed satellite intensities, therefore the multiple-ionization process would

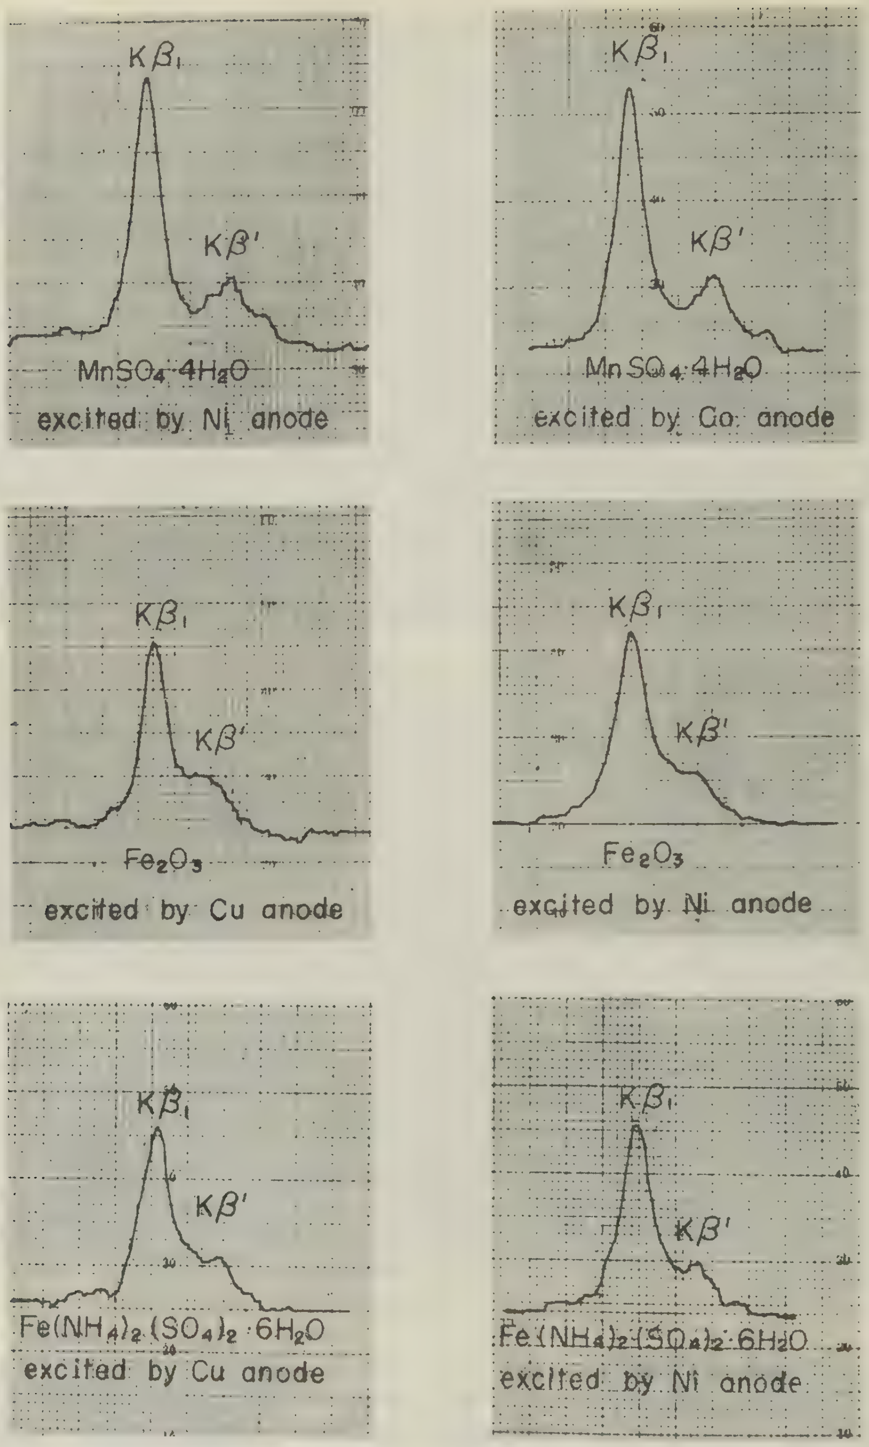

Photo. 4. Photometer records of the $K\beta_1$ and $K\beta'$ spectra on about 1/2.10 of original size.

have to take place by a single impact. Then, the energy of photons necessary to excite the $K\alpha_{3,4}$ satellite lines is approximately equivalent to the total energy required to remove a K electron of an atom of atomic number Z plus the energy required to remove an L electron of an atom $(Z+1)$, since, owing to the vacancy in the inner K shell, the outer L electron can be considered to move in the field of an atom $(Z+1)$. of Table III, the excitation potentials of iron $K(26)$ which is necessary to remove only one K electron, $K(26)+L(27)$ which is required to remove simultaneously the K and L electrons of an iron atom, the energy of Cu$K\alpha_1$ rays and the energy of Ni $K\alpha_1$ rays are given in ev respectively. As seen from this table, Cu $K\alpha$ rays excite simultaneously a K and an L electrons of an iron atom, and therefore the Fe $K\alpha_{1,2}$ and $K\alpha_{3,4}$ lines are emitted, but Ni $K\alpha$

rays excite only a K electron, thus giving rise to only the Fe $K\alpha_{1,2}$ lines. This fact can be clearly seen in Table I, Photo. 1, Photo. 3 and Fig. 1. In the case of excitation with Ni K rays, however, weak $K\alpha_{3,4}$ lines are observed, and this is probably due to the presence of Ni $K\beta$ and general radiations. It is difficult to estimate the influence of general radiation on the present fluorescent spectra because the effect of general radiation is not easily determined theoretically or experimentally. However, this experimental result on the $K\alpha_{3,4}$ lines of iron shows that the contribution of general radiation to the production of the present fluorescent spectra is negligibly small. It can be considered that this is also the case with the experiments on $K\beta'$ lines. The intensity ratio of the $K\alpha_{3,4}$ to $K\alpha_1$ lines observed by Parratt[18] is a little larger than the present result. It may be considered to

be due to the difference of the excitation method.

ii) $K\beta'$: On the origin of the $K\beta'$ line, following explanations have been proposed by various investigators:

(1) N. Seljakow and A. Krasnikow[1)] interpreted the $K\beta'$ and $K\beta_1$ lines to be a relativity doublet. But its $\Delta\lambda$ does not coincide with the value calculated from the frequency difference of the M_{II} and M_{III} levels.

(2) D. Coster and M. J. Druyvesteyn[2)] considered the $K\beta'$ line to arise from the higher multiplicity due to the influence of the incomplete $M_{IV,V}$ shells on the $M_{II,III}$ levels; and so this line is a component of the $K\beta_1$ line. This theory was supported by S. Yoshida[8)].

(3) G. Ortner[3)] assumed new M' levels in the iron group and explained that the $K\beta'$ line was due to the transition from the M' level.

(4) G. B. Deodhar[6)] adopted the Richtmyer double jump theory and explained the $K\beta'$ line as due to a transition

$$KL_{III} \longrightarrow L_{III}M_I ,$$

but the wavelengths calculated from this theory seem to be rather large.

(5) M. Sawada[7)] also explained the $K\beta'$ line from the double jump theory as

$$KL_{II,III} \longrightarrow L_IM_{IV,V} .$$

The wavelengths calculated from this theory coincide fairly good with the experimental results.

(6) M. A. Blochin[10)] assumed that a part of energy quantum of the $K\beta_1$ line was absorbed by a $3d$ electron and this electron was excited to a conduction level.

(7) L. G. Parratt[11)] is attempting to explain from the exciton theory.

According to the Sawada or the Deodhar theory, it is necessary to eject simultaneously one K and one L electrons in order to emit the $K\beta'$ line, and the energy of X-ray photon necessary to excite the $K\beta'$ line is approximately equivalent to the total energy required to remove a K electron of an atom (Z) and an L electron of an atom $(Z+1)$. Table III shows the excitation potential $K(Z)$ required to remove a K electron of an atom (Z), the energy $K(Z)+L(Z+1)$ required to remove simultaneously a K and an L electrons of the atom (Z) and the energies of $K\alpha_1$ rays of anticathodes used for excitation. As shown in this table, the $K\beta_1$ and $K\beta'$ lines must be both emitted by photons with energy higher than $K(Z)+L(Z+1)$, but the $K\beta'$ line must not be emitted by photons with energy lower than $K(Z)+L(Z+1)$. This situation is the same as in the case of the $K\alpha_{3,4}$ lines.

Contrary to the prediction of their double jump theory, the $K\beta_1$ and $K\beta'$ lines are emitted by photons of energy lower than $K(Z)+L(Z+1)$ as shown in Table II, Photo. 2, Photo. 4 and Fig. 2, and no difference is found between intensity ratios of the $K\beta'$ to $K\beta_1$ lines in both cases of excitation. This shows that the origin of the $K\beta'$ line is not the KL double ionization process but the single ionization process.

iii) Origin of $K\beta'$: We may consider that the $K\beta_1$ and $K\beta'$ lines are emitted by transitions from the states having the total spins equal to $S+1/2$ and $S-1/2$ respectively, where S is the total spin of the incomplete $3d$ shell and $1/2$ is that of the incomplete $3p$ shell in the final state having one vacancy in the $3p$ shell owing to the transition of an electron from the complete $3p$ shell to the $1s$ shell. The total spin of $3d$ shell is 5/2 for both Mn^{++} in $MnSO_4 \cdot 4H_2O$ and Fe^{+++} in Fe_2O_3 and 3/2 for Cr^{+++} in Cr_2O_3. Then the energy difference between the $K\beta_1$ and $K\beta'$ lines corresponds to the difference between the exchange energies[19)20)] for $(S+1/2)$ and for $(S-1/2)$.

The exchange interaction of the state having a total spin $(S+s)$ is given by[19)20)21)]

$$-1/2J(1+4\boldsymbol{S}\cdot\boldsymbol{s}) ,$$

where J is the exchange integral having a usual meaning, S is the total spin vector of $3d$ shell and $\boldsymbol{s}$ is that of $3p$ shell.

Then the magnitude of the energy difference ΔE between the exchange interactions for $S+1/2$ and for $S-1/2$ is given by

$$\Delta E = J[(S+1/2)(S+1/2+1) - (S-1/2)(S-1/2+1)] .$$

The ΔE values are $6J$ for Mn^{++}, Fe^{+++} $(S=5/2)$ and $4J$ for Cr^{+++} $(S=3/2)$. The author calculated the J values of $MnSO_4 \cdot 4H_2O$ and Fe_2O_3 in which the five $3d$ electrons occupy each one of $3d$ orbitals and that of Cr_2O_3 in which the three $3d$ electrons belong to each one of d_ε orbitals. Their values are given in Table IV. In this calculation the hydrogen-like wavefunctions[22)] of the $3p$ and $3d$ electrons were used. The effective nuclear charges $(Z-\sigma)$ were determined by Slater's rules[23)] and are also given in Table IV. Two

Table IV. The effective nuclear charges and the calculated J values.

material	Z	Z-σ_{3p}	Z-σ_{3d}	J	Z-σ_{mean}*	J*
Cr	24	12.75	5.3	1.023	9.025	1.622
Mn	25	13.75	5.6	1.02	9.675	1.74
Fe	26	14.75	6.6	1.62	10.675	1.92

$$\sigma_{\text{mean}}{}^{*}=\frac{\sigma_{3p}+\sigma_{3d}}{2}$$

Table V. The calculated and observed energy differences and relative intensities of the $K\beta'$ and $K\beta_1$ lines.

material	energy difference			relative intensity	
	calculated		observed	calculated	observed
	from J	from J*			
		ev	ev		
Cr_2O_3	4.09	6.49	14.29	0.6	0.5
$MnSO_4\cdot 4H_2O$	6.12	10.44	15.70	0.71	0.62
Fe_2O_3	9.72	11.52	14.19	0.71	0.33

alternative J values were calculated for each material, in one of them the effective nuclear charges $Z-\sigma_{3p}$ and $Z-\sigma_{3d}$ were used for the $3p$ and $3d$ wavefunctions and in the other the same nuclear charge $Z-\sigma_{\text{mean}}$ was used for both $3p$ and $3d$ wavefunctions.

As shown in Table V, the values of the energy difference ΔE obtained from the above calculations nearly agree with the energy separations of the $K\beta_1$ and $K\beta'$ lines observed in the above experiments.

The relative intensities of the $K\beta'$ and $K\beta_1$ lines are estimated from the ratio of the multiplicity of each state, that is, $2(S-1/2)+1$: $2(S+1/2)+1$. For Mn^{++} and Fe^{+++} these become 5:7 and for Cr^{+++} 3:5. These values are slightly larger than the observed ones.

The reasons for discrepancies between the calculated and observed values of the energy difference and of the relative intensities may be supposed as follows: (1) the wavefunctions used for $3p$ and $3d$ orbitals are rather approximate (2) the screening constants are not determined precisely, and (3) the influences of neighboring atoms are not taken into consideration. Further it is supposed that some other origins proposed by various authors[1)-11)] may partially contribute to the emission of the $K\beta'$ line.

Thus it may be concluded that the $K\beta'$ line is due not to the double but to the single ionization process and is derived from the difference of the exchange interactions of the states having different total spins $(S+1/2)$ and $(S-1/2)$ where S is the total spin of the incomplete $3d$ shell and 1/2 is that of the incomplete $3p$ shell in the final state.

The author expresses his sincere thanks to Professor M. Sawada, Professor T. Nagamiya, Assistant Professor K. Yoshida and Assistant Professor K. Sakurai for their variable advices and to the members of their laboratories for their kind assistances. His thanks are also due to Professor T. Watanabe, Professor R. Nathans and Assistant Professor T. Horie for criticizing this manuscript.

X-ray Study on Molecular Rotation in Tetragonal Ammonium Nitrate

By Yasuhiro SHINNAKA
Faculty of Literature and Science, Yamaguchi University

(Received August 6, 1959)

Hindered rotation of nitrate groups in the tetragonal ammonium nitrate was studied by using X-ray diffuse scattering. The first, second, third and fourth order diffuse scatterings of plate-like shape perpendicular to the C^*-direction in the reciprocal lattice were observed. These diffuse scatterings were analyzed referring to the crystal structure as determined previously by using Laue-Bragg scattering. It was found that the correlation among rotating nitrate groups is strong in the C-direction, while it is weak in the direction perpendicular to it and its type is different from that to be expected from the lower temperature modification.

§ 1. Introduction

It is known that ammonium nitrate has five modifications.[1] In the previous papers[2),3)] the author treated the rotation of nitrate groups in the cubic and tetragonal modifications of ammonium nitrate. With regard to the cubic modification[2)] (125.2°C∼169°C), it was found from the study on the X-ray diffuse scattering that the nitrate groups are rotating with one another under considerable correlation. But owing to the complexity of correlation, the observed diffuse scattering could not be discussed by taking full correlation into consideration. With regard to the tetragonal modification[3)] (84.2°C∼125.2°C), the hindered rotation of the nitrate groups was considered from the study on the Laue-Bragg scattering, but the study on the diffuse scattering due to the rotation of nitrate groups was not carried out yet.

In the present paper, the diffuse scattering in the tetragonal modification will be studied and the correlation among the hindered rotating nitrate groups will be discussed. In the tetragonal modification the strength of correlation in the direction of the C-axis will be different from that in the direction perpendicular to the C-axis and so the diffuse scattering will have a characteristic form. Further, on account of the comparatively simple mechanism of rotation in this modification the interpretation of diffuse scattering can be made somewhat satisfactorily. Therefore the present study may also be of interest in giving us additional informations about the diffuse scatterings due to molecular rotation in crystal and further may be useful to deepen the understanding of the diffuse scattering in cubic ammonium nitrate.

§ 2. Observation of Diffuse Scattering

The single crystal was obtained by using the single crystal transformation [orthorhombic modification (32.3°C ∼ −18°C) $\xleftrightarrow[\sim 50^{\circ}\mathrm{C}]{\text{metastable transition}}$ tetragonal modification] as was done in the previous study.[3)] Since the needle axis of the crystal is the A-axis, Laue photographs were taken with the A-axis vertical at about 5° intervals over the whole rotational range by using filtered Cu radiation on cylindrical films (camera radius = 50.7 mm) at about 100°C. In each photograph several diffuse lines were observed in addition to the Laue spots and the ordinary thermal diffuse scatterings as shown in Photo. 1. The broadenings of these diffuse lines are very narrow and their intensities are strong in contrast to those in cubic ammonium nitrate.

The intensity distribution of diffuse scattering in reciprocal lattice was obtained by the usual geometrical method. But the familiar diffuse scatterings due to ordinary thermal vibration observed in neighbouring regions of reciprocal-lattice points were omitted, because they had no particular correlation with the diffuse scattering in question. The obtained distribution in reciprocal space has a plate-like shape: diffuse-scattering densities are distributed in each thin flat volume which has its flat faces normal to the C^*-direction and contains just reciprocal-lattice points (001),

(002) and (003) respectively. This general feature is shown in Fig. 1. Hereafter these plate-like diffuse scatterings will be called the first, second and third order diffuse scatterings respectively. The fourth order was also observed in several photographs, but the zeroth order was not observed.

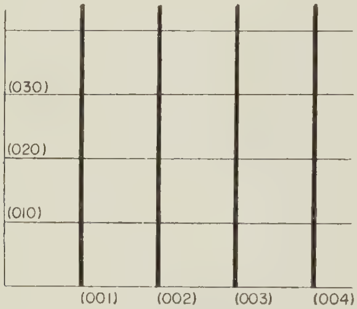

Fig. 1. Schematic reciprocal-lattice representation of observed diffuse scattering showing the general feature of plate-like of the first, second, third and fourth order diffuse scatterings.

The intensity distributions in the first, second and third order diffuse scatterings are shown respectively in Figs. 2(a), 2(b) and 2(c), where the numbers (10, 9, ···, 1, 0) indicate the measure of visual contrast, but they have no exact quantitative meanings. It is to be noticed that these distributions have close relation with the reciprocal lattice; the intensities about the reciprocal-lattice points are weak, while the intensities about centers of each square formed on the reciprocal net are strong.

For the purpose of determining the broadening of each order diffuse scattering in the C^*-direction, photographs were also taken by X-ray impinged on a small part of the crystal in order to avoid the error to be caused by the malorientation of subcrystalline units in the metastable transition. Thus the broadening of the second order diffuse scattering was determined by using the photograph taken under the condition that the sphere of reflec-

tion intersects the plate-like second order diffuse scattering at right angles (see Photo. 2). Its half-peak breadth was given as 1°34′ in terms of the scattering angle by using microphotometer. Then, subtracting the half-peak breadth 13′ of Laue spots in the original orthorhombic modification from the value 1°34′, the value 1°21′ was determined approximately as the half-peak breadth of the second order diffuse scattering.

§ 3. Interpretation of Diffuse Scattering

From the plate-like feature of the observed diffuse scatterings, it is assumed that there seems to exist anisotropy of the randomness in the arrangement of the nitrate groups: nitrate groups will take a rather orderly arrangement in the **C**-direction, while a rather random arrangement in the direction perpendicular to it. It is possible to introduce such anisotropy into the tetragonal ammonium nitrate.

According to the previous study[3], atomic positions in the tetragonal unit ($A=5.74$Å, $C=4.95$Å) are approximately as follows:

$2\mathrm{NH_4}$: 0, 0, 0; 1/2, 1/2, 0

two orientations of nitrate

$2\mathrm{NO_3}$ one nitrate group

$$\begin{array}{ll} \mathrm{N} & \frac{1}{2},\ 0,\ u \\ \mathrm{O(1)} & \frac{1}{2},\ 0,\ v \\ \mathrm{O(2)} & \frac{1}{2}+x,\ x,\ w \\ & \frac{1}{2}-x,\ \bar{x},\ w \end{array} \left.\vphantom{\begin{array}{l}1\\1\\1\\1\end{array}}\right\} \text{or} \left\{\begin{array}{l} \frac{1}{2},\ 0,\ \bar{u} \\ \frac{1}{2},\ 0,\ \bar{v} \\ \frac{1}{2}+x,\ x,\ \bar{w} \\ \frac{1}{2}-x,\ \bar{x},\ \bar{w} \end{array}\right.$$

another nitrate group

$$\begin{array}{ll} \mathrm{N} & 0,\ \frac{1}{2},\ u \\ \mathrm{O(1)} & 0,\ \frac{1}{2},\ v \\ \mathrm{O(2)} & \bar{x},\ \frac{1}{2}+x,\ w \\ & x,\ \frac{1}{2}-x,\ w \end{array} \left.\vphantom{\begin{array}{l}1\\1\\1\\1\end{array}}\right\} \text{or} \left\{\begin{array}{l} 0,\ \frac{1}{2},\ \bar{u} \\ 0,\ \frac{1}{2},\ \bar{v} \\ \bar{x},\ \frac{1}{2}+x,\ \bar{w} \\ x,\ \frac{1}{2}-x,\ \bar{w} \end{array}\right. \qquad (1)$$

with $x=0.12$, $u=0.53$, $v=0.75$ and $w=0.42$ (see Fig. 3). The rotation of the nitrate group is required not to be free, but is almost bound in two orientations (in opposite directions). In that structure it may be successfully allowed to approximate the dynamical hindered rotation by the randomness of orientations.

As to the mutual orientations of neighbouring nitrate groups in the *C*-direction, three cases as shown in Fig. 4 are considered to be possible. But among these cases, that the case (3) occurs is clearly improbable judging from the aspect of interatomic distances and the case (2) is to occur in the same frequency with the case (3), for they are in a geometrical relation where they are to occur only alternately along the **C**-direction. From

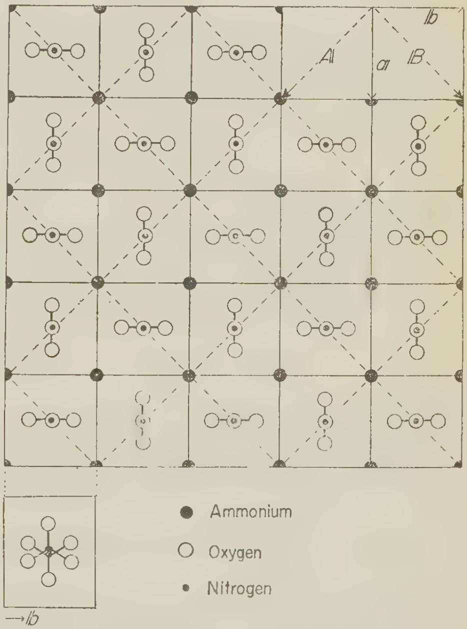

Fig. 3. The structure of tetragonal ammonium nitrate projected on (001). Full line represents the unimolecular pseudocell (**a**, **b**, **c**) and broken line the true unit (**A**, **B**, **C**=**c**).

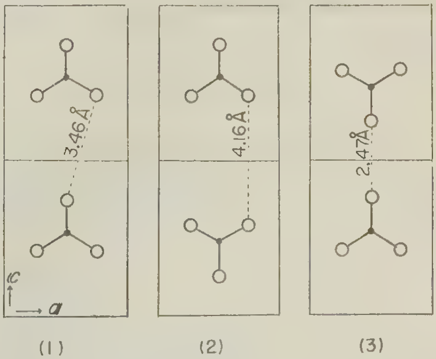

Fig. 4. All sorts of mutual orientations of neighbouring nitrate groups in the **C**-dicrection.

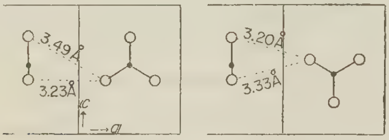
the above consideration it seems that the case (1) will occur more often than the cases (2) and (3). And neighbouring nitrate groups in the direction perpendiculr to the C-direction will be able to take the states such as shown in Fig. 5. In this case it is expected that these states will occur almost to the same degree.

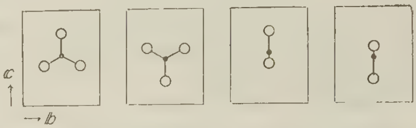


(1) (2)

Fig. 5. All sorts of mutual orientations of neighbouring nitrate groups in the **a**-direction (**a** being the axis of unimolecular pseudocell).

i) *Calculation of intensity distribution*

In the above-mentioned model the crystal is composed of four kinds of unimolecular pseudocells. Suppose that the structure factors of these pseudocells are F_1^+, F_1^-, F_2^+ and F_2^- respectively as follows:



$F_1(+)$ $F_1(-)$ $F_2(+)$ $F_2(-)$

Then the structure amplitude (Y) of the whole crystal due to some instantaneous configuration of nitrate groups and the intensity (I) of the coherent X-ray scattering are respectively given by

$$Y=\sum_n \exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n)F_1^n+\sum_n \exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n+\boldsymbol{a})F_2^n\ , \tag{2}$$

$$\begin{aligned}I&=I_e\langle YY^*\rangle\\&=I_e[\sum_n\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\langle F_1^n(F_1^{n'})^*\rangle+\sum_n\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'})\langle F_2^n(F_2^{n'})^*\rangle\\&\quad+\sum_n\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'}-\boldsymbol{a})\langle F_1^n(F_2^{n'})^*\rangle+\sum_n\sum_{n'}\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_n-\boldsymbol{R}_{n'}+\boldsymbol{a})\langle F_2^n(F_1^{n'})^*\rangle]\ ,\end{aligned} \tag{3}$$

where

I_e: the Thomson factor,
$\boldsymbol{R}_n$: position vector of the nth true lattice point,
$\boldsymbol{h}$: $\boldsymbol{h}=\boldsymbol{k}-\boldsymbol{k}_0$ ($\boldsymbol{k}_0$: the wave vector of incident beam, $\boldsymbol{k}$: the wave vector of scattered beam),
F_1^n; F_2^n: the structure factor (F_1^+ or F_1^-; F_2^+ or F_2^-) of the pseudocell pointed by $\boldsymbol{R}_n$; $\boldsymbol{R}_n+\boldsymbol{a}$,
$\langle\ \rangle$: the averages of the product of the F's of two pseudocells separated by $\boldsymbol{R}_n-\boldsymbol{R}_{n'}\equiv\boldsymbol{R}_{nn'}$, $\boldsymbol{R}_{nn'}-\boldsymbol{a}$ and $\boldsymbol{R}_{nn'}+\boldsymbol{a}$ respectively,
$\sum_n\sum_{n'}$: summation is taken over all the lattice points.

In calculating each average value ($\langle\ \rangle$) the probability $P(\boldsymbol{t})$ of finding out that two nitrate groups separated by a constant vector $\boldsymbol{t}$ have the same orientation (++ or −−), was introduced. Suppose that the values of $P(\boldsymbol{t})$ for fundamental vectors $\boldsymbol{C}$, $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{A}$ and $\boldsymbol{B}$ are placed as follows:

$$P(\boldsymbol{C})=P(-\boldsymbol{C})=1-\alpha,\qquad P(\boldsymbol{a})=P(-\boldsymbol{a})=P(\boldsymbol{b})=P(-\boldsymbol{b})=1-\beta\ ,$$

$$P(\boldsymbol{A})=P(-\boldsymbol{A})=P(\boldsymbol{B})=P(-\boldsymbol{B})=1-\gamma\ .$$

Now since $\alpha\sim0$, $\beta\sim1/2$ and $\gamma\sim1/2$ are expected from the observed diffuse scattering, the values of $P(\boldsymbol{t})$ for the other vectors may be put approximately as follows:

$$\begin{aligned}&P(n_3\boldsymbol{C})=\{1+(1-2\alpha)^{|n_3|}\}/2\equiv q(n_3)\ ,\\&P(\pm\boldsymbol{a}+n_3\boldsymbol{C})=P(\pm\boldsymbol{b}+n_3\boldsymbol{C})=(1-\beta)q(n_3)+\beta\{1-q(n_3)\}\ ,\\&P(\pm\boldsymbol{A}+n_3\boldsymbol{C})=P(\pm\boldsymbol{B}+n_3\boldsymbol{C})=(1-\gamma)q(n_3)+\gamma\{1-q(n_3)\}\ ,\\&P(n_1\boldsymbol{a}+n_2\boldsymbol{b}+n_3\boldsymbol{C})=1/2\quad(\text{if } |n_1\boldsymbol{a}+n_2\boldsymbol{b}|>|\boldsymbol{A}|)\ ,\end{aligned} \tag{4}$$

where n_1, n_2 and n_3 are any integers, positive, negative, or zero.

By using these values, if we go to the limit of an infinite crystal, the first term in the formula (3) is given by

$$\begin{aligned}
&\sum_n \sum_{n'} \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'}) \langle F_1{}^n (F_1{}^{n'})^* \rangle \\
&\quad = \sum_{\substack{n \quad n' \\ (\boldsymbol{R}_{nn'} = n_3 \boldsymbol{C})}} \sum \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'}) [|\overline{F_1}|^2 + (1-2\alpha)^{|n_3|} (\overline{|F_1|^2} - |\overline{F_1}|^2)] \\
&\qquad + \sum_{\substack{n \quad n' \\ (\boldsymbol{R}_{nn'} = \pm \boldsymbol{A} + n_3 \boldsymbol{C},\ \pm \boldsymbol{B} + n_3 \boldsymbol{C})}} \sum \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'}) [|\overline{F_1}|^2 + (1-2\gamma)(1-2\alpha)^{|n_3|} (\overline{|F_1|^2} - |\overline{F_1}|^2)] \\
&\qquad + \sum_{\substack{n \quad n' \\ (\boldsymbol{R}_{nn'} = \text{the other values})}} \sum \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'}) |\overline{F_1}|^2 \\
&\quad = |\overline{F_1}|^2 \sum_n \sum_{n'} \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'}) \\
&\qquad + N[(\overline{|F_1|^2} - |\overline{F_1}|^2) + 2(\cos 2\pi \boldsymbol{h}\cdot \boldsymbol{A} + \cos 2\pi \boldsymbol{h}\cdot \boldsymbol{B})(1-2\gamma)(\overline{|F_1|^2} - |\overline{F_1}|^2)] \\
&\qquad \times [1 + (1-2\alpha) 2 \cos(2\pi \boldsymbol{h}\cdot \boldsymbol{C}) + (1-2\alpha)^2 2 \cos(4\pi \boldsymbol{h}\cdot \boldsymbol{C}) + \cdots]\ , \qquad (5)
\end{aligned}$$

where

$$\overline{F_1} = (1/2)(F_1{}^+ + F_1{}^-), \qquad \overline{|F_1|^2} = (1/2)(|F_1{}^+|^2 + |F_1{}^-|^2),$$

N is the total number of lattice points and $\sum\limits_{\substack{n \quad n' \\ (\boldsymbol{R}_{nn'} = n_3 \boldsymbol{C})}} \sum$ denotes the double summation taken over the lattice points which satisfy the relation $\boldsymbol{R}_n - \boldsymbol{R}_{n'} \equiv \boldsymbol{R}_{nn'} = n_3 \boldsymbol{C}$ and so on.

In the formula (5) the function[4]:

$$J(\boldsymbol{h}\cdot \boldsymbol{C}) \equiv [1 + (1-2\alpha) 2 \cos(2\pi \boldsymbol{h}\cdot \boldsymbol{C}) + (1-2\alpha)^2 2 \cos(4\pi \boldsymbol{h}\cdot \boldsymbol{C}) + \cdots]\ , \qquad (6)$$

is a periodic function of $\boldsymbol{h}\cdot \boldsymbol{C} = l + w$ (l: integer; w: $-1 \sim 1$). If the values of $J(\boldsymbol{h}\cdot \boldsymbol{C})$ near $\boldsymbol{h}\cdot \boldsymbol{C} = 0$ can be obtained, it will serve the present purpose. This series could be summed up strictly, but for the present purpose it suffices to approximate the sum by an integral:

$$J(w) \fallingdotseq 2 \int_0^\infty (1-2\alpha)^m \cos(2\pi w m)\, dm \fallingdotseq \frac{\alpha}{\alpha^2 + \pi^2 w^2}\ , \qquad (7)$$

where in executing the integration the approximation $[-\log(1-2\alpha) \fallingdotseq 2\alpha]$ has been used.

After treating the other terms in the formula (3) in the same way, the formula (3) becomes finally

$$I = I_1 + I_2\ , \qquad (8)$$

with

$$I_1 = I_e |\overline{F_1} + \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{a}) \overline{F_2}|^2 \sum_n \sum_{n'} \exp(2\pi i \boldsymbol{h}\cdot \boldsymbol{R}_n - \boldsymbol{R}_{n'})\ , \qquad (9)$$

$$\begin{aligned}
I_2 = I_e N [&(\overline{|F_1|^2} + \overline{|F_2|^2} - |\overline{F_1}|^2 - |\overline{F_2}|^2)\{1 + 2(1-2\gamma)(\cos 2\pi \boldsymbol{h}\cdot \boldsymbol{A} + \cos 2\pi \boldsymbol{h}\cdot \boldsymbol{B})\} \\
&+ \left\{ \frac{1}{2} (F_1{}^+ (F_2{}^+)^* + F_1{}^- (F_2{}^-)^* + F_2{}^+ (F_1{}^+)^* + F_2{}^- (F_1{}^-)^*) - \overline{F_1} (\overline{F_2})^* - \overline{F_2} (\overline{F_1})^* \right\} \\
&\times \{2(1-2\beta)(\cos 2\pi \boldsymbol{h}\cdot \boldsymbol{a} + \cos 2\pi \boldsymbol{h}\cdot \boldsymbol{b})\}]\, J(\boldsymbol{h}\cdot \boldsymbol{C})\ , \qquad (10)
\end{aligned}$$

where I_1 represents the Laue-Bragg scattering discussed in the previous papers[3] and I_2 represents the diffuse scattering. It is clear that I_2 has a suitable form for explaining the general feature of the observed diffuse scattering.

ii) *Determination of α*

The curve of $J(w)$ as a function of w is shown in Fig. 6. Its half-peak breadth is $w = 2\alpha/\pi$, while the observed one was approximately 1°15′. Hence α was determined approximately to be 0.11.

iii) *Determination of β and γ*

In calculating the intensity distributions in the reciprocal-lattice planes ($\boldsymbol{h}\cdot\boldsymbol{C}=1, 2, 3$), I_eN was replaced by $K(1+\cos^2 2\theta)/2$ and further it was assumed that atomic scattering factors f_N and f_O are the same as those determined for NaNO$_3$ by P. E. Tahvonen[5] and that both of their temperature factor (e^{-M}) are given by $\exp(-1.5\sin^2\theta)$, where K is a constant for a given crystal and 2θ is the angle of scattering.

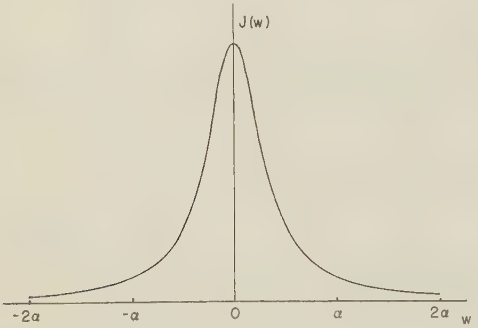


Fig. 6. Variation of $\frac{\alpha}{\alpha^2+\pi^2w^2}$ as a function of w.

The calculated distributions for $\beta=\gamma=1/2$ by using the atomic positions shown in (1) are shown in Figs. 7(a), 7(b) and 7(c). These distributions are clearly different from the observed ones (Figs. 2(a), 2(b) and 2(c)), but it is to be noticed that the regions having strong intensity correspond to the observed ones except for the reduction of the intensity about the reciprocal-lattice points as noticed in observed diffuse scatterings. In order to obtain such reduction, it is required to give the more weight to the factor $(1-2\gamma)$ $(\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{A}+\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{B})$ than to the factor $(1-2\beta)$ $(\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{a}+\cos 2\pi\boldsymbol{h}\cdot\boldsymbol{b})$ in the formula (10). The calculated distributions for $\beta=0.58$, $\gamma=0.49$ and for $\beta=0.5$, $\gamma=0.58$ are shown respectively in Figs. 8(a), 8(b), 8(c) and 9(a), 9(b), 9(c). These distributions as shown in Fig. 9 are in fairly good agreement with the observed ones, but they are still somewhat different from the observed ones quantitatively. This discrepancy may be diminished by taking the more detailed $\boldsymbol{P}(\boldsymbol{t})$ into consideration and further by using more detailed atomic positions.

Moreover, a few words should be added on the zeroth order diffuse scattering. The calculated distribution of it vanishes on account of non-irregularity in the assumed atomic positions projected on the C-face. This facts

coincides with the fact that the zeroth order could not be observed in the present study.

§ 4. Discussion

According to the above results it is considered that the randomness of the nitrate groups in the tetragonal modification will be specified by $\alpha\sim0.11$, $\beta\sim0.5$ and $\gamma\sim0.58$. These values show that the first neighbouring nitrate groups on the *C*-face take the orientations almost independently, but, on the other hand, the second neighbouring nitrate groups are likely to the rather different orientation with one another. Such a behaviour of the nitrate groups is different from that to be expected from the orthorhombic modification (32.3°C∼−18°C).

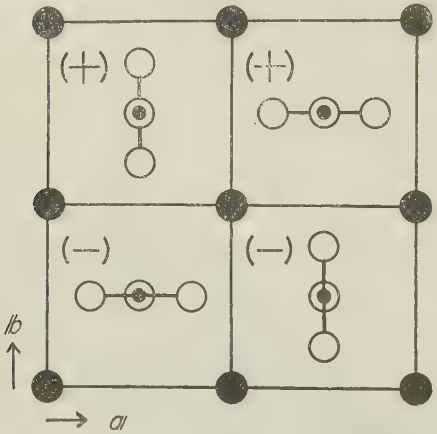

Fig. 10. One of the four equivalent configurations of the nitrate group for $\beta=1/2$, $\gamma=1$.

This fact may be explained by assuming that the weakness of hydrogen bonds are in favour of such a configuration as shown in Fig. 10. As to such configurations specified formally by $\beta=1/2$, $\gamma=1$, four equivalent configurations are to be considered. If the nitrate groups are in favour of taking such configurations locally, the values similar to the observed ones for β, γ will be obtained.

Acknowledgements

The author expresses his cordial thanks to Prof. K. Tanaka of Kyoto University for his kind guidance and discussion throughout the course of this research. He also wishes to thank Messrs. K. Nakamura and Y. Honda for their assistance. A part of this work was supported by the Scientific Research Expenditure of the Ministry of Education.

Proton Magnetic Relaxation in Solutions of a Manganous Salt

By Hide YOSHIOKA and Tetsuo FUJITA
Physics Institute, Nagoya University, Nagoya

(Received July 29, 1959)

The spin-lattice relaxation time T_1 and the spin phase-memory time T_2 of protons in methanol solutions containing manganous ions have been studied by use of the coherent-pulse technique. The relaxation curves were resolved into two components, *i.e.*, a short-time component corresponding to hydroxyl group protons and a long-time component corresponding to methyl group protons. The T_1/T_2 ratio for methyl group protons is considerably larger than unity. This indicates a finite density of unpaired electrons on the methyl group protons of alcohol ligands around a manganous ion. Similar studies are reported for a mixture of methanol and water containing manganous ions.

§ 1. Introduction

The spin-lattice relaxation time T_1 and the spin phase-memory time T_2 of protons in aqueous solutions of paramagnetic salts have been studied by several workers$^{1),2),3)}$. The proton spins in these solutions are relaxed mainly by magnetic interactions between protons and paramagnetic ions. The dipole-dipole interaction between protons can be ignored, because the relaxation time in pure water is of the order of several seconds, and is much longer than that in paramagnetic solutions. Theoretically, it is expected that T_1 is nearly equal to T_2 when the correlation time of the interaction modulated by Brownian motions is very short compared with the Larmor period$^{1)}$. This equality was found experimentally for aqueous solutions of Fe^{+2} and other paramagnetic ions$^{2)}$. However, several solutions containing Mn^{+2} or Cr^{+3} were found to show T_1/T_2 that is considerably larger than unity$^{3)}$. Bloembergen ascribed the abnormally large T_1/T_2 to the existence of a spin exchange interaction between a paramagnetic ion and protons in the hydration shell of the ion$^{4)}$. According to his theory, the anomalous ratio of T_1/T_2 is closely related to (*a*) the covalent bonding between paramagnetic ions and neighboring solvent molecules and also to (*b*) a long electron spin relaxation time. Therefore, it is interesting to study the behavior of T_1 and T_2 using solvents other than water. In this paper, we report the result of experiments using methanol as a solvent.

§ 2. Apparatus and Procedures

The relaxation times were measured by means of the coherent-pulse technique$^{5)}$. A block diagram of an apparatus employed is shown in Fig. 1. The apparatus consists of a magnet, a pulser, a transmitter, an induction head, a receiver, a synchroscope, and a signal integrator.

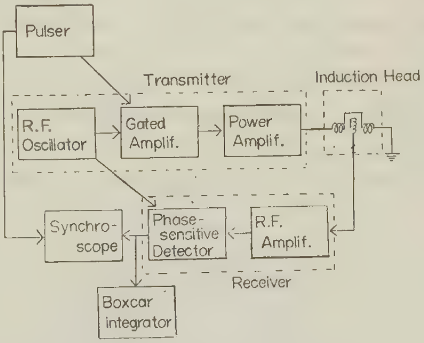

Fig. 1. Block Diagram of the apparatus.

Magnet.—A static magnetic field of 3850 oersteds was obtained from a permanent magnet having a pole face of 14 cm in diameter and a gap width of 4 cm. The field inhomogeneity over the sample of 0.5 cc in volume was about 0.1 oersteds, giving a decay time of the order of 0.5 milliseconds to the free precession.

Transmitter.—A continuously operating rf oscillator was followed by a gated amplifier, which was cut off except when a negative *dc* pulse is applied from the pulser to the cathode of the amplifier tube. The phase-coherent rf pulse, thus obtained, was further amplified and fed to a push-pull power amplifier which was operated in C-class. The output was taken from the tank circuit of the power amplifier by means of an adjustable link coil. One side of this link was grounded through an impedance-matching variable capacitor, while the other side was connected with a transmitting coil placed inside the induction head.

Induction head.—The head was designed in a similar manner as Weaver's[6]. The Helmholz-type transmitting coil had a diameter of 25 mm and a total winding of 12 turns. The receiving coil was wound around the sample in the middle of the transmitting coil and at a right angle to the latter coil. The flux linkage between the transmitting coil and the receiving coil could be made very small by shifting slightly half of the transmitting coil in the direction perpendicular to its axis by means of a micrometer screw. The maximum rf rotating field, H_1, obtained was about 6 oersteds.

Receiver.—The nuclear induction signals from the receiving coil were amplified in four stages of broad-band amplifiers. The over-all gain of the amplifiers was *ca.* 70 *db* and the band pass was *ca.* 0.6 Mc. The amplified rf signals were detected by a diode after superposing a rf carrier from the rf source of the transmitter. This phase-sensitive device made possible the linear detection of the weak signals, and gave a better signal to noise ratio and the sign of the free decay and echoes.

Synchroscope and signal integrator.—The output of the detector of the receiver was displayed on a synchroscope and also fed into the "boxcar integrator". The latter was an electronic measuring circuit which was set up modifying Holcomb and Norberg's design[7]. The experimental results obtained by use of this circuit have been proved to be much accurate compared with those by the photographic recording of signals on a synchroscope.

Pulser.—The pulser gated the transmitter by means of a *dc* negative pulse. A block diagram of the pulser is shown in Fig. 2. Th procedure of producing gate pulses is illustrated in Fig. 3, where the output pulse o each stage is shown on a common time axis The obtained gate pulses had rectangula shapes with the width ranging from 3μsec t 100μsec. The interval between the two gat pulses was equal to an integral multiple o the period of the audio-oscillator, and coul be varied step by step when the delay tim of the second delay circuit was changed b means of a volume control. The measuremen of the time interval was very easy and accurate.

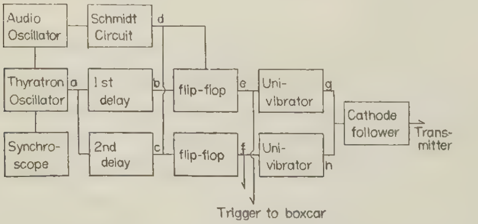

Fig. 2. Block diagram of the pulser. The letter at the output of each stage corresponds to that in Fig. 3.

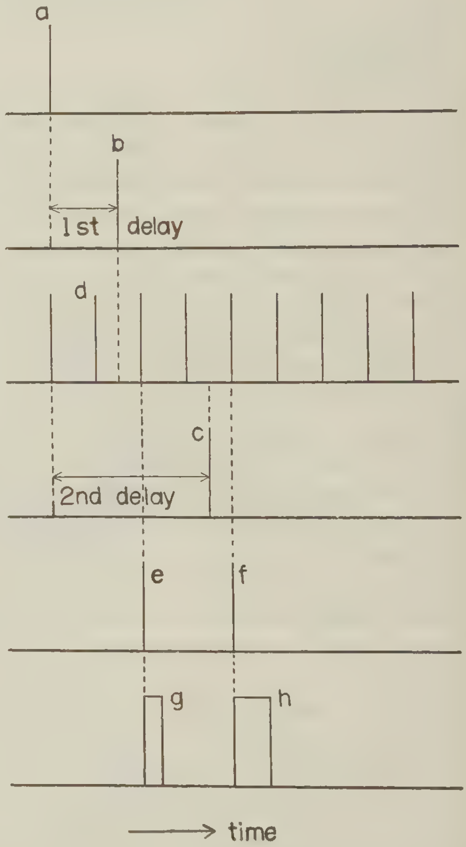

Fig. 3. Illustration of the procedure of making gate pulses. The letter on each pulse corresponds to that in Fig. 2.

The phase-sensitive detection produced a beat between the carrier frequency and the Larmor frequency of induction signals, when the field was off resonance. However, even when the rf carrier was not fed to the phase-sensitive detector, a similar beat was observed when the adjustment of the induction head was not adequate. This beat was caused by the leakage of the carrier through the power amplifier and could readily be made very small compared with amplitudes of the free decay and echo by finely adjusting the micrometer screw of the induction head. This adjustment assured normal operation of the receiver. The remaining small beat caused no trouble when the phase-sensitive detection was performed. The free decay following the rf pulse was obscured by the ringing of the transmitter as well as by the saturation of the initial stage of the receiver. This "dead time" could be reduced by the afore mentioned adjustment to less than 20μ sec.

The spin phase-memory time was measured by the 90°–180° pulse method. According to the Bloch equation[8)], the amplitude E of the echo following a 90–180° pulse sequence is given by

$$E=E_0 \exp(-2\tau/T_2) \qquad (1)$$

where τ is the time interval between the pulses. Thus, T_2 is determined from the slope of a straight line in a semilogarithmic plot.

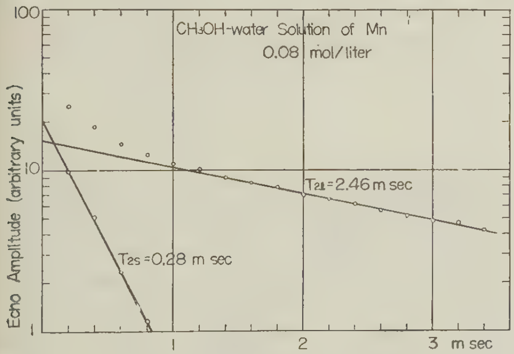

Fig. 4. A spin phase-memory curve for a methanol-water solution of $MnCl_2$.

For methanol solutions and methanol-water solutions, however, $\log E$ *versus* 2τ plot did not give a straight line. An example is shown in Fig. 4, where the curve is resolved in the usual manner and yields two components. Similar decomposition was possible for all solutions. Therefore, we have

$$E=E_{0s}\exp(-2\tau/T_{2s})+E_{0l}\exp(-2\tau/T_{2l}) , \qquad (2)$$

where the two spin phase-memory times, T_{2s} and T_{2l}, are determined from the slopes of the component lines, and the amplitudes, E_{0s} and E_{0l}, are obtained from the extrapolation of the component lines to $2\tau=0$.

The spin-lattice relaxation times were measured by use of the 180°–90° pulse sequence[9)]. In this experiment, the amplitude F of free decay following the second pulse was measured as a function of pulse intervals τ. For a single relaxation time, we have

$$F=F_0\{1-2\exp(-\tau/T_1)\} . \qquad (3)$$

From the null time τ_n for F equal to zero, we have $T_1=\tau_n/\log 2$. In methanol solutions and methanol-water solutions, however, (3) is not valid, but F can be analyzed as

$$F=F_{0s}\{1-2\exp(-\tau/T_{1s})\} \\ +F_{0l}\{1-2\exp(-\tau/T_{1l})\} ,$$

or

$$F_{0s}+F_{0l}-F=2F_{0s}\exp(-\tau/T_{1s}) \\ +2F_{0l}\exp(-\tau/T_{1l}) , \qquad (4)$$

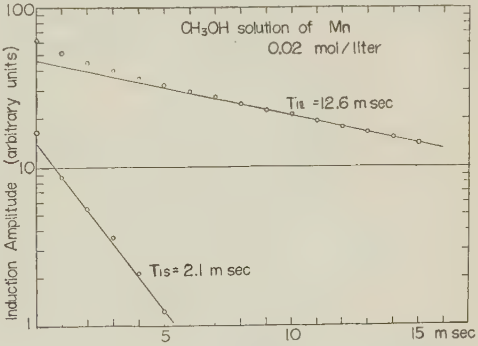

Fig. 5. A spin-lattice relaxation curve for a methanol solution of $MnCl_2 \cdot 4H_2O$.

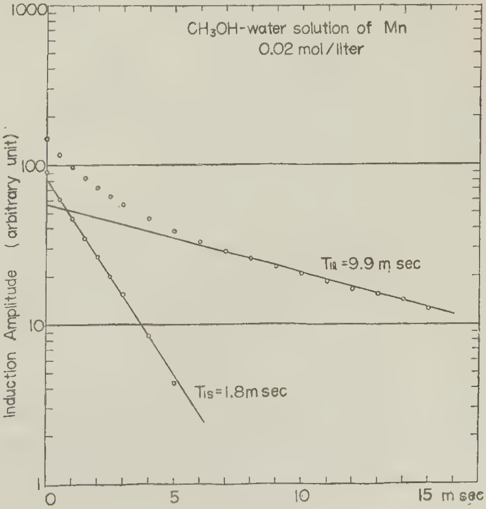

Fig. 6. A spin-lattice relaxation curve for a methanol-water solution of $MnCl_2$.

where $F_{0s}+F_{0l}$ is the value of F for $\tau=\infty$ and was obtained experimentally from the amplitude of the free decay following a 90° pulse in the absence of the 180° pulse. Thus, the relaxation times, T_{1s} and T_{1l}, and the amplitudes, F_{0s} and F_{0l}, can be obtained from a $\log(F_{0s}+F_{0l}-F)$ *versus* τ plot (Fig. 5 and Fig. 6). In this case, the null time is given by

$$F_{0s}+F_{0l}=2F_{0s}\exp(-\tau_n/T_{1s}) +2F_{0l}\exp(-\tau_n/T_{1l}) \ . \qquad (5)$$

When the first term at the right hand side can be ignored, we have

$$T_{1l}=\tau_n/\log\{2F_{0l}/(F_{0s}+F_{0l})\} \ . \qquad (6)$$

§ 3. Result

The values of T_1 and T_2 for aqueous solutions of $MnCl_2\cdot 4H_2O$ are shown as functions of ion concentrations in Fig. 7. They are in good agreement with those reported by Morgan et al.[3] The relaxation curves for methanol solutions of $MnCl_2\cdot 4H_2O$ show the existence of two components as descrined above. In addition, T_{1l} obtained from the null time by the use of (6) taking $F_{0l}/F_{0s}=3$ is in good agreement with that obtained from the semilogarithmic plot. These results indicate that the two kinds of protons, *i.e.*, protons of a hydroxyl group and of a methyl group, are subject to different local field environments. Also, the relaxation curves for methanol-water solutions of $MnCl_2\cdot 4H_2O$ have two components. The mixture solutions have three kinds of protons, *i.e.*, those of a water molecule, of a hydroxyl group and of a methyl group. How ever, chemical exchange of protons betwee a hydroxyl group and a water molecule take place presumably in a much shorter time tha the relaxation time. Accordingly, the tw kinds of protons have the same relaxatio time, giving one component of the relaxatio curves. The other component is due to th methyl group protons. A similar observatio has been reported by Morgan et al.[10] Th ratios, E_{0l}/E_{0s} and F_{0l}/F_{0s} are compared wit those of the numbers of protons in differen groups in Table I.

H_{CH} is the number of methyl group protons in the solution, H_{OH} is the number of protons belonging to either hydroxyl groups or water molecules.

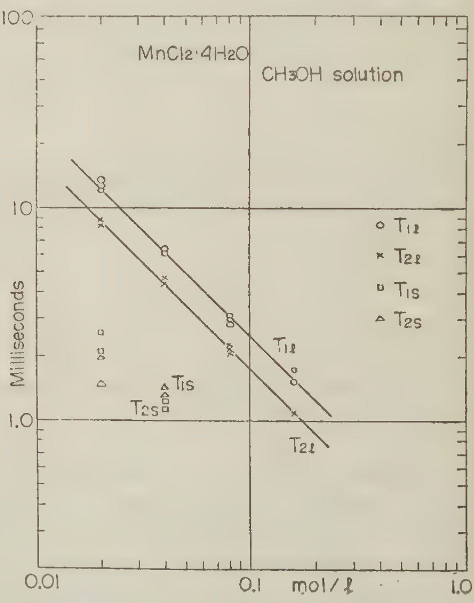

Fig. 8. Relaxation times as functions of ion concentration for methanol solution.

Relaxation times in the methanol solutions and the methanol-water solutions are plotted as functions of ion concentrations in Fig. 8 and Fig. 9. The volume ratio of methanol and water in the latter solution was 1:1. Commercial samples graded as "special pure"

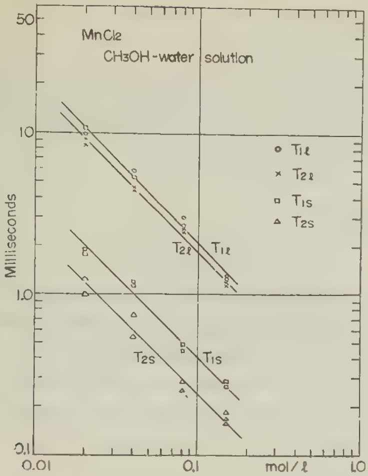

Fig. 9. Relaxation times as functions of ion concentration for methanol-water solution.

were used in this experiment at 10°–15°C.

§ 4. Discussion

The solubility of Mn salt in water and methanol is fairly high. It is known that manganous ions chemically combine with solvent molecules to form complex ions in these solutions. In aqueous solutions, the complex ion is assumed to be $\mathrm{Mn(H_2O)_6^{+2}}$ which has an octahedral symmetry as in Mn Tutton salt crystals. The rate of chemical exchange between the protons in a complex and those in the bulk solvent is considered to be very fast compared with the proton relaxation times, since only single T_1 and T_2 are obtained for each chemical group and these are inversely proportional to the concentration of manganous ions.

The relaxation of protons by the dipole-dipole interaction with manganous ions takes place mainly during the time when the protons stay as members of complex ions. If we neglect the relaxation process taking place while the protons are in the bulk solvent, the relaxation time is given by

$$\left(\frac{1}{T_1}\right)_{\mathrm{dip}}=\frac{2}{15}\frac{\hbar^2\gamma_I{}^2\gamma_s{}^2S(S+1)}{a^6}\left\{\frac{\tau_c}{1+(\omega_I-\omega_s)^2\tau_c{}^2}+\frac{3\tau_c}{1+\omega_I{}^2\tau_c{}^2}+\frac{6\tau_c}{1+(\omega_I+\omega_s)^2\tau_c{}^2}\right\}\frac{zn}{N}\,, \tag{7}$$

$$\begin{aligned}\left(\frac{1}{T_2}\right)_{\mathrm{dip}}=\frac{1}{15}\frac{\hbar^2\gamma_I{}^2\gamma_s{}^2S(S+1)}{a^6}\Bigg\{&4\tau_c+\frac{\tau_c}{1+(\omega_I-\omega_s)^2\tau_c{}^2}+\frac{3\tau_c}{1+\omega_I{}^2\tau_c{}^2}+\frac{6\tau_c}{1+\omega_s{}^2\tau_c{}^2}\\&+\frac{6\tau_c}{1+(\omega_I+\omega_s)^2\tau_c{}^2}\Bigg\}\frac{nz}{N}\,,\end{aligned} \tag{8}$$

where a is the distance between a proton and the manganous ion in the complex; γ_I and γ_s are the gyromagnetic ratios of a proton and a manganous ion respectively; S is the total electron spin of the manganous ion; ω_I and ω_s are Larmor frequencies of a proton and a manganous ion; N and n are the numbers of sovent molecules and manganous ions per unit volume; z is the coordination number of manganous ion; τ_c is the correlation time which is of the order of $4\pi\eta r_0{}^3/3kT$ according to the BPP theory, where η denotes viscosity and r_0 the radius of the complex ion. The order of magnitude of τ_c is 10^{-11} sec with the present solutions. This order was also confirmed by the analysis of the line-width data of electron spin resonance of manganous ions in alcohol-water solutions[11]. Therefore we have $\omega_I\tau_c\ll 1$, and from (7) and (8)

$$\left(\frac{T_1}{T_2}\right)_{\mathrm{dip}}\doteqdot\frac{10+3.5\omega_s{}^2\tau_c{}^2}{10+3\omega_s{}^2\tau_c{}^2}\,.$$

Thus,

$$1<\left(\frac{T_1}{T_2}\right)_{\mathrm{dip}}<1.16\,. \tag{9}$$

This inequality will not be altered if we take into account the relaxation process neglected above, because the interaction between the proton in the bulk solvent and the manganous ions contributes to the relaxation only when the manganous ions sufficiently near the proton so that the correlation time τ_c' satisfies $\omega_I\tau_c'\ll 1$.

Thus, T_1/T_2 larger than 1.16 indicates the existence of other relaxation mechanism. This mechanism is due to the Fermi contact interaction

$$\sum a_i(\boldsymbol{I}\cdot\boldsymbol{S}_i)=\sum_i \frac{16\pi\gamma\hbar\beta}{3}|\psi_i(0)|^2(\boldsymbol{I}\cdot\boldsymbol{s}_i) \tag{10}$$

where $\boldsymbol{s}_i$ is the spin of the i-th magnetic electron and $|\psi_i(0)|^2$ is the probability density of the electron at the resonating nucleus, and β is the Bohr magneton. Since the ground state of the complex is determined by Hund's rule, (10) can be transformed into

$$A(\boldsymbol{I}\cdot\boldsymbol{S})=\left(\frac{1}{n}\sum a_i\right)(\boldsymbol{I}\cdot\boldsymbol{S}) \tag{11}$$

where n is the number of magnetic electrons in a manganous ion. Expression (11) is the spin exchange interaction which was first suggested by Bloembergen[4]. Since this interaction is unaffected by the rotation of the complex, its correlation time is identical with the hydration time or with the relaxation time of the electron spin, whichever is the shorter. Since the large difference between T_1 and T_2 is only observed for ions having long electron spin relaxation times, the correlation time seems to be identical with the latter. Then the expressions for the nuclear relaxation times are given by

$$\left(\frac{1}{T_1}\right)_{\text{ex}}=\frac{2}{3}S(S+1)\hbar^{-2}A^2\tau_s\{1+(\omega_I-\omega_s)^2\tau_s^2\}^{-1}\frac{zn}{N}\ , \tag{12}$$

$$\left(\frac{1}{T_2}\right)_{\text{ex}}=\frac{1}{3}S(S+1)\hbar^{-2}A^2[\tau_s+\tau_s\{1+(\omega_I-\omega_s)^2\tau_s^2\}^{-1}]\frac{zn}{N} \tag{13}$$

where τ_s is the electron spin relaxation time.

The observed T_1 and T_2 are given by

$$\frac{1}{T_1}=\left(\frac{1}{T_1}\right)_{\text{dip}}+\left(\frac{1}{T_1}\right)_{\text{ex}} \tag{14}$$

$$\frac{1}{T_2}=\left(\frac{1}{T_2}\right)_{\text{dip}}+\left(\frac{1}{T_2}\right)_{\text{ex}}\ . \tag{15}$$

$(1/T_1)_{\text{ex}}$ in (14) can be disregarded, since $\omega_s^2\tau_s^2\gg1$ for the present solutions. Then if we assume according to (9)

$$\left(\frac{T_1}{T_2}\right)_{\text{dip}}=1.1 \tag{16}$$

we have

$$\left(\frac{1}{T_2}\right)_{\text{ex}}=\frac{1}{T_2}-\frac{1.1}{T_1} \tag{17}$$

which will be used to estimate the value of A in the following.

Aqueous solution.—From the data on the aqueous solution of MnCl_2 of 0.026 mol/liter concentration, we have $T_1=3.6$ msec and $T_2=1.0$ msec. Then, using (17) and (13) taking $S=5/2$, $z=6$ and $\tau_s=3\times10^{-9}$ sec,[11] we have $A/h=1.0\times10^6\ \text{sec}^{-1}$. This value is larger than that given by Bloembergen. His value seems less accurate than ours since it largely depends upon the estimation of the distance between the manganous ion and the proton of the ligand.

Methanol solution.—The value of T_1 for methyl group protons is *ca.* 5.2 times that for hydroxyl group protons. (Fig. 8). This result indicates that the distance between the manganous ion and the hydroxyl group proton in a ligand molecule is shorter than that between the manganous ion and the metyl group proton. Since T_1 is proportional to the sixth power of the distance, the ratio of the two distances is 1.3. This ratio is resonable if we suppose a geometrical configuration of a manganous ion and a methanol molecule as shown in Fig. 11.

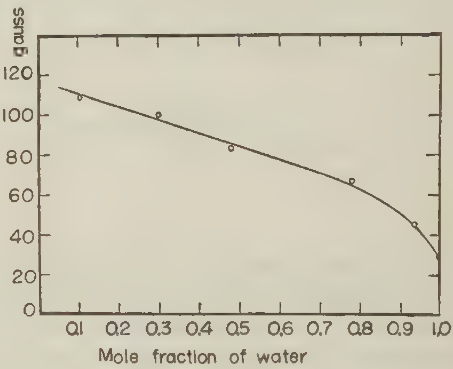

Fig. 10. Line width of hyperfine line of a manganous ion in alcohol-methanol mixture of 0.2 mol MnCl_2 according to McGarvey.[11]

The observed ratio of T_{1s}/T_{2s} for hydroxyl group protons has an experimental error too large to permit any conclusion. However, T_{1l}/T_{2l} for methyl group protons is *ca.* 1.43

from Fig. 8. This ratio indicates the existence of the spin exchange interaction. The value of the electron spin relaxation time, which is necessary to calculate the value of A from (13), has not been reported for methanol solutions. However, we assume that τ_s for the methanol solution is 1/3 times that for the aqueous solution, taking into account the fact that the line width for the alcohol solution is about 3 times that for the aqueous solution[11] (Fig. 10). Then, assuming $z=6$, we have $A/h=2.1\times10^5$ sec^{-1} for methyl group protons.

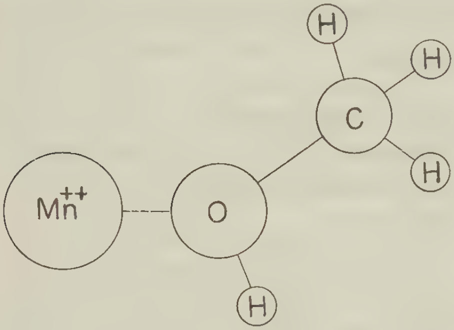

Fig. 11. A model for the geometrical configuration of a manganous ion and a methanol molecule in a complex.

Since A is proportional to the density of unpaired electrons at the resonating nucleus, the existence of the exchange interaction is rather striking. However, this existence was also confirmed by the chemical shift observed by Phillips et al.[12] The $A(\boldsymbol{IS})$ interaction gives a paramagnetic shift quite similar to the Knight shift in metals. The shift is given by

$$\varDelta H=-\frac{1}{\gamma\hbar}A\langle S_z\rangle\frac{nz}{N} \tag{18}$$

where $\langle S_z\rangle$ is the thermal-equilibrium value of S_z, namely

$$\langle S_z\rangle=2\beta S(S+1)H/(3kT)\ . \tag{19}$$

Thus, when $A/h\sim2\times10^5$ sec^{-1}, we have $\varDelta H/H\sim1.7\times10^{-5}$ for 1 mol/liter solution. Phillips et al. observed the shifts of this order for methyl group protons in propyl alcohol and butyl alcohol solutions of $CoCl_2$. They also reported the existence of a similar shift for methanol solutions of $MnCl_2$ although the data have not been published. The spin exchange interaction between methyl group protons and manganous ions gives a proof for the delocalization of magnetic electrons of a manganous ion giving a finite probability of staying on the ligand molecule. Isotropic hyperfine splitting due to a similar interaction with methyl group protons has been observed in the electron spin resonance of methyl-substituted semiquinones.[13),14)]

Methanol-water solution.—The distance of closest approach of the two species of protons to a manganous ion have a ratio of 1.3 as estimated from the observed ratio of $T_{1l}/T_{1s}=5.2$. The exchange interaction constant A for the short-time component becomes 8×10^5 sec^{-1} from the observed ratio $T_{1s}/T_{2s}=1.67$ if it is assumed that $\tau_s\sim1\times10^{-9}$ sec. For the long-time component, T_{1l}/T_{2l} is nearly equal to 1.1. Therefore, the effect of the spin exchange interaction is almost unobservable in contrast to the case of pure methanol solutions. The reason for this result is open to questions, but the result seems to indicate that the weak covalent bonds between manganous ions and methanol molecules are broken by the action of water molecules.

Acknowledgment

The authors wish to thank Prof. R. Uyeda for his support of this research, and to thank Prof. S. Kubo for reading the manuscript. The authors also thank Mr. T. Ohta for his aid in constructing some of the apparatus. One of the authors (H.Y.) thanks to Prof. J. Itoh of Osaka University who introduced him into the field of the nuclear magnetic resonance. This study was partially financed by the Scientific Research Fund of the Ministry of Education.

Paramagnetic Susceptibility of Single Crystals of Some Nickel Salts

By Taiichiro HASEDA, Hanako KOBAYASHI
and Muneyuki DATE

The Research Institute for Iron, Steel and Other Metals,
Tôhoku University, Sendai, Japan

(Received July 13, 1959)

Paramagnetic susceptibility of single crystals of NiK Tutton salt and $NiCl_2 \cdot 6H_2O$ were measured in the temperature range between 1.40°K and 20.4°K. The anisotropic susceptibilities found in NiK Tutton salt are in very good agreement with the calculated values using the splitting parameters which are determined by paramagnetic resonance experiment. In $NiCl_2 \cdot 6H_2O$, the antiferromagnetic transition was found at about 6°K. The easy axis is along the axis perpendicular to crystalline *c* axis in *ac* plane.

§ 1. Introduction

In the previous paper, T. Haseda and M. Date reported the paramagnetic susceptibilities of some of the nickel salts in powdered samples and made theoretical consideration on characteristics of susceptibilities of Ni^{+2} ions. It was, in the first place, found out that the susceptibility *vs* temperature curve was expected to be flat at the lowest temperature in all samples. The susceptibilities of $Ni^{+2}(3d^8)$ ion in the rhombic crystalline field were calculated in the wide temperature range. The calculated susceptibilities on each axis were expected to be strongly anisotropic in the lowest temperature range. The value of susceptibility in one of the axis is larger than the value expected from the Curie law, and the value of one of the other axis has the maximum value at some temperature. The measured susceptibilities in powdered samples are, of course the average of these values. The calculated average of the susceptibilities showed the tendency to be flat in the lowest temperature range. The comparison of the calculated value with the experimental ones was made in the powdered sample of $NiNH_4$ Tutton Salt. Though the good agreement was obtained, it will be more definite when some experiments on single crystals are carried on and the expected strong anisotropy is observed.

In this paper, the measurements are made on single crystals of NiK Tutton salt and the results are discussed on the bases of the theory developed in the previous paper.

One of the other noticeable results in the former investigation, was the large Weiss constant 7°K and the flat behaviour below considerably high temperatures (10°K) found in $NiCl_2 \cdot 6H_2O$. Though the explanation of the latter behaviour was intended under the above mentioned consideration assuming the strongly deformed crystalline field, the large Weiss constant was not examined.

One of the present authors (T.H.) and E. Kanda have found an antiferromagnetic behaviour in $CoCl_2 \cdot 6H_2O$ below 3.0°K[2]. The X-ray investigation of $NiCl_2 \cdot 6H_2O$ is now in progress by J. Mizuno and it has been found that the crystal structure is quite isomorphous to $CoCl_2 \cdot 6H_2O$[3]. Considering from the large Weiss constant of $NiCl_2 \cdot 6H_2O$ and its isomorphism to $CoCl_2 \cdot 6H_2O$ it will be expected that $NiCl_2 \cdot 6H_2O$ is also antiferromagnetic below about 10°K. The measurements on single crystals of $NiCl_2 \cdot 6H_2O$ are intended and the antiferromagnetic nature is revealed in this salt.

§ 2. The Susceptibility of Single Crystals of NiK Tutton Salt

Measurements were made using the a.c. bridge method in the temperature range between 20°K and 1.3°K. The results are listed in Table I and shown in Fig. 1 where K_1, K_2 and K_3 are magnetic principal axes determined by paramagnetic resonance experiment[4),5)]. Considerable anisotropy are found out as expected in the previous paper. However, as is known, in NiK Tutton salt crystal, there are two kinds of Ni^{+2} ions in unit cell. The relation among magnetic principal axes and axes of two kinds of octahedron which is formed by six water molecules around each Ni^{+2} ion in unit cell, is shown in Fig. 2 (a) and (b). The susceptibilities of single Ni^{+2} ion in a rhombic field (in slightly deformed octahedron) are given as

Table I. Molar susceptibility of single crystals of NiK Tutton salt.

T°K	K_1-axis	K_2-axis	K_3-axis
20.4	0.0611	0.0534	0.0531
17.6	0.0720	0.0602	0.0593
16.1	0.0795	0.0665	0.0664
14.9	0.0870	0.0744	0.0737
4.20	0.353	0.204	0.209
3.49	0.435	0.239	0.236
2.91	0.524	0.259	0.260
2.49	0.616	0.278	0.282
1.91	0.813	0.276	0.312
1.48	1.02	0.331	0.335

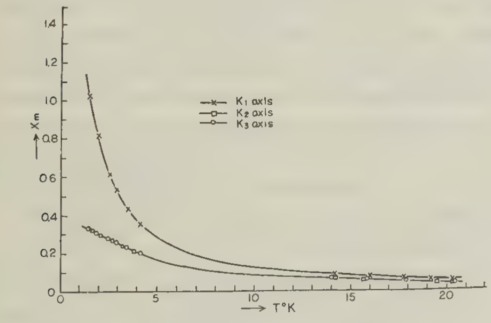

Fig. 1. Paramagnetic susceptibility of NiK Tutton salt.

$$\chi_x = \frac{2Ng^2\beta^2}{\frac{D+E}{2}} \frac{\sinh \frac{D+E}{2kT}}{\exp-\left(\frac{3E-D}{2kT}\right)+2\cosh\frac{D+E}{2kT}},$$

$$\chi_y = \frac{2Ng^2\beta^2}{\frac{D-E}{2}} \frac{\sinh \frac{D-E}{2kT}}{\exp-\left(\frac{3E+D}{2kT}\right)+2\cosh\frac{D-E}{2kT}},$$

$$\chi_z = \frac{2Ng^2\beta^2}{E} \frac{\sinh \frac{E}{kT}}{\exp\left(\frac{D}{kT}\right)+2\cosh\frac{E}{kT}}.$$

Here, x, y and z are the axes of a rhombic field. D and E are the splitting parameters appeared in the spin Hamltonian. The measured susceptibilities along each principal axis are the average value of two kind Ni^{+2} ions in units cell. It is easy to calculate the susceptibility on each principal axis in terms of χ_x, χ_y and χ_z, taking account for the situation shown in Fig. 2. Calculated values of χ_x, χ_y, χ_z and χ_{k_1}, χ_{k_2} and χ_{k_3} are shown in Fig. 3 for NiK Tutton salt. The values of constant used, are as follow,

$$D=-3.50\ \mathrm{cm}^{-1}\,,\quad E=-0.55\ \mathrm{cm}^{-1}\,,$$
$$g=2.25\,,\quad \theta=11^\circ\,,\quad \varphi=-12.5^\circ\,.$$

The ageement between the calculated and

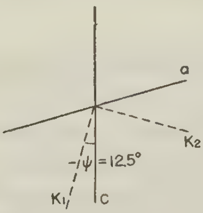

Fig. 2 (a)

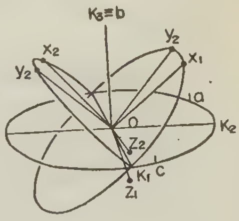

Fig. 2 (b)

(a) Susceptibility axes K_1, K_2 in ac plane of NiK Tutton salt. K_3 is parallel to b-axis and perpendicular to the plane of the figure.

(b) Relative directions of the axes in NiK Tutton salt. (a, b, c)=crystallograyhic axes, $(K_1K_2K_3)$= susceptibility axes, (x, y, Z)=axes of rhombic crystalline field. Z_1Z_2 lie in K_1K_3 plane. $\angle K_1OZ_1=\theta=11°$.

experimental values is very good showing the correctness of the above analysis. If the values given by Griffiths and Owen[5] are used, the results do not alter by the amount up to a few percent.

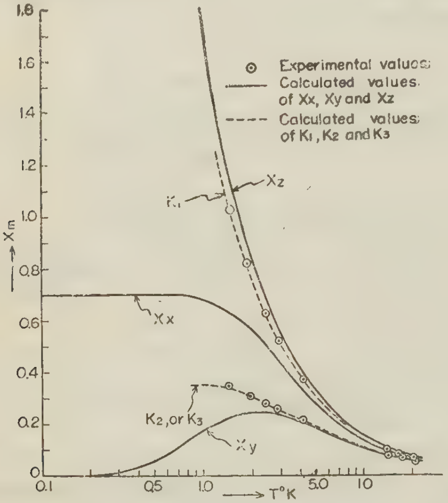

Fig. 3. Calculated susceptibility of NiK Tutton salt.

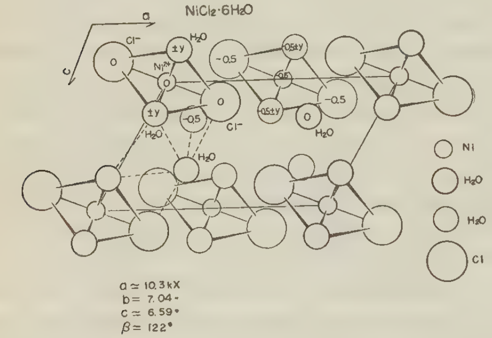

Fig. 4. A rough sketch of crystal structure of $NiCl_2 \cdot 6H_2O$.

§ 3. The Susceptibility of Single Crystals of $NiCl_2 \cdot 6H_2O$

As was mentioned in § 1, the crystal structure of this salt is quite isomorphous to $CoCl_2 \cdot 6H_2O$. Each Ni^{+2} ion is surrounded by four water molecules in a plane and by two chlorine ions along the axis perpendicular to the square of water molecules. Though the detail of the crystal analysis is not yet determined, the rough sketch of the crystal structure is shown in Fig. 4[6]. The measurements of the susceptibility on single crystal of this salt are made by a.c. bridge method, and results are shown in Fig. 5. Measurements are made along the crystalline b and c axis, and the axis perpendicular to c axis in the ac plane ($c\perp$).

As is apparent from Fig. 5, $NiCl_2 \cdot 6H_2O$ is antiferromagnetic below 6.2°K. The Weiss constant Θ of this salt determined in the sample is 10°K[1]*. T_N/Θ is about 0.6. The axis of easy magnetization is along $c\perp$ axis. It will be worthwhile to note that the easy axis in antiferromagnetic state of $CoCl_2 \cdot 6H_2O$ is along $c_{//}$ axis[7], though the detail of spin structure in these salts, is not clear now.

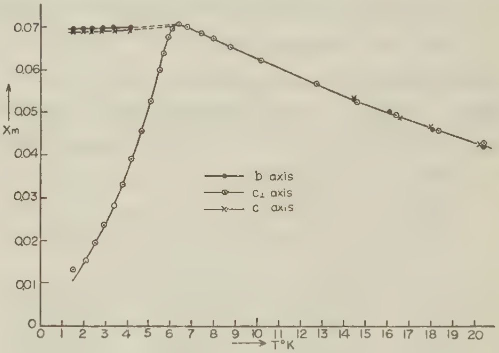

Fig. 5. Molar susceptibility of $NiCl_2 \cdot 6H_2O$.

Special interest may be on the nature of antiferromagnetism in the salt of Ni^{+2} ions concerning with the spin quenching in paramagnetic state of this salt.

As is seen in NiK Tutton salt, the susceptibility becomes anisotropic showing spin quenching of this ion. If, in $NiCl_2 \cdot 6H_2O$, the susceptibility is also anisotropic in paramagnetic range (above 6°K), the transition to antiferromagnetic state will occur in somewhat different manner from the usual cases.

In the present measurement, the anisotropy has not been observed in paramagnetic region within the experimental error which is about ±1.5%. The finer experiment is required and now being intended.

Recently, T. Sugawara have detected the proton resonance in $NiCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 6H_2O$ below their Néel point[9]. And one of the present authors (M.D.) have succeeded to measure the antiferromagnetic resonance in $CoCl_2 \cdot 6H_2O$ below 2.1°K[10].

Detailed discussion on antiferromagnetic state in $NiCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 6H_2O$ will be made in the following paper.

---

* In the paper of ref. (1), Weiss constant was determined to be 7°K. However, it is more suitable to decide it as 10°K.

The authors wish to express their sincere thanks to Mr. J. Mizuno for permission to quote the results of crystal analysis of $NiCl_2 \cdot 6H_2O$ before the publication. The authors indebted deeply to Mr. Takashi Satō for preparing the single crystals used in this investigation.

Relative Intensities of Zeeman Components in Nuclear Quadrupole Resonance Spectrum

By Masaharu TOYAMA

Department of Chemistry, Faculty of Science
University of Tokyo, Tokyo

(Received August 17, 1959)

The transition probabilities for the Zeeman components in nuclear quadrupole resonance spectrum were formulated in the case of arbitrary field gradient. Interesting behaviours were revealed especially for a nucleus of half-integral spin. When a magnetic field is applied in a direction perpendicular to the principal z-axis in the case of nonaxial field gradient due to the surrounding charges, the inner pair of the Zeeman components is produced by the x-component of the rf field and the outer pair by the y-component. The dependence of the intensities on the Zeeman field is in general not symmetric with respect to the principal axes of the field gradient.

§1. Introduction

Since the Zeeman effect of nuclear quadrupole resonance was first treated by Krüger[1] in the case of axially symmetric field, a large number of studies[2]–[4] have been made on the splitting of energy levels, but few on the intensities of the Zeeman components. The intensities in the nonaxial case have only partially been treated by Dean,[3] Cohen,[4] and others.[5],[6] Such a circumstance depends upon the fact that the calculation of the intensities is fairly complicated compared with that of the energy levels and upon the presupmtion that it would not have any possibility to give useful informations in spite of its complicated nature. For axially symmetric case, the intensity of the outer pair of Zeeman components due to the transitions of $|m|=1/2 \rightleftarrows 3/2$ has been proved to have a maximum value and to be equal to that of the inner pair when the Zeeman field is applied in the direction perpendicular to the principal z-axis of the field gradient. It decreases gradually and finally vanishes as the direction of the Zeeman field approaches to that of the z-axis. It was revealed, however, in the Zeeman experiment on the Cl^{35} resonance in cyanuryl chloride[7] ($\eta_{av}=0.24$) that the intensity in the nonaxial case fairly deviated from the above rule, and in addition it could not be explained by any extension of the axially symmetric case. When the direction of the applied field was not close to the principal xy-plain, the observed intensities obeyed approximately the rule, but in the vicinity of the xy-plane the intensity of the outer pair decreased abruptly, contrary to the expectation from the rule.

Similar phenomenon has been observed even in the case of axially symmetric field ($\eta=0$) by Ting, Manring, and Williams.[8] The third order Zeeman effect for the Cl^{35} resonance line in $NaClO_3$ was observed by applying strong field in the direction perpendicular to the principal z-axis. The resonance line was split into four lines as in the nonaxial case, of which the inner pair was vanishing below the noise level. This intensity relation was interpreted by the dependence of the transition to the direction of the rf field. Similar interpretation is expected to be possible in the nonaxial case.

Dean[3] discussed qualitatively the transition moments in the nine cases when the Zeeman field parallel to the axis x, y, and z, combined with the rf field parallel to the axis x, y, and z. His discussion is, however, not enough to explain the above phenomenon, in particular, the abrupt change in the intensity in the vicinity of the xy-plain. Cohen's calculation[4] was attempted in a special case of the nuclei with spins 5/2, 7/2, and 9/2, in which the rf field was applied parallel to the x-axis. It can not be applied to the resonance of Cl^{35} whose spin is 3/2.

§ 2. Calculation

The electric field gradient $\{q_{ij}\}$ produced at a nucleus by surrounding charges has in general an asymmetry described by an asymmetry parameter

$$\eta=(q_{xx}-q_{yy})/q_{zz}\ , \quad (|q_{xx}|\leq|q_{yy}|\leq|q_{zz}|) \quad (1)$$

where q_{xx}, q_{yy}, and q_{zz} denote the principal components of the field gradient: under this definition η always takes a non-negative number from zero to unity. The nuclear quadrupole interacts with this electric field gradient under the influence of a static magnetic field. The Hamiltonian which defines the system is then expressed as follows:

$$\mathcal{H}_0=\mathcal{H}_Q+\mathcal{H}_M\ ,$$

where

$$\mathcal{H}_Q=-A[(3I_z^2-I^2)+\eta(I_x^2-I_y^2)]\ ,$$

$$\mathcal{H}_M=-\gamma I\cdot H=-\gamma[H_xI_x+H_yI_y+H_zI_z]\ , \quad (2$$

$$A=\frac{eQq_{zz}}{4I(2I-1)}\ ,$$

and eQ denotes the scalar nuclear quadrupole moment, γ the nuclear gyromagnetic ratio, H_x, H_y, and H_z the components of H along the principal axes of the field gradient, and I the nuclear spin operator with the quantum number $I>1/2$ and with the components I_x, I_y, and I_z.

If the eigenvectors $|m\rangle$'s of I_z are taken as the bases, non-vanishing matrix elements for the spin operators are given by[9]

$$\langle m|I_z|m\rangle=m\ ,$$

and

$$\langle m|I_\pm|m\mp1\rangle=[(I\pm m)(I\mp m+1)]^{1/2}, \quad (3)$$

$$(m=I,\ I-1,\cdots,-I)$$

where $I_\pm=I_x\pm iI_y$. The eigenvectors of $\mathcal{H}_0$ are then represented by linear combinations of the basic vectors, from which the energy levels and the intensities are calculated.

Now in the case of half-integral spins two pure quadrupole states $\pm mQ$ are degenerate in the absence of a magnetic field, where mQ designates an eigenstate of $\mathcal{H}_Q$ which should be reduced to the states m for $\eta=0$. This degeneracy is removed by a Zeeman field so that an absorption line due to the transition $|mQ|=m'Q\rightleftarrows m''Q$ (m', $m''>0$) splits into two pairs, $\pm m'M\rightleftarrows\pm m''M$ and $\pm m'M\rightleftarrows\pm m''M$, as shown in Fig. 1, where mM designates an eigenstate of $\mathcal{H}_0$ similarly to mQ. Non-

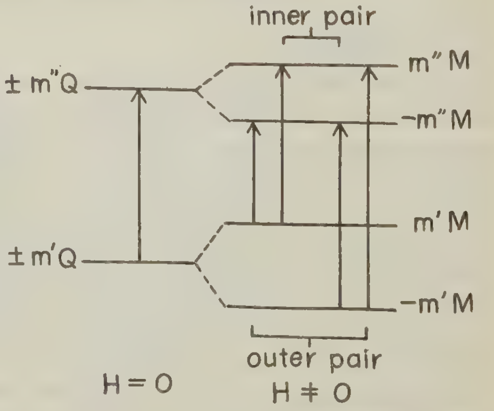

Fig. 1. Zeeman splitting of the nuclear quadrupole energy levels.

vanishing elements of $\mathscr{H}^0$ are expressed in the representation by $|m>$'s as follows:

$$\langle m|\mathscr{H}_Q|m\rangle=-A[3m^2-I(I+1)]\ ,$$

and

$$\langle m\pm1|\mathscr{H}_Q|m\mp1\rangle=-\eta A f^{1/2}(I,\ m)\ , \qquad (4)$$

where

$$f(I,\ m)=\frac{1}{4}(I^2-m^2)[(I+1)^2-m^2]\ . \qquad (5)$$

The eigenvectors of $\mathscr{H}_Q$ are, therefore, given by

$$|mQ>=\sum_{\mu}|m+2\mu><m+2\mu|mQ>$$
$$(|m+2\mu|\leq I)\ . \qquad (6)$$

The coefficients $\langle m+2\mu|mQ\rangle$'s are calculated by use of Eqs. (4) as shown later. It is noted here that

$$\langle m'|mQ\rangle=\langle -m'|-mQ\rangle\ , \qquad (6)'$$

which is derived for half-integral spins from the quadratic property of the original Hamiltonian. (In the later treatment m, m', and other quantum numbers are taken as positive numbers, except when special signs are referred to them).

For the calculation of the intensity parameters described below, it is necessary to have the transition moments between pure quadrupole states. They are classified into two types by the condition $\Delta|m|$ even or odd. Non-vanishing terms of them are derived from Eqs. (6) and (6)′ as follows:

Type I $(\Delta|m|=\text{odd})$

$$\langle\pm(m+2n+1)Q|\boldsymbol{I}_x|\pm mQ\rangle=I_{x,m,m+2n+1}\ ,$$

$$\langle\pm(m+2n+1)Q|\boldsymbol{I}_y|\pm mQ\rangle=\pm\frac{1}{i}I_{y,m,m+2n+1}\ ,$$

$$\langle\mp(m+2n+1)Q|\boldsymbol{I}_z|\pm mQ\rangle=\pm I_{z,m,m+2n+1}\ ,$$

Type II $(\Delta|m|=\text{even})$

$$\langle\mp(m+2n)Q|\boldsymbol{I}_x|\pm mQ\rangle=I_{x,m,m+2n}\ ,$$

$$\langle\mp(m+2n)Q|\boldsymbol{I}_y|\pm mQ\rangle=\pm\frac{1}{i}I_{y,m,m+2n}\ ,$$

$$\langle\pm(m+2n)Q|\boldsymbol{I}_z|\pm mQ\rangle=\pm I_{z,m,m+2n}\ . \qquad (7)$$

For the approximation to the first order of $\boldsymbol{H}$ it is necessary to have the matrix elements of $\mathscr{H}_M$ between each pair of degenerate pure quadrupole states $\pm mQ$. They are derived from Eqs. (2) and (7) to be

$$\langle\pm mQ|\mathscr{H}_M|\pm mQ\rangle=\mp\gamma I_{z,m,m}H_z\ ,$$

and

$$\langle\pm mQ|\mathscr{H}_M|\mp mQ\rangle=-\gamma[I_{x,m,m}H_x\pm iI_{y,m,m}H_y] \qquad (8)$$

The eigenvalues of $\mathscr{H}_0$ are then given to the first order in $\boldsymbol{H}$ by

$$E(\pm mM)=E_Q(\pm m)-\gamma E_M(\pm m)\ , \qquad (9)$$

where $E_Q(\pm m)$'s are the unperturbed quadrupole energies and $E_M(\pm m)$'s the energy shifts of the split levels in the unit of γ:

$$E_M(\pm m)=\pm[I^2_{x,m,m}H_x^2+I^2_{y,m,m}H_y^2+I^2_{z,m,m}H_z^2]^{1/2} \qquad (9)'$$

From Eqs. (8) and (9) the eigenvectors of $\mathscr{H}_0$ in the zeroth order in $\boldsymbol{H}$ are given by

$$|mM>=a_m|mQ>+b_m|-mQ>\ ,$$

and

$$|-mM>=-b_m^*|mQ>+a_m^*|-mQ>\ , \qquad (10)$$

where the coefficients a_m and b_m are given by the following relations:

$$\frac{I_{x,m,m}H_x}{E_M(m)}=a_mb_m^*+a_m^*b_m\ ,$$

$$\frac{I_{y,m,m}H_y}{E_M(m)}=a_mb_m^*-a_m^*b_m\ ,$$

$$\frac{I_{z,m,m}H_z}{E_M(m)}=a_ma_m^*-b_mb_m^*\ ,$$

and

$$a_m a_m^* + b_m b_m^* = 1 \tag{11}$$

In ordinary nuclear spin resonance the transition between two eigenstates E' and E'' $(E'' > E')$ is produced by a magnetic interaction of the nuclear magnetic moment with the rf field $2\boldsymbol{H}_r \cos 2\pi\nu t$. The total Hamiltonian has to include the interaction term given by

$$\mathscr{H}_1 = -2\gamma \boldsymbol{I}\cdot \boldsymbol{H}_r \cos 2\pi\nu t\ .$$

The transition probability is then expressed to the second order of approximation as follows:[10]

$$w(E',\ E'') = \hbar^{-2} T^2(E',\ E'') g(\nu)\ , \tag{12}$$

where $g(\nu)$ is the distribution function of frequencies and $T^2(E',\ E'')$ may be called a square transition moment, which is obtained from Eq. (2)′ as follows:

$$T^2(E',\ E'') = |\langle E''|\gamma \boldsymbol{I}\cdot \boldsymbol{H}_r|E'\rangle|^2 = \gamma^2 \sum_{i,\,j} H_{ri} H_{rj} J_{ij}(E',\ E'')\ , \qquad (i,\ j = x,\ y,\ \text{and}\ z) \tag{13}$$

where

$$J_{ij}(E',\ E'') = \frac{1}{2}[\langle E''|\boldsymbol{I}_i|E'\rangle\langle E'|\boldsymbol{I}_j|E''\rangle + \langle E''|\boldsymbol{I}_j|E'\rangle\langle E'|\boldsymbol{I}_i|E''\rangle] \tag{13$'$}$$

and H_{rx}, H_{ry}, and H_{rz} are the components of the rf field along the principal axes of the field gradient. The distribution $g(\nu)$ is originated from spin-spin interactions, thermal motions of lattice, and inhomogeneity of the external applied field $\boldsymbol{H}$.

Under unsaturation condition,[11] the peak intensity at a resonance frequency $\nu = (E'' - E')/h$ in the absorption spectrum is proportional to

$$P(E',\ E'') = \frac{4\pi N \nu^2}{(2I+1)\Delta\nu \cdot kT} \cdot T^2(E',\ E'')\ , \tag{14}$$

provided that $|E_{\max} - E_{\min}| \ll kT$, where $\Delta\nu$ is the half-value width of the absorption line described by $g(\nu)$, T the absolute temperature, k Boltzmann constant, and N the total number of the resonating nuclei.

In this article let us confine ourselves to the discussion of the case of strong quadrupole coupling and weak magnetic field. Thus the energy levels may be calculated to the first order of $\boldsymbol{H}$ as shown above, but the transition probabilities are enough to be calculated in the zeroth order in $\boldsymbol{H}$, since the accuracy in the measurement of the intensity is far lower than that of the frequency.

In the case of half-integral spins two transitions belonging to the same pair, that is, $\pm m'M \rightleftarrows \pm m''M$ or $\pm m'M \rightleftarrows \mp m''M$, occur with equal probabilities. As the contribution of the splitting of the energy levels to ν^2 in Eq. (14) may be neglected in the zeroth order of approximation in $\boldsymbol{H}$, the relative intensity of these two pairs is given by

$$P_r(m',\ m'') = \frac{T^2(-)}{T^2(+) + T^2(-)} \tag{15}$$

where the plus sign denotes the inner pair $\pm m'M \rightleftarrows \pm m''M$ and the minus sign the outer pair $\pm m'M \rightleftarrows \mp m''M$.

The next problem is to formulate the intensity parameters:

$$J_{ij}(\pm) = J_{ij}(m'M,\ \pm m''M) = J_{ij}(-m'M,\ \mp m''M)\ . \qquad (i,\ j = x,\ y,\ \text{and}\ z) \tag{16}$$

They are obtained from the eigenvectors of $\mathscr{H}_0$ given by Eq. (10) and the transition moments between pure quadrupole states (Eq. (7)) as follows:

Type I $(m''=m'+2n+1)$

$$J_{xx}(\pm)=\frac{1}{2}I^{2}_{x,m',m''}[1\pm F_{m',m''}\{I_{x,m',m'}I_{x,m'',m''}H_x^2+I_{y,m',m'}I_{y,m'',m''}H_y^2+I_{z,m',m'}I_{z,m'',m''}H_z^2\}]\ ,$$

$$J_{yy}(\pm)=\frac{1}{2}I^{2}_{y,m',m''}[1\pm F_{m',m''}\{-I_{x,m',m'}I_{x,m''m''}H_x^2-I_{y,m',m'}I_{y,m'',m''}H_y^2+I_{z,m',m'}I_{z,m'',m''}H_z^2\}]\ ,$$

$$J_{zz}(\pm)=\frac{1}{2}I^{2}_{z,m',m''}[1\pm F_{m',m''}\{-I_{x,m',m'}I_{x,m''m''}H_x^2+I_{y,m',m'}I_{y,m'',m''}H_y^2-I_{zm',m'}I_{z,m'',m''}H_z^2\}]\ ,$$

$$J_{yz}(\pm)=\pm\frac{1}{2}I_{y,m',m''}I_{z,m',m''}[-I_{y,m',m'}I_{z,m'',m''}-I_{z,m',m'}I_{y,m'',m''}]F_{m',m''}H_yH_z\ ,$$

$$J_{zx}(\pm)=\pm\frac{1}{2}I_{z,m',m''}I_{x,m',m''}[I_{z,m'm'}I_{x,m'',m''}-I_{x,m',m'}I_{z,m'',m''}]F_{m',m''}H_zH_x\ ,$$

$$J_{xy}(\pm)=\pm\frac{1}{2}I_{x,m',m''}I_{y,m',m''}[-I_{x,m',m'}I_{y,m'',m'''}+I_{y,m',m'}I_{x,m'',m''}]F_{m',m''}H_xH_y\ . \tag{17}$$

Type II $(m''=m'+2n)$

$$J_{xx}(\pm)=\frac{1}{2}I^{2}_{x,m',m''}[1\pm F_{m',m''}\{I_{x,m',m'}I_{x,m'',m''}H_x^2-I_{y,m',m'}I_{y,m'',m''}H_y^2-I_{z,m',m'}I_{z,m'',m''}H_z^2\}],$$

$$J_{yy}(\pm)=\frac{1}{2}I^{2}_{y,m',m''}[1\pm F_{m',m''}\{-I_{x,m',m'}I_{x,m'',m''}H_x^2+I_{y,m',m'}I_{y,m'',m''}H_y^2-I_{z,m',m'}I_{z,m'',m''}H_z^2\}]\ ,$$

$$J_{zz}(\pm)=\frac{1}{2}I^{2}_{z,m',m''}[1\pm F_{m',m''}\{-I_{x,m',m'}I_{x,m'',m''}H_x^2-I_{y,m',m'}I_{y,m'',m''}H_y^2+I_{z,m',m'}I_{z,m'',m''}H_z^2\}]\ ,$$

$$J_{yz}(\pm)=\pm\frac{1}{2}I_{y,m',m''}I_{z,m',m''}[I_{y,m',m'}I_{z,m'',m''}+I_{z,m',m'}I_{y,m'',m''}]F_{m',m''}H_yH_z\ ,$$

$$J_{zx}(\pm)=\pm\frac{1}{2}I_{z,m',m''}I_{x,m',m''}[I_{z,m',m'}I_{x,m'',m''}+I_{x,m',m'}I_{z,m'',m''}]F_{m',m''}H_zH_x\ ,$$

$$J_{xy}(\pm)=\pm\frac{1}{2}I_{x,m',m''}I_{y,m'.m''}[I_{x,m',m'}I_{y,m'',m''}+I_{y,m',m'}I_{x,m'',m''}]F_{m',m''}H_xH_y\ . \tag{18}$$

Here we put for brevity

$$F_{m',m''}=1/E_M(m')E_M(m'')\ . \tag{19}$$

In equation (17) and (18), $I_{i,m',m''}$ $(m'\neq m'')$ may be regarded as a parameter describing the dependence of the transitions $|mM|=m'M\rightleftarrows m''M$ upon the i-component ($i=x$, y, or z) of the rf field and $I_{i,m,m}$, as the parameter concerning with the orientation of the Zeeman field.

The ordinary spectrum arises from the transitions $\Delta|m|=1$ which belong to the type I. The intensity of this spectrum is expressed by the intensity parameters $J_{ij}(mM, \pm(m+1)M)$ which depend on such pure quadrupole transition moments as $I_{i,m,m}$, and $I_{i,m,m+1}$. Other transitions $\Delta|m|\neq 1$, so-called forbidden transitions, belonging to both types should occur in the case of nonaxial field gradient, but their intensities are ordinarily so weak that they can hardly be detected except for large asymmetry, because they are at most of the second order of magnitude in η.

A. Second order approximation in η

A perturbation method of the second order in η leads to the determination of the coefficients in Eq. (6) as follows,

$$\langle m|mQ\rangle=1-\frac{1}{288}\eta^2\left[\frac{f(I,\ m+1)}{(m+1)^2}+\frac{f(I,\ m-1)}{(m-1)^2}\right]$$

$$\langle m\pm2|mQ\rangle=\mp\eta\frac{f^{1/2}(I,\ m\pm1)}{12(m\pm1)}$$

$$\langle m\pm4|mQ\rangle=\eta^2\frac{f^{1/2}(I,\ m\pm1)f^{1/2}(I,\ m\pm3)}{288(m\pm1)(m\pm2)}\ . \tag{20}$$

Thus the transition moments between pure quadrupole states for allowed transitions ar obtained as follows:

$$\left.\begin{matrix} I_{x,1/2,1/2} \\ I_{y,1/2,1/2} \end{matrix}\right\} = \pm\frac{1}{2}\left(I+\frac{1}{2}\right)-\frac{\eta}{12}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)$$

$$\mp\frac{\eta^2}{648}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\left(I^2+I+\frac{21}{4}\right),$$

$$\left.\begin{matrix} I_{x,3/2,3/2} \\ I_{y,3/2,3/2} \end{matrix}\right\} = \frac{\eta}{12}\left(\pm1+\frac{\eta}{3}\right)\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right),$$

$$\left.\begin{matrix} I_{x,5/2,5/2} \\ I_{y,5/2,5/2} \end{matrix}\right\} = \pm\frac{\eta^2}{648}\left(I-\frac{3}{2}\right)\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\left(I+\frac{5}{2}\right),$$

$$\left.\begin{matrix} I_{x,m,m} \\ I_{y,m,m} \end{matrix}\right\} \leqq O(\eta^3), \qquad \left(m \geqq \frac{7}{2}\right)$$

$$I_{z,m,m} = m + \frac{\eta^2}{72}\left[\frac{f(I,\ m+1)}{(m+1)^2} - \frac{f(I,\ m-1)}{(m-1)^2}\right]; \tag{21}$$

$$\left.\begin{matrix} I_{x,m,m+1} \\ I_{y,m,m+1} \end{matrix}\right\} = \frac{1}{2}\,[(I-m)(I+m+1)]^{1/2}\left[1 \pm \frac{\eta}{24}\cdot\frac{I(I+1)+3m(m+1)}{m(m+1)}\right.$$

$$\left. + \frac{\eta^2}{288}\left\{\frac{(m-2)f(I,\ m-1)}{m(m-1)^2} + \frac{(m+3)f(I,\ m+2)}{(m+1)(m+2)^2} - \frac{f(I,\ m)}{m^2} - \frac{f(I,\ m+1)}{(m+1)^2}\right\}\right],$$

$$I_{z,1/2,3/2} = \frac{\eta}{6}\left(I-\frac{1}{2}\right)^{1/2}\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)^{1/2},$$

$$I_{z,3/2,5/2} = \frac{\eta^2}{108}\left(I-\frac{3}{2}\right)^{1/2}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\left(I+\frac{5}{2}\right)^{1/2},$$

$$I_{z,m,m+1} \leqq O(\eta^3) \qquad \left(m \geqq \frac{5}{2}\right). \tag{21$'$}$$

In these equations I_x components take the upper of the double signs, and I_y the lower ones. It is to be noted that when the asymmetry parameter η is sufficiently small compared with unity and the nuclear spin I is not large, $I_{y,m,m}$ components are negative, while other transition moments are all positive.

The dependence of the relative intensity on the rf field and on the Zeeman field is calculated from Eqs. (15), (17), (21), and (21)′. In particular, when the Zeeman field is applied parallel to each principal axis, the intensity parameters for the allowed transitions $|m| = m \rightleftarrows$

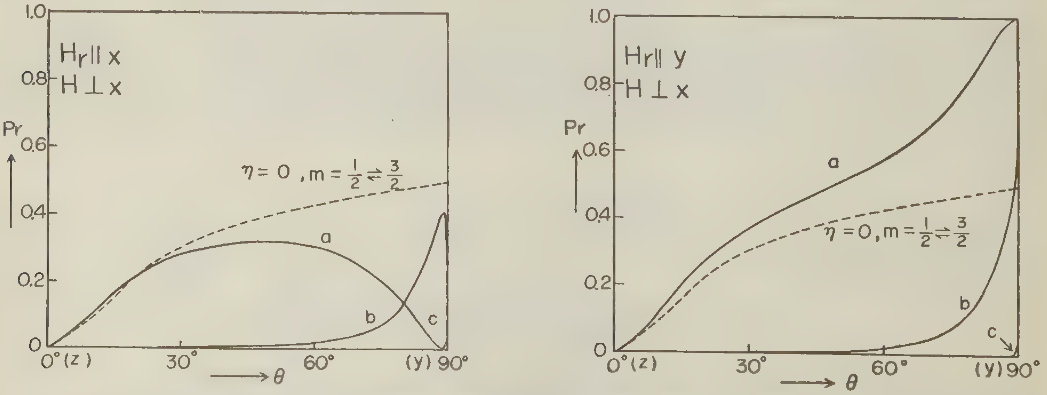

Fig. 2. Relative intensities of the Zeeman components in the case of $I=7/2$ and $\eta=0.05$, where a, b, and c denote three allowed transitions $|m|=1/2\rightleftarrows3/2$, $3/2\rightleftarrows5/2$, and $5/2\rightleftarrows7/2$, respectively, and θ the direction of the static magnetic field measured from the principal z-axis.

$m+1$ are reduced as follows:

$$\begin{aligned}
&\boldsymbol{H}\|x; \quad J_{xx}(+)=I^2_{x,m,m+1}, \quad && J_{yy}(-)=I^2_{y,m,m+1}, \quad && J_{zz}(-)=I^2_{z,m,m+1},\\
&\boldsymbol{H}\|y; \quad J_{xx}(+)=I^2_{x,m,m+1}, && J_{yy}(-)=I^2_{y,m,m+1}, && J_{zz}(+)=I^2_{z,m,m+1},\\
&\boldsymbol{H}\|z; \quad J_{xx}(+)=I^2_{x,m,m+1}, && J_{yy}(+)=I^2_{y,m,m+1}, && J_{zz}(-)=I^2_{z,m,m+1},
\end{aligned} \tag{22}$$

whereas other parameters all vanish. In Fig. 2 the relative intensities are plotted against the orientation of the Zeeman field for the allowed transitions $|m|=1/2 \rightleftarrows 3/2$, $3/2 \rightleftarrows 5/2$, and $5/2 \rightleftarrows 7/2$ in the case of $I=7/2$ and $\eta=0.05$.

B. Exact Treatment for $I=3/2$

For the nuclei with $I=3/2$ only one absorption due to the allowed transition $|m|=1/2 \rightleftarrows 3/2$ is observed in the absence of a magnetic field. The pure quadrupole Hamiltonian $\mathscr{H}_Q$ can be solved analytically in this case as made by Dean,[3)] and the intensities of the Zeeman components are also calculated exactly in terms of η. The results are as follows:

Transition moments between pure quadrupole states:

$$\begin{aligned}
&I_{x,1/2,1/2}=\frac{1}{2\rho}(\rho+1-\eta), && I_{x,3/2,3/2}=\frac{1}{2\rho}(\rho-1+\eta), && I_{x,1/2,3/2}=\frac{\sqrt{3}}{2\rho}\left(1+\frac{1}{3}\eta\right),\\
&I_{y,1/2,1/2}=-\frac{1}{2\rho}(\rho+1+\eta), && I_{y,3/2,3/2}=-\frac{1}{2\rho}(\rho-1-\eta), && I_{y,1/2,3/2}=\frac{\sqrt{3}}{2\rho}\left(1-\frac{1}{3}\eta\right),\\
&I_{z,1/2,1/2}=\frac{1}{2\rho}(2-\rho), && I_{z,3/2,3/2}=\frac{1}{2\rho}(2+\rho), && I_{z,1/2,3/2}=\frac{\eta}{\sqrt{3}\,\rho},
\end{aligned} \tag{23}$$

where

$$\rho=\left(1+\frac{1}{3}\eta^2\right)^{1/2}.$$

Energy levels:

$$\begin{aligned}
&E_Q\left(\pm\frac{3}{2}\right)=-E_Q\left(\pm\frac{1}{2}\right)=3A\rho,\\
&E_M\left(\pm\frac{1}{2}\right)=\pm\frac{1}{2\rho}\left[(\rho+1-\eta)^2H_x^2+(\rho+1+\eta)^2H_y^2+(2-\rho)^2H_z^2\right]^{1/2},\\
&E_M\left(\pm\frac{3}{2}\right)=\pm\frac{1}{2\rho}\left[(\rho-1+\eta)^2H_x^2+(\rho-1-\eta)^2H_y^2+(2+\rho)^2H_z^2\right]^{1/2},
\end{aligned} \tag{24}$$

Intensity parameters for $m=1/2 \rightleftarrows 3/2$:

$$\begin{aligned}
&J_{xx}(\pm)=\frac{3}{8\rho^2}\left(1+\frac{1}{3}\eta\right)^2\left[1\pm\rho^{-2}F_{1/2,3/2}\left\{\frac{3}{4}\left(1-\frac{1}{9}\eta^2\right)H_z^2+\frac{\eta}{2}\left[\left(1-\frac{1}{3}\eta\right)H_x^2+\left(1+\frac{1}{3}\eta\right)H_y^2\right]\right\}\right],\\
&J_{yy}(\pm)=\frac{3}{8\rho^2}\left(1-\frac{1}{3}\eta\right)^2\left[1\pm\rho^{-2}F_{1/2,3/2}\left\{\frac{3}{4}\left(1-\frac{1}{9}\eta^2\right)H_z^2-\frac{\eta}{2}\left[\left(1-\frac{1}{3}\eta\right)H_x^2+\left(1+\frac{1}{3}\eta\right)H_y^2\right]\right\}\right],\\
&J_{zz}(\pm)=\frac{\eta^2}{6\rho^2}\left[1\mp\rho^{-2}F_{1/2,3/2}\left\{\frac{3}{4}\left(1-\frac{1}{9}\eta^2\right)H_z^2+\frac{\eta}{2}\left[\left(1-\frac{1}{3}\eta\right)H_x^2-\left(1+\frac{1}{3}\eta\right)H_y^2\right]\right\}\right],\\
&J_{yz}(\pm)=\pm\frac{3\eta}{8\rho^4}\left(1-\frac{1}{9}\eta^2\right)\left(1+\frac{1}{3}\eta\right)F_{1/2,3/2}H_yH_z,\\
&J_{zx}(\pm)=\mp\frac{3\eta}{8\rho^4}\left(1-\frac{1}{9}\eta^2\right)\left(1-\frac{1}{3}\eta\right)F_{1/2,3/2}H_zH_x,\\
&J_{xy}(\pm)=\mp\frac{3\eta}{4\rho^4}\left(1-\frac{1}{9}\eta^2\right)F_{1/2\,3/2}H_xH_y
\end{aligned} \tag{25}$$

In the above equations $F_{1/2,3/2}$ is given by Eqs. (19) and (24).

These equations hold for $I=3/2$ over the whole range of the asymmetry parameter. In Fig. the relative intensities are plotted against the orientation of the Zeeman field for variou asymmetry parameters from zero to unity in the case of rf field parallel to each principa axis of the field gradient. Fig. 4 illustrates the angular dependence for $\eta=0.4$ in the cas that rf field is applied in various directions deviated from the principal axes.

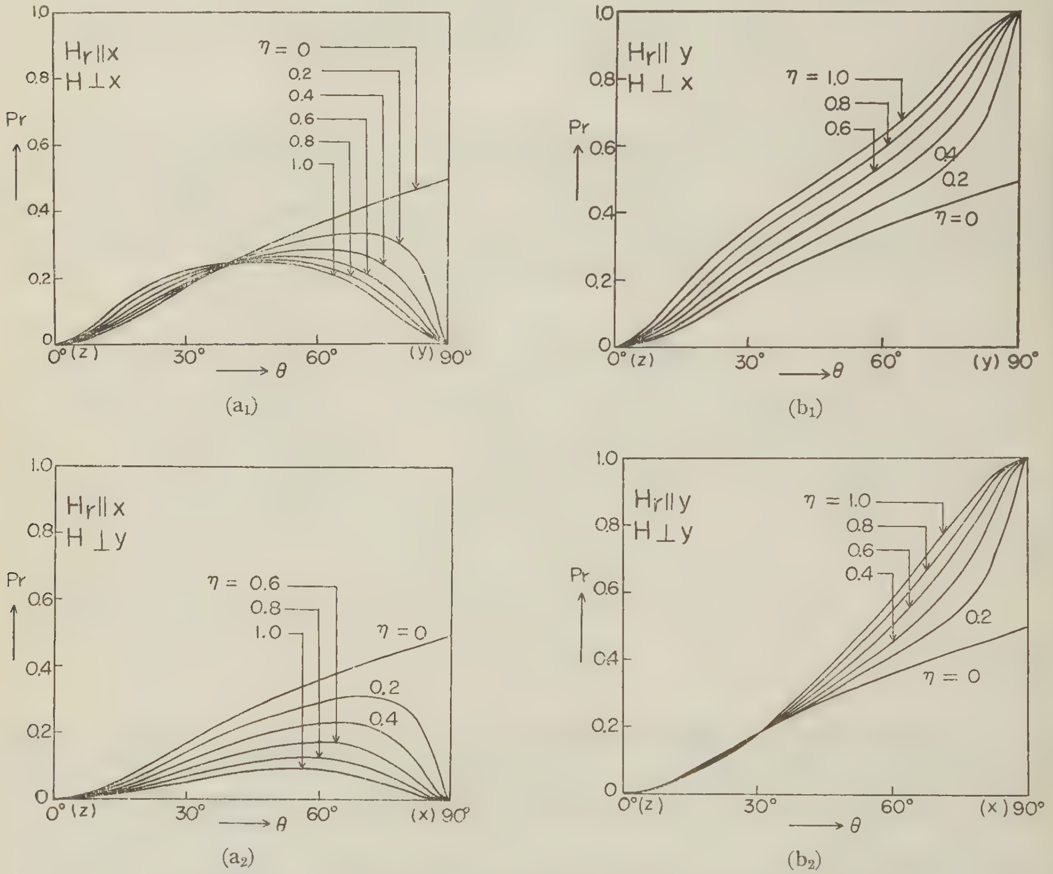

Fig. 3. Relative intensities of the Zeeman components in the case of $I=3/2$, where θ denotes the direction of the static magnetic field.

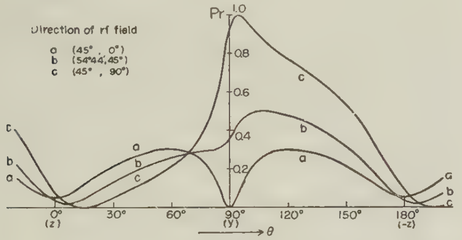
§ 3. Discussion

From Eqs. (21)′ and (23) (or Eq. (25)), the allowed transitions are concluded to be mainly produced by the x- and y- components of the rf field, of which the x-component contributes more strongly to the intensities. The contribution of the z-component is only in the second order of η^2 even to the transitions $|m|=1/2 \rightleftarrows 3/2$, and to other transitions it is so small for small asymmetry that it may be neglected.

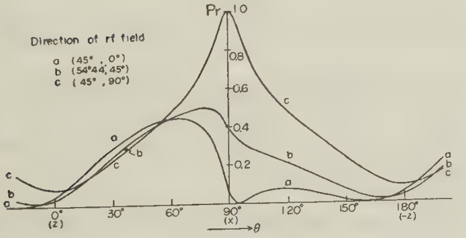
The dependence of the relative intensity on the Zeeman field appears strongly in the transitions $|m|=1/2 \rightleftarrows 3/2$, as shown in Fig. 2; in this case the outer pair of the Zeeman components is observed with considerable intensity. In other transitions, however, the outer pair is so weak for small asymmetry that we can hardly detect but the inner pair, except when the magnetic field is applied in the vicinity of the xy-plane. This fact can be explained in terms of mixing of the degenerate pure quadrupole states $\pm mQ$ (see Eq. (10)); that is, the outer pair of transitions is produced by their mixing, which is complete for the states $|m|=1/2$ with the x- and y-components of the Zeeman field, but for other states $|m|\geqq 3/2$ in the first or higher order of magnitude in η.

Finally let us consider the lowest transitions

$|m|=1/2 \rightleftarrows 3/2$. In the case of small asymmetry the rule for $\eta=0$ holds approximately when the direction of the Zeeman field is not close to the principal xy-plane. Thus, for the Zeeman field parallel to the principal z-axis, the outer pair is so weak in intensity that only the inner pair may be detected, because the inner pair of transitions is produced by the x- and y-components of the rf field, while the outer pair is produced by the z-component (see Eq. (22)). As the direction of the Zeeman field deviates from the z-axis, the intensity of the outer pair increases gradually, whereas the inner pair decreases. The agreement with the rule is remarkable especially in the case of the Zeeman field perpendicular to the rf field (compare Figs. 3(a_1) and (b_2) with (a_2) and (b_1)).



(a) H ⊥ x.



(b) H ⊥ y

Fig. 4. Contribution of the cross terms of intensity parameters to the relative intensities of the Zeeman components in the case of $I=3/2$ and $\eta=0.4$, where θ denotes the direction of the static magnetic field.

The deviation from the rule is, however, expected in the case of the Zeeman field perpendicular to the z-axis. In this case the inner pair is produced by the x-component of the rf field while the outer pair by the y-component (see Eq. (22)). Hence, as the direction of the Zeeman field approaches to the xy-plane, the relative intensity P_r will be observed to decrease abruptly to zero or to increase to unity, according to the rf field parallel to the x-axis or to the y-axis, respectively, as illustrated in Figs. 2 and 3. The intensities $P_\perp(\pm)$ of both pairs for the Zeeman field perpendicular to the z-axis are then expressed to the first order of accuracy in η as follows:

$$P_\perp(+)=KI^2_{x,m,m+1}\sin^2\theta_r\cos^2\varphi_r\ ,$$
$$P_\perp(-)=KI^2_{y,m,m+1}\sin^2\theta_r\sin^2\varphi_r\ . \qquad (26)$$

where K is a constant factor common between both pairs and $(\theta_r,\ \varphi_r)$ is the polar coordinate of the rf field with the pole on the z-axis and with the initial line of φ_r on the x-axis. Even in this case, therefore, it is possible that both pairs are observed with equal intensities as expected from the rule for $\eta=0$; it is fulfilled with the rf field applied in the intermediate direction between the x- and the y-axis.

The above relation explains well the anomaly in the intensities observed in cyanuryl chloride[7] described in the introduction. At the same time it will make us possible to determine the location of the principal x- and y-axes. It has been fairly difficult by other methods, for instance, by the method of no-splitting locus,[12] because the eccentricity of the locus is very small (in the first order in η). It is recommended to apply the intensity relation after a rough estimation by other methods easy to handle. Actual application has proved to give a good result for the Cl^{35}-resonance in 1, 3, 5-trichlorobenzene.[13]

Here we must remind that the above relations hold only when the asymmetry parameter η is small and the spin I is not large; otherwise the situation may be reversed between both pairs, since $I_{i,m,m'}$'s may change their signs for large asymmetry and for large spins, and, in addition, the z-component of the rf field may contribute to the transitions to the order comparable with other components.

In Fig. 3 there is shown the dependence of the relative intensity on the asymmetry parameter for $I=3/2$. The fractional importance of the x-component of the rf field decreases for the outer pair of transitions with the increase in the asymmetry parameter, while that of the y-component increases. Since the signs of the transition moments in Eq. (23) are invariant for arbitrary asymmetry parameters, the situation is never reversed between both pairs in the case of $I=3/2$, but the z-component of the rf field is expected to contribute considerablly to the transitions in the case of large asymmetry. Its contribution is entirely opposite to those of the x- and y-components as is easily seen from Eq. (25); it makes the outer pair of transitions stronger.

The contribution of the cross terms of intensity parameters is at most in the first order of magnitude in η. For large asymmetry, however, they are important for the relative intensity when the direction of the rf field deviates from the principal axes. The dependence of the intensity on the Zeeman field is no more symmetric with respect to the principal axes of the field gradient, as illustrated in Figs. 4(a) and 4(b). The direction of the Zeeman field in which the relative intensity is maximum or minimum is deviated away from the directions of the principal axes.

§ 4. Integral Spins

In the case of integral spins a static magnetic field produces only shifts of the energy levels, since the degeneracy which appears between two pure quadrupole states $\pm mQ$ for half-integral spins has already been removed by an asymmetry of the field gradient. In addition there are only a few kinds of stable nuclei with integral spins and with considerable natural abundances;[14] Li ($I=1$), B^{10} ($I=3$), and N^{14} ($I=1$). The general formulation, then, seems to be not so important as in the case of half-integral spins.

The process to lead the final formulae is quite analogous to that used in the Stark effect of rotational levels.[15] The result for $I=1$ which is most frequently used will be summarized; here are three energy levels designated by $0M$, and $\pm 1M$, so that three transitions should occur corresponding to $0M \rightleftarrows \pm 1M$ and $1M \rightleftarrows -1M$;

Energy levels;

$$E(0M)=2A\ ,$$

$$E(\pm 1M)=-A\left[1\pm\left(\eta^2+\frac{\gamma^2 H_z^2}{A^2}\right)^{1/2}\right],$$

where

$$A=\frac{1}{4}eQq_{zz}\ . \tag{27}$$

Non-vanishing intensity parameters;* for $0M \rightleftarrows \pm 1M$

$$J_{xx}=\frac{1}{2}\left[1\pm\left(1+\frac{\gamma^2 H_z^2}{\eta^2 A^2}\right)^{-1/2}\right]$$

$$J_{yy}=\frac{1}{2}\left[1\mp\left(1+\frac{\gamma^2 H_z^2}{\eta^2 A^2}\right)^{-1/2}\right], \tag{28}$$

for $+1M \rightleftarrows -1M$

$$J_{zz}=\left(1+\frac{\gamma^2 H_z^2}{\eta^2 A^2}\right)^{-1}. \tag{28$'$}$$

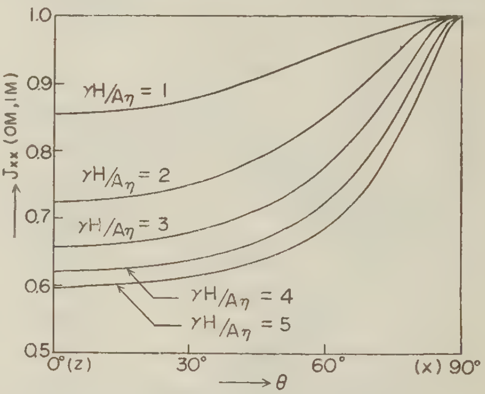


Fig. 5. Dependence of the intensity parameter J_{xx} ($0M$, $1M$) for $I=1$ on the direction of the static magnetic field (θ) and on the parameter $\gamma H/A\eta$.

In Fig. 5 the intensity parameter $J_{xx}(0M, 1M)$ is plotted against the orientation of the Zeeman field to the z-axis. The change in the intensity is symmetric with respect to the principal axes, and depends only on the z-component of the Zeeman field. Its contribution is, however, of much importance only when the asymmtery parameter is comparable with the perturbation by the Zeeman field; otherwise the intensity is almost independent of the Zeeman field. For $|\gamma H| \gg |A\eta|$, the transitions $0M \rightleftarrows \pm 1M$ are produced with equal probabilities by the x- and y-components of the rf field. For $|\gamma H| \ll |A\eta|$, however, the transition $0M \rightleftarrows 1M$ is produced by the x-component while the transition $0M \rightleftarrows -1M$ by the y-component. In the latter case one should consider rather the contribution of ν^2 in Eq. (6), because the asymmetry parameter contributes in the first order to the splitting of energy levels $m=\pm 1$. The transition $1M \rightleftarrows -1M$ is produced by the z-component, but it will hardly be observed in the case of $|\gamma H| \gg |A\eta|$ for two reasons: (1) the transition probability is very small; and (2) the absorption spectrum exists at the region of extremely low frequency.

---

* The results are in good agreement with those by Casabella and Bray, J. Chem. Phys. **28**, 1182 (1958), but their formulae include the Zeeman field only implicitly so that the present ones will be more applicable to actual purposes.

§ 5. Conclusion

For half-integral spins the following properties are derived:

(1) For small asymmetry the rule for $\eta=0$ holds approximately in the case when the direction of the Zeeman field is not so close to the principal xy-plane.

(2) The deviation from the rule is remarkable when the direction of the Zeeman field approaches to the xy-plane: the inner pair of transitions is produced by the x-component of the rf field and the outer pair by the y-component. The critical behaviour in this region suggests a method of precise determination of the principal axes.

(3) The contribution of the product intensity parameters can not be neglected except for very small asymmetry ($\eta \geqq 0.1$); it is of much importance when the rf field deviates from the directions of principal axes, and makes the change in the intensity asymmetric with respect to the principal axes.

For integral spins the intensity is affected by the magnitude of a factor $|\gamma H/\eta A|$, and its dependence on the Zeeman field would be observed only for $|\gamma H/\eta A| \cong 1$ in the case of $I=1$.

In conclusion the author wishes to express his appreciation to Professor Y. Morino under whose guidance this research was developed.

APPENDIX

Corrected Bersohn's Formulae for Zeeman Energies

R. Bersohn[2)] has proposed the formulae for the first order Zeeman effect of nuclear quadrupole energy levels for half-integral spins to the second order of accuracy in η. His formulae, however, should be corrected in the coefficients of η^2-terms as pointed out in the preceeding paper.[7)] The corrected formulae are derived from Eqs. (9)′ and (21) as follows:

$$\begin{aligned}E_M\left(\pm\frac{1}{2}\right)=\pm\Bigg[&\frac{1}{4}H_z^2+\frac{1}{4}(H_x^2+H_y^2)\left(I+\frac{1}{2}\right)^2\\&-\frac{1}{12}\eta(H_x^2-H_y^2)\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)\\&-\frac{1}{81}\eta^2H_z^2\left(I-\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\left(I^2+I+\frac{3}{4}\right)\\&+\eta^2(H_x^2-H_y^2)\Bigg\{\frac{1}{144}\left(I-\frac{1}{2}\right)^2\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)^2\\&-\frac{1}{648}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)\left(I^2+I+\frac{21}{4}\right)\Bigg\}\Bigg]^{1/2},\end{aligned}$$

$$\begin{aligned}E_M\left(\pm\frac{3}{2}\right)=\pm\Bigg[&\frac{9}{4}H_z^2\\&+\frac{1}{24}\eta^2H_z^2\left\{\frac{1}{25}\left(I-\frac{5}{2}\right)\left(I-\frac{3}{2}\right)\left(I+\frac{5}{2}\right)\left(I+\frac{7}{2}\right)-\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)\right\}\\&+\frac{1}{144}\eta^2(H_x^2+H_y^2)\left(I-\frac{1}{2}\right)^2\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)^2\\&+\frac{1}{216}\eta^3(H_x^2-H_y^2)\left(I-\frac{1}{2}\right)^2\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)^2\Bigg]^{1/2},\end{aligned}$$

$$\begin{aligned}E_M\left(\pm\frac{5}{2}\right)=\pm\Bigg[&\frac{25}{4}H_z^2\\&+\frac{5}{72}\eta^2H_z^2\Bigg\{\frac{1}{49}\left(I-\frac{7}{2}\right)\left(I-\frac{5}{2}\right)\left(I+\frac{7}{2}\right)\left(I+\frac{9}{2}\right)\end{aligned}$$

$$-\frac{1}{9}\left(I-\frac{3}{2}\right)\left(I-\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\left(I+\frac{5}{2}\right)\Big\}$$

$$+\frac{1}{419,904}\eta^4(H_x^2+H_y^2)\left(I-\frac{3}{2}\right)^2\left(I-\frac{1}{2}\right)^2\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right)^2\left(I+\frac{5}{2}\right)^2\Big]^{1/2},$$

and

$$E_M(\pm m)=\pm\left|mH_z+\frac{1}{72}\eta^2H_z\left\{\frac{f(I,\ m+1)}{(m+1)^2}-\frac{f(I,\ m-1)}{(m-1)^2}\right\}\right|\qquad\left(m\geqq\frac{7}{2}\right),\tag{29}$$

where the energies are measured in the unit of $-\gamma$. In his formulae Bersohon has omitted the terms of η^3 and η^4 in the states $|m|=3/2$ and 5/2, which come from the second order corrections to the pure quadrupole eigenvectors. However, it seems reasonable to keep these terms as in the above equations, because they contribute to the energies in the second order in η in the special case where the Zeeman field is applied in the direction perpendicular to the z-axis.

Spectroscopic Investigation of Hydrogen Plasma Produced by an Impulsive Discharge

By Manabu YAMAMOTO
Hitachi Central Research Laboratory, Kokubunji, Tokyo, Japan

(Received June 23, 1959)

Time variation of the radiation intensity was observed during an impulsive discharge through hydrogen gas. Oscillogram traces of the intensity of the Balmer lines and continuum are shown, and the temperature dependence of the spectral intensity is discussed. Temperature of the plasma at various phases of the discharge current is deduced from the time variation of the radiation intensity, from spectral energy distribution of the Balmer continuum, and from electrical conductivity. It is shown that the agreement between theory and experiment is fairly good for ionization and kinetic temperatures, but poor for the excitation temperature. The H_β line tends to vanish more rapidly than theoretically predicted.

§ 1. Introduction

During an impulsive discharge through a gas, the spectrum of radiation emitted from the plasma is observed to vary with the time. For example, lines of the neutral atom are expected to vanish at such phases of the discharge current when the plasma attains very high temperature, while the intensity of continuous radiation increases with increasing temperature, since the latter is emitted during encounters of ions and electrons. The continuous radiation itself extends to the shorter wavelengths with increasing temperature.

The spectroscopic investigations described here were carried out in order to determine the temperature of plasma at various phases of the discharge current, using methods which are based in principle on the spectral characteristics as mentioned above.

§ 2. Discharge Apparatus

The discharge apparatus that was used in shown in Fig. 1. It consists of a fused silica torus of 10 cm mean diameter and 0.9 cm tube radius. It is linked by an oriented iron core, $5\times5\,\text{cm}^2$ in cross section and 80 cm in length. Four turn primary windings wound around the core are connected to the 5 μF capacitor bank through an air gap, which is triggered automatically when the capacitor is charged up to 10 kV. The discharge tube was baked before filling with hydrogen gas of 1 mmHg pressure. The gas is preionized by a 2 Mc high frequency discharge.

The discharge current is measured with a Rogowski coil combined with an R–C integrator. The oscilloscope is synchronized to the pulse put out from the saturable reactor inserted in the primary winding. The current and voltage waveforms are shown in Fig. 2. The discharge lasts for 100 μsec. The peak value of current and corresponding voltage per turn are ca. 10 kA and 1 kV, respectively.

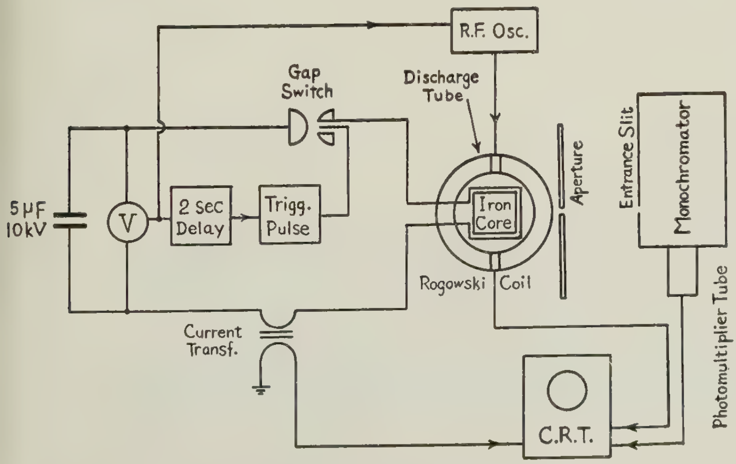

Fig. 1. Schematic diagram of the apparatus.

§ 3. Optical System

In order to study the time

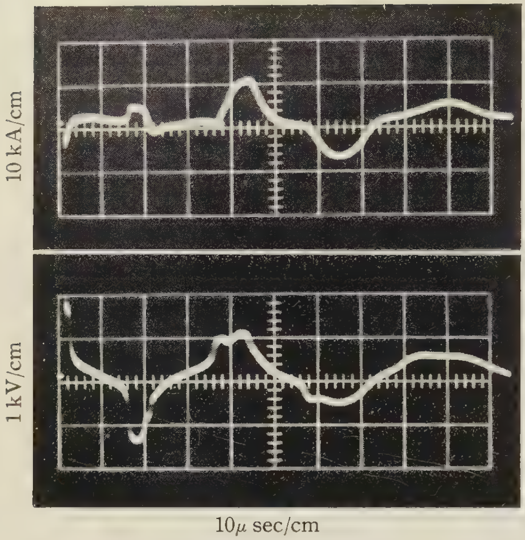

Fig. 2. Current (above) and voltage per turn (below) waveforms.

variation of spectral intensity, light beam emitted from the center of plasma is projected onto the entrance slit of a monochromator, which can select any region between λλ10,000 and 2,000 Å with any desired wavelength interval. The monochromatic light is received by a photomultiplier tube of $S-13$ spectral response (having a fused silica bulb and an Sb–Cs photocathode). To calibrate the relative response of the whole optical system, the radiation emitted from the center of the plasma in a 160 W xenon short arc lamp was chosen as a standard, the intensity distribution of which has been shown to be

$$J(\nu)d\nu=\text{const}\times\exp(-h\nu/kT)d\nu \qquad (1)$$

with $T=7{,}400$°K[1]. The overall response of the optical system for the fixed width of the monochromator slits is shown in Fig. 3.

§ 4. Spectrograms

Before studying the time variation of the spectral intensity, spectra were taken in the usual way (see Fig. 4). Stark effect broadening of the Balmer lines is noticed, the breadth increasing with increasing quantum number of the line (compare with the spectrogram of high frequency discharge of weak excitation). The lines arising from the higher levels form an apparent continuum near the series limit, beyond which extends the true continuum into the ultra-violet region. Since the continuous radiation is due to free-free (Bremsung) or free-bound (recombination) transitions of electrons, the highly excited atoms

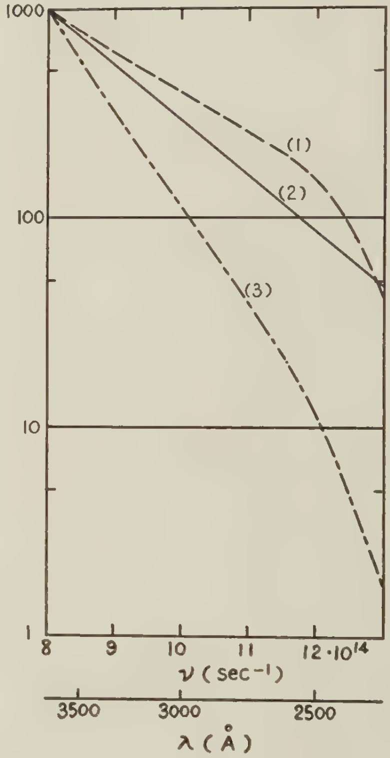

Fig. 3. Calibration of the optical system for the spectral sensitivity. (1) Relative spectral response, (2) exp($-h\nu/kT$) with $T=7{,}400$°K and (3) xenon lamp measured.

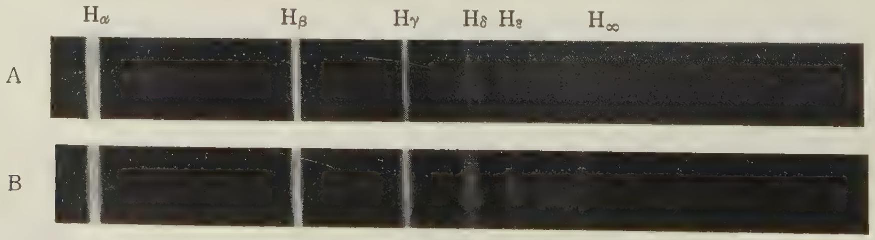

Fig. 4. Spectrograms of the hydrogen discharge. A. High frequency discharge of weak excitation. B. Capacitor discharge. Continuum emitted by the high frequency discharge is due to molecular hydrogen.

may also be regarded as virtually ionized. Hence the ionization potential of an atom placed in the field of neighbouring ions is somewhat lowered. The amount of decrease is, after Unsöld[2],

$$\Delta V_i = 7.0 \times 10^{-7} n_i^{1/3} \text{ (volt)}\,, \tag{2}$$

where n_i is the ion density.

To obtain the ion density n_i, Inglis-Teller's formula is used:

$$\log N = 23.46 - 7.5 \log n_m\,, \tag{3}$$

where n_m is the quantum number of the highest line which lies in the neighbourhood of the continuum but still observed as a separate line. N, the density of perturbers, is given by

$$N \begin{cases} = n_i + n_e & \text{for } T < 10^5/n_m \\ = n_i = n_e & \text{for } T > 10^5/n_m \end{cases} \tag{4}$$

where T is the temperature of plasma. In our case $n_m = 7$ (H_ε), hence $n_e = (5\sim10) \times 10^{16}$ /cm³, which corresponds to 70∼100% ionization of the gas. From Eq. (2),

$$\Delta V_i = 0.3 \text{ (volt)}\,, \tag{5}$$

that is, the ionization potential of hydrogen atom is lowered to 13.3 volt.

These values obtained here are now inserted into Saha's equation

$$\frac{n_e n_i}{n_H} = \frac{2U_i}{U_H} \frac{(2\pi mkT)^{3/2}}{h^3} \times \exp\left[-\frac{e}{kT}(V_i - \Delta V_i)\right], \tag{6}$$

from which the temperature of plasma is deduced. In this expression U_i is the partition function of the ion, and m is the mass of electron. k, h and e are well known physical constants. U_H, the partition function of the hydrogen atom, is

$$U_H = \sum_n g_n \exp(-eV_n/kT)\,, \tag{7}$$

where the sum was taken over $n \leqq 7$. Inserting numerical values obtained above, it is seen that the temperature should exceed 14,000°K for over 70% ionization. As the present calculation is based on the spectrogram taken in the usual manner (time integrated exposure), the plasma must have attained still higher temperature. This is discussed in the following sections.

§ 5. Time Variation of the Intensity of Continuous Radiation

Fig. 5 shows oscillogram traces of the intensity of continuous radiation. It should be noted that the intensity variation accurately follows the variation of current, irrespective of the selected wavelength. A slight but important difference is found, however, between waveforms for the different wavelength. Intensity variation of the shorter wavelength radiation is characterized by a sharp peak at the intensity maximum and a rapid decrease toward the minimum. On the other hand, the variation of the intensity of the longer wavelength radiation is relatively flattened, and a slight, parasitic decrease is observed at the top of intensity (see the waveform of λ3473Å, $t = 45$ μsec; time is measured from the point when the oscillogram trace starts.) This indicates that the continuous radiation extends to the shorter wavelength

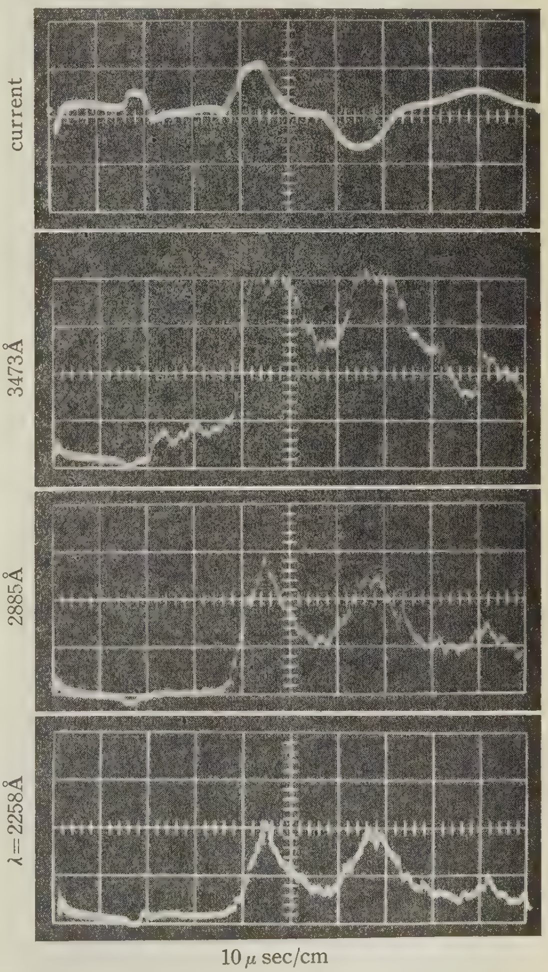

Fig. 5. Time variation of the intensity of continuous radiation. The slit width corresponds to $\Delta\lambda = 5$Å.

at the time of the maximum of current, than it does at the minimum.

From these observed characteristics of the waveforms of the radiation intensity the temperature of plasma was deduced in the following ways. The intensity of continuous radiation is[3)]

$$J_\nu(T)\,d\nu=\frac{32\pi^2e^6}{3\sqrt{3}\,c^3(2\pi m)^{3/2}}\frac{n_in_e}{(kT)^{1/2}}e^{u_1-u}$$

$$\times\left(1+2u_1\sum_{u_2}^{u_4}\frac{1}{n^3}e^{u_n-u_5}\right)d\nu\,, \qquad (8)$$

where $u=h\nu/kT$, $u_1=eV_i/kT$, $u_n=h\nu_n/kT$ and $h\nu_n$ is the energy of the level n measured from the level $n=\infty$.

A. *Temperature Dependence of $J_\nu(T)$*

Fig. 6 shows variation of the intensity of continuous radiation with temperature. The rapid increase of intensity in the temperature range up to 18,000°K is due to increasing ionization, while the gradual decrease beyond that is ascribed to the factor $T^{-3/2}$. Contribution of the intensity of Bremsstrahlung, which depends on $T^{-1/2}$, to the total intensity is less than 12% for $T<20,000$°K. From the slight decrease of intensity observed at the peak of intensity of λ3473Å, it is reasonable to assume that the temperature has reached 20,000°K at $t=45\,\mu$sec. If this temperature is assumed also for the peak intensity of other wavelengths, each of the oscillogram traces gives the temperature of plasma as a function of time. In Table I is shown the value deduced in this way.

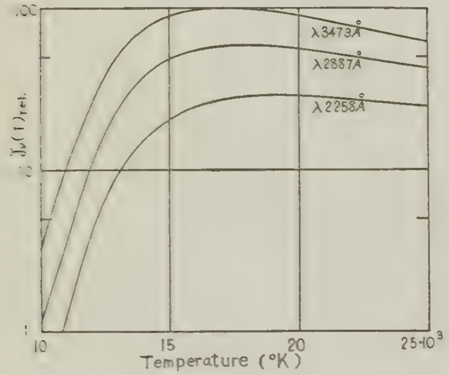

Fig. 6. Intensity of continuous radiation at various wavelengths as a function of temperature.

Table I. Temperature deduced from the time variation of the intensity of continuous radiation.

Time (μ sec)	Temperature (°K)		
	λ3473 Å	λ2887 Å	λ2258 Å
45	20,000	20,000	20,000
50	16,000	14,000	14,000
53	14,000	13,000	13,000
55	14,000	13,000	13,000
60	14,000	14,000	13,000
65	18,000	18,000	17,000
68	19,000	19,000	19,000
70	16,000	15,000	16,000

B. *Frequency Dependence of $J_\nu(T)$*

From Eq. (8)

$$\frac{d\ln J_\nu(T)}{d\nu}=-\frac{h}{kT}\,, \qquad (9)$$

that is, the temperature can be deduced from the relative intensity distribution of the con-

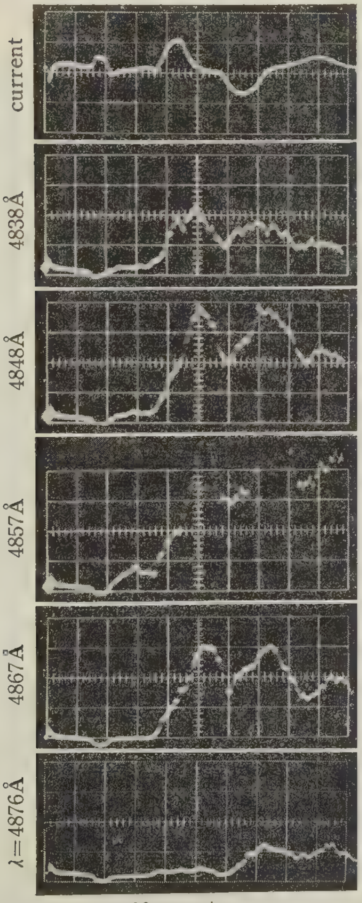
tinuous radiation. Fig. 7 shows an example of intensity distribution measured at $t=65$ μsec. The error flags represent ranges of the distribution of data obtained from three successive discharges under the same condition. The temperature measured in this way is shown in Table II.

§ 6. Time Variation of the Line Intensity

Fig. 8 shows time variation of the H_β intensity observed during the discharge. Note that the maximum of intensity does not coincide with that of current, as was the case for the most part of the continuum. Instead, a minimum of the intensity is seen to correspond to the maximum of the current. This is explained by the fact that the line is emitted by neutral atoms that remain still unionized. The intensity of H_β line is given by

$$J_{H_\beta}(T) \propto n_H(T)\exp(-eV_4/kT)\,. \tag{10}$$



10 μ sec/cm

Fig. 8. Time variation of the intensity of the H_β line. $\Delta\lambda=4$Å

$J_{(H_\beta)}(T)$ is shown in Fig. 9. It has a maximum at $T=16{,}000$°K, and decreases with further increase of the temperature. We assume, therefore, that the temperature of plasma is 16,000°K at the instant when the H_β intensity attains its maximum ($t=53$ μsec in our case). Temperatures at other phases of the discharge current can be deduced from the decrease of the intensity relative to this maximum (see Table III).

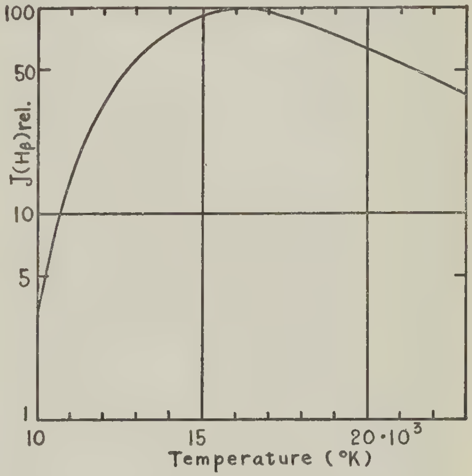


Fig. 9. Variation of the intensity of the H_β line with temperature.

Table III. Temperature deduced from the time variation of the H_β intensity.

Time (μ sec)	Temperature (°K)
45	21,000
50	18,000

60	21,000
64	20,000
66	20,000
70	18,000

Fig. 10 shows the intensity variation of other Balmer lines. It can be noticed that, towards the shorter wavelength, the waveform approximates that of the continuum. The H_ε line, which lies adjacent to the pseudo-continuum, has a waveform similar to that of the intensity of λ3473Å.

Fig. 11 shows the time variation of the intensity of the line 0 II λ2303Å. The oxygen is contained in the plasma as an impurity. The intensity of 0 II lines rises steeply in the temperature range up to 30,000°K[4),5)], so that it follows very closely the variation of current.

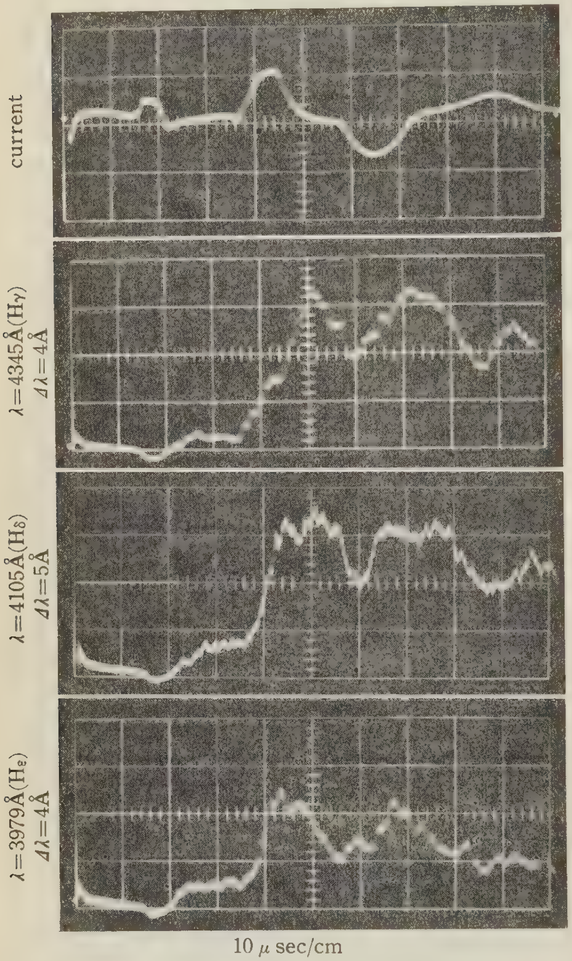

Fig. 10. Time variation of the intensity of the Balmer lines.

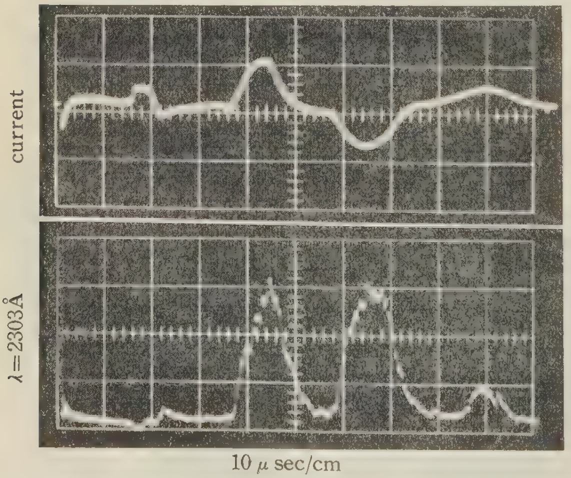

Fig. 11. Time variation of the intensity of the line OII λ 2303 Å.

§ 7. Electrical Conductivity

Electrical conductivity of the plasma was calculated from the observed value of discharge current and electric field, assuming a uniform distribution of the current over the cross section of the tube. Magnetic contractions do not take place in this experiment; the magnetic pressure is still less than the material pressure. The electrical conductivity is not high enough for a sheet current to be assumed.

The value of electrical conductivity calculated in this way is inserted into the conductivity expression

$$\sigma=e^2n_e(3mkT)^{-1/2}(n_HQ_H+n_iQ_i)^{-1}\ , \qquad (11)$$

where

$$Q_H=130\times10^{-16}\ \text{cm}^2$$
$$\text{(cross section of atoms)} \qquad (12)$$

and

$$Q_i=e^4(kT)^{-2}\ln\,[kT/(e^2n_i^{1/3})]$$
$$\text{(cross section of ions)} \qquad (13)$$

after Maecker, Peters and Schenk[5),6)]. The temperature deduced from Eq. (11) is shown in Table IV.

Table IV. Temperature deduced from electrical conductivity.

Time (μ sec)	Conductivity (Ω^{-1} cm^{-1})	Temperature (°K)
42	140	21,000

70	90	16,000

§ 8. Discussions

So far a Maxwell-Boltzmann distribution has been assumed both for electrons and excited neutral atoms. If this is valid, the "temperature" may still be different for different processes considered. The intensity of continuous radiation depends below 20,000°K mainly upon n_en_i, and hence the temperature deduced from the temperature dependence of the intensity of continuous radiation (§ 5. A) gives the value associated with the ionization process (ionization temperature). On the other hand, the frequency dependence of the intensity of continuous radiation is related to the kinetic temperature of electrons. It can also be deduced from the electrical conductivity. Finally the intensity of the H_β line depends below 16,000°K on the excitation temperature, and the decrease beyond that is due to the competition between excitation and ionization.

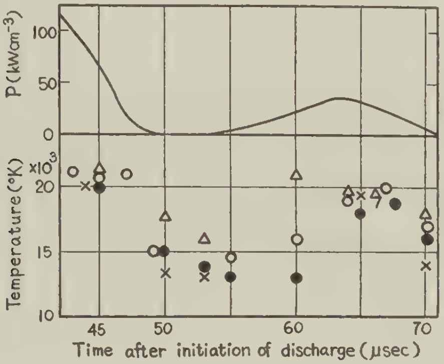

Fig. 12. Temperature deduced from temperature dependence (●) and frequency dependence (×) of the intensity of continuous radiation, from temperature dependence of the H_β intensity (△) and from electrical conductivity (○). Input power density P is also shown.

Now in Fig. 12 the temperatures hitherto obtained by various methods are summarized. It is seen that the agreement is fairly good between ionization and kinetic temperatures. But the excitation temperature shows relatively poor agreement with either one of other temperatures. In particular, a large discrepancy is noticed between excitation and other temperatures at $t=60\ \mu$sec. This is due to the decrease of the H_β intensity, which is unusually larger than theoretically predicted (see Fig. 8). There is further evidence that the equilibrium state cannot be assumed for the excitation process, especially in the early stages of the discharge. From the waveform of the discharge current, it is expected that the H_β intensity has its first peak at around $t=40\ \mu$sec, just prior to the first maximum of current. The intensity of H_β line actually shows a monotonous increase toward the maximum which is first attained after the current peak. In the early stages of the discharge the ionization of the gas is rapidly going on, and the condition seems to be unfavorable for the equilibrium to be established. This may have something to do with the observed fact that the intensity of continuous radiation shows occasionally poor reproducibility at its first peak (see Fig. 13).

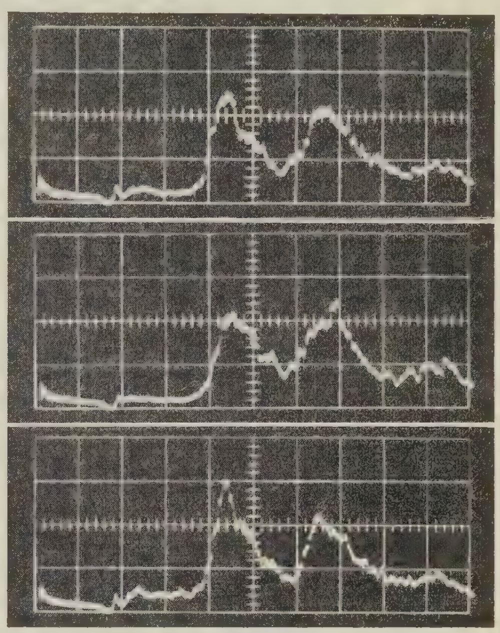

Fig. 13. Oscilloscope traces of the intensity of continuous radiation (λ=2278Å) taken during three successive discharges under the same condition.

The ion temperature has not directly been determined in this experiment. However, it can be shown that the ion temperature is not far below the electron temperature. The energy obtained by an electron in the mean free path λ is

$$\Delta\mathcal{E}=e\lambda E\,, \tag{14}$$

where E is the electric field in the plasma. In our case $\lambda<10^{-3}$ cm, $E<30$ volt/cm and $\Delta\mathcal{E}<3\times10^{-2}$ eV. This is less than 1% of the electron kinetic energy. If this energy were to be dissipated only through the elastic collision against ions, the ion temperature would be 3% lower than the electron temperature7).

The author wishes to express his sincere thanks to Prof. K. Yamamoto for his valuable discussions. He is indebted to Dr. J. Nakamura who has directed the research. He is grateful to Mr. M. Yanaka for his assistance in the experiment.

Anodic Oscillation in Glow Discharge

(I) Simple Correspondences of the Internal Phenomena to the Oscillation

By Kazuyuki OGAWA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki

(Received July 3, 1959)

Preliminary experiments on the anodic oscillation in glow discharge having no positive column are carried on, and they yield the following results. (1) Whenever the oscillation exists a faint small glow ball appears at a small part of the anode. When only one glow ball appears, one series of wave consists of the only kind of wave-form. On the contrary, in case of two balls two distinct wave-forms appear, and they are smoothly connected when the ratio of the period of each wave-form is integer. (2) It is easy to make the glow ball appear, when the anode has very small surface area compared with that of the cathode. (3) The oscillating zone is located only in the glow ball. (4) The degree of modulation of light intensity variation of the glow ball is 100%. The light intensity pulse builds up at the point where the current is minimum, and it reaches to peak preceding the maximum of the current wave. When two glow balls exist they alternately flush, and one of them corresponds to one of current wave and the other to another one.

The results are discussed in comparison with a hypothesis hitherto accepted, and they lead to a conclusion in which the conventional theory seems to be not always applicable to quantitative treatment of the oscillatory phenomena.

§ 1. Introduction

The fluctuation of tube voltage or that of circuit current in low pressure gaseous discharge is generally divided into two groups. One is noise, which is characterized by irregularity in the phase and amplitude and by being extended over the wide frequency band. The other is oscillation, which has fine coherency and exists within a limited range of frequency. Of course, above classification is made by the external appearances of the fluctuation, not by the cause of it, that is, one observer may receive the phenomena as oscillation what the other receives as noise when the individual occurrences are instable or superimposed irregularly on each other.

Many investigators worked at the field of oscillation, especially related to *striation*, and they found that many types of oscillation related rather to the anode side such as the Faraday dark space[1], the positive column[2], and narrow region around anode[3] than to the cathode side such as the negative glow, the Crookes dark space or the cathode fall and cathode itself. However, the exact relationship between the oscillation and the state of the anode side has yet never been clear. Presumably, the principal cause of this situation may be sought in the complexity of the phenomena. In 1940 Druyvesteyn and Penning[4] suggested the posibility of presence of oscillation when a red sphere appeared at the anode in Ne discharge having no positive column, although the details of the phenomena are remained still unknown. Repeating their experiment, author discovered that the specially designed cold-cathode glow discharge tube generated the anodic oscillation in very simple features as described following sections. The oscillations studied here were found in the frequency band 1 to 15 kc per second and in peak-to-peak amplitude about 7 to 16 volt.

§ 2. Experiments, Results and Discussion

The test tube was kept in discharge by well known electrical device, which consisted of a low impedance power source and a noninductive series resistance (its value was choiced at 40 kΩ, for the oscillation was stable at high resistance). To vary the tube current, the primary a.c. voltage of the power source was regulated by means of an autotransformer. The oscillation* was observed by a cathode-ray oscilloscope (pass band: d.c. to 30 Mc), and when necessity arised, the static valtage-current characteristics of the gap was also observed by both balance-type vacuum-tube voltmeter and ordinary milliammeter. In any case, the total input capacitance and resistance of the measuring system were respectively less than about 20 pf and 5 MΩ. Spectroscopically pure Ne, Ar, and Hg-contaminated Ar were tested at the pressure range 1 to 50 mmHg; these gases were equally capable of generating oscillations. The essential parts of the relationship between the oscillation and the anodic phenomena were not affected by any sorts of gases. Some caution taken in preparing the test tube has been described in the former paper[5].

***Experiment 1**: Studies on electrode configuration and visual observations*

The tests were carried on under the conditions where ordinary glow discharge was maintained; the tube current and gas pressure were required to be relatively small value in order that the contracted or arc discharge might not start. In this category, the tube, which consisted of cylindrical cathode and concentric wire anode or of disk cathode and needle anode perpendicular to the cathode plane, easily generated the oscillations. Hereafter, the former type of the test tube will be called " A " type and the latter " B " type. The oscilliation was found above a defined value of the average tube current, as well as of the gas pressure, which depended upon the construction of the test tube (see Fig. 1). In case of parallel plane electrodes the oscillation did not occur except the case having positive column.

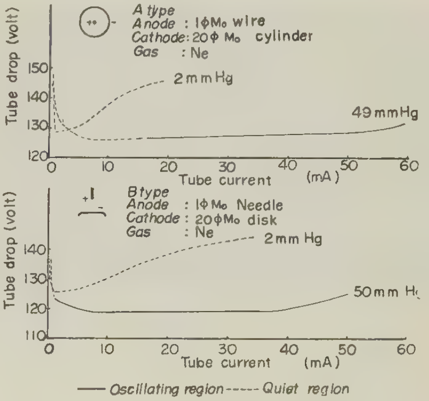

Fig. 1. Typical V-I characteristics and oscillating regions.

When oscillation existed, the faint glow ball attached to a small part of the anode. In such situation the other luminous portion in the discharge space was the negative glow only, as illustrated in Fig. 2. If the appropriate uniform magnetic field was applied along the direction perpendicular to the anode wire in B-type tube, the glow ball was blown out and at the same time the oscillation vanished. Similary, when the polarity of the voltage source was reversed and therefore the glow ball was absent from the beginning, the oscillation did not start. The

---

* In the present paper, unless otherwise appointed, the " oscillation " means voltage fluctuation between anode and cathode.

point where the glow ball would attache could not be expected in A-type tube, but in B-type tube the glow ball was always fastened to the tip of the anode and consequently the oscillation was very stable. It is based upon such a knowledge that *oscillatron* reported in the former paper5) has the form of B type.

The appearance of the voltage oscillation was influenced by the number of glow ball. When there existed only one glow ball, a series of wave consisted of the only kind of wave-form. On the contray, in case of two balls two distinct wave-forms appeared, and they were smoothly connected when the ratio of the period of each wave-form was integer. Often the change of this ratio caused by changing the tube current was an irreversible process and therefore, in that circumstance, the curve of frequency vs tube current, as illustrated in the former paper⁵⁾, drew a hysteresis loop. Fig. 3 shows an example of oscillation* which changes in the way above mentioned.

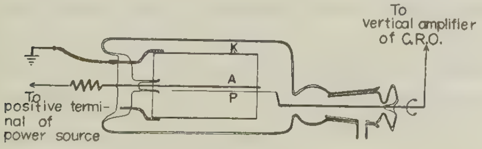
Now consider the Langmuir probe. When the electron current to the probe reaches a critical value, the probe surface is surrounded by the electron sheath and its potential becomes positive against the plasma. The critical current I is expressed by the relation,

$$I=F\cdot j_r\ .$$

Hence, F is the surface area of the probe and J_r is random electron current density in the plasma. The smaller F becomes, the more I decreases, provided that j_r is fixed. Analogously, the positive anode fall may develop more easily when the anode has small surface area compared with that of the cathode; the electrons are accelerated towards the anode by the anode fall and they excite or ionize the gas atom. Thus, it is possible to conclude that the oscillation is tightly related to the positive anode drop. Similar results are reported by Cobine, Gallagher⁶⁾ and Pupp⁷⁾.

***Experiment 2**: Direct detection of oscillating zone by means of a movable probe*

The location of oscillating zone was directely detected by means of a movable probe. Fig. 4 shows the construction of an experimental tube; the probe is made of 0.1 mm-dia. and 45 mm-length tungsten wire and is driven along a arch from the cathode to the anode side or *vice versa* by simple device utilizing a glass stopcock.



To vertical amplifier of C.R.O.
K
A
P
To positive terminal of power source

Fig. 4. Construction of test tube with a movable probe. K: Cathode. A: Anode. P: Mavable probe.

When the probe was immersed into a glow ball, marked oscillation whose frequency was identically equall to that of the interelectrode oscillation was caught between the probe and the cathode, while the Faraday dark space was quite quiet. The probe, which is connected to an input of a cathode-ray oscillscope through a small condenser, will float on the discharge space at wall potential. Hence, the signal from the probe is to correspond to the fluctuation of wall potential which indicates something to be related to the fluctuation of plasma parameters such as electron or ion temperature and space potential, although it is difficult to measure these factors separately. In the actual case there should exist some disturbances caused by the parts of the discharge space besides the glow ball, for the stretch of the glow ball was much smaller than the length of the probe. Therefore the potential of the probe may be determined to be somewhat smaller than that strictly determined by the glow ball only.

***Experiment 3**: Observation of light intensity oscillation of the glow ball*

The light intensity oscillation of the glow ball in B-type tube was observed in relation to the current (or voltage) oscillation. Fig. 5 shows the experimental arrangement. The rays from the glow ball were brought to focus upon the pinhole P by the aid of converging lens L, lest the light originated from other positions should fall on the photomultiplier tube MS-9S. Phase relation between the

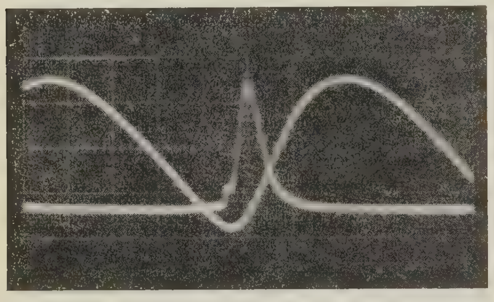
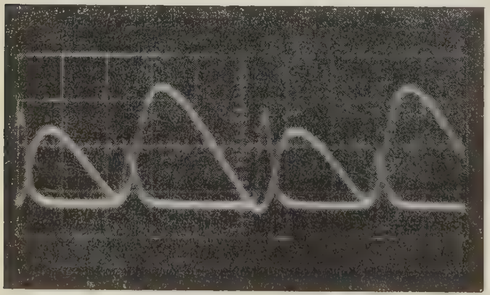
* Nearly sinusoidal wave-form has been shown in reference 5.

current oscillation and the light intensity variation was observed by two-channel oscilloscope utilizing an electronic switch. It was previously checked that the current wave-form agreed closely with the inverted voltage wave-form, if a noninductive resistor was used as a current-limiter. According to this proof, the voltage oscillation inverted by the amplifier of the oscilloscope was observed as a current oscillation. The total output of the phototube was observed by the oscilloscope operated at d.c. sense; this measurement was achieved by taking off both of the preamplifier and channel B from the testing circuit by the switch Sw. Then the degree of modulation of the light intensity variation was found to be 100%.



(a) Detail. Each major division of the time scale is 50μ sec.



(b) Entire correspondence, when two glow balls exist. Each major division of the time scale is 200μ sec.

Fig. 6. Phase relation between current oscillation and light intensity variation which is shown as sharp pulse. Ne 50 mmHg, B-type tube, Current 14 mA.

From Fig. 6 (a) it will be seen that the current minimum coincides with the build-up point of the optical pulse, and that the rise time of the current pulse is longer than that of the optical pulse by the amount of two to five times. These relations were always unchanged during the change of the average tube current. The diameter of the image of the glow ball was about a half as large as the diameter of the pinhole, and the glow ball was at rest on one point. So, the intensity variation obtained by the phototube may not be ascribable to spacial fluctuation of the glow ball. This fact indicates that the origin of the oscillation exists in the discharge space. Because, if an oscillator exists in the outer circuit and simply modulates the discharge, the light intensity peak is to coincide with the current peak. When two glow balls existed they alternately flushed, and one of them corresponded to one of current wave and the other to another one. Fig. 6 (b) shows such a case.

Another important features of the results relate to a hypothesis which has been hitherto used to explain the mechanism of the anodic oscillation. This hypothesis was firstly proposed by Pupp[7)] in 1933 and recently developed by Yoshimoto[3)] et al. in order to explain the anodic oscillation in arc discharge like commercial fluorescent lamp. It consists of two principal parts:

(1) The ionization in the anode fall occurs suddenly when the potential drop across the anode fall reaches a critical value.

(2) The excess ions generated by sudden ionization reduce the electron space-charge and then anode fall decreases. The difference of anode potential is absorbed by both positive column and series resistance in the outer circuit. The excess ions may be lost by diffusion, and anode fall reappears; thus the anodic oscillation has been interpreted as the alternation of above two processes.

If this conception is valid in the present case, the rise time of the current pulse is to be almost equall to that of the optical pulse, while the experimental facts were not so. It has to be recognized that the oscillation is accompanied by alternative ionization in the anode region, however, the conventional simple theory seems to be not always applicable to quantitative treatment of the oscillatory phenomena.

§ 3. Conclusions

Experiments 1 and 2 showed the reason why the anodic oscillation in the glow discharge is so called, and also showed the desirable experimental conditions for promoting next investigations. From the experiment 3 (opitical data), it became cleare that the conventional theory could not qualitatively interpret the phenomena.

Author wishes to express his cordial thanks to Prof. K. Honda and Dr. H. Tamagawa in Tokyo University for their invaluable advices. Thanks are also due to Prof. I. Takahashi of Kyoto University for his interest and encouragement.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 12, DECEMBER, 1959

Ion-Electron Relaxation of Plasmas in a Strong Magnetic Field. I

By Taro KIHARA
Department of Physics, Faculty of Science, University of Tokyo

(Received August 12, 1959)

Relaxation between ion and electron temperatures, T_1 and T_2, of dilute fully ionized gases in a magnetic field is discussed. The mean gyration radius, r_g, is assumed to be much smaller than the Debye length, l_D. The rate of relaxation, R, defined by

$$d(T_2-T_1)/dt=-(T_2-T_1)R$$

is calculated to be

$$R=(n_1+n_2)(4m_2/3m_1)(2\pi kT_2/m_2)^{1/2}(Ze^2/kT_2)^2[\ln(l_D/r_g)]^2$$

for

$$r_g\sim Ze^2/kT_2\,.$$

§1. Introduction

Relaxation phenomena in a magnetic field are worth investigating both from academic point of view and in connection with the problem of controlled nuclear fusion. Since the mass ratio of an ion to an electron is far from unity, energy transfer between ion and electron is much smaller than that between ions or between electrons. Hence the ion temperature T_1 and the electron temperature T_2 are often different even when the velocity distributions are both uniform and Maxwellian. The aim of this paper is to derive an expression for the rate of relaxation between ion and electron temperatures in a fully ionized gas composed of one type of positive ion and electrons. Both the gas and the magnetic field are assumed to be uniform in space.

In a previous paper by the same author[1] a corresponding expression in the absence of the magnetic field has been given. The result is

$$\frac{d}{dt}(T_2-T_1)=-(T_2-T_1)R \tag{1.1}$$

with the time t and the rate of relaxation

$$R=\frac{8}{3}(n_1+n_2)\frac{m_2}{m_1}\left(\frac{2\pi kT_2}{m_2}\right)^{1/2}\left(\frac{Ze^2}{kT_2}\right)^2\ln\frac{3kT_2}{4Ze^2\kappa_{12}}\,, \tag{1.2}$$

Here m_1, Ze, and n_1 are the mass, charge, and number density of the ion respectively; m_2, $-e$, n_2 are those of the electron ($Zn_1=n_2$,

$Z^2 \ll m_1/m_2$); k is the Boltzmann constant; κ_{12} is a shielding constant in the effective potential

$$-\frac{Ze^2}{r}\exp(-\kappa_{12}r) \tag{1.3}$$

between an ion and an electron, and it is not far from the Debye shielding constant. The "3/4" in the argument of the logarithm is in reality an irrational number close to 3/4.

The expression (1.2) is exact as a weak-interaction asymptote for $kT_2/Ze^2\kappa_{12} \gg 1$ so far as the effective potential (1.3) is assumed. When the plasma is so hot and dilute that $\ln(kT_2/Ze^2\kappa_{12})$ is much larger than unity, the formula (1.2) is approximated by

$$R=\frac{8}{3}(n_1+n_2)\frac{m_2}{m_1}\left(\frac{2\pi kT_2}{m_2}\right)^{1/2}\left(\frac{Ze^2}{kT_2}\right)^2\ln\frac{kT_2 l_D}{Ze^2}\,, \tag{1.4}$$

where l_D is the Debye length, the inverse of the Debye shielding constant. This expression is independent of the "model constant" κ_{12}. The condition of this approximation is that $[\ln(kT_2 l_D/Ze^2)]^{-1}$ can be neglected in comparison with unity or that a numerical factor of the order of unity can be neglected in the argument of the logarithm.

In the present article this kind of approximation will be used throughout: any logarithm in the following is assumed to be much larger than unity.

The method of deriving (1.2) by use of (1.3) can hardly be applied to plasmas in a magnetic field. Another formulation is given in § 2, by use of which the same result as (1.4) is obtained in § 3. The present method is applied in § 4 to plasmas in a strong magnetic field. Magnetic fields of intermediate strength will be treated in Part II.

§ 2. General Theory of the Ion-Electron Relaxation

The particle velocities of the ion and electron will be denoted by $\boldsymbol{c}_1$ and $\boldsymbol{c}_2$, respectively, with $|\boldsymbol{c}_1| \equiv c_1$ and $|\boldsymbol{c}_2| \equiv c_2$. Since the average value of $m_1 c_1^2/3$ is kT_1, the time rate of change of kT_1 is given by the average value of the time rate of change of $m_1 c_1^2/3$:

$$\left.\begin{aligned}&\frac{d}{dt}kT_1=\frac{1}{3}m_1\nu\langle|\boldsymbol{c}_1+\Delta\boldsymbol{c}_1|^2-c_1^2\rangle_{\mathrm{Av}}\\ &\text{or}\\ &\frac{d}{dt}kT_1=\frac{1}{3}m_1\nu\langle(2\boldsymbol{c}_1+\Delta\boldsymbol{c}_1)\cdot\Delta\boldsymbol{c}_1\rangle_{\mathrm{Av}}\,.\end{aligned}\right\} \tag{2.1}$$

Here $\Delta\boldsymbol{c}_1$ indicates the increment in ion velocity due to encounter with an electron; $\langle\ \rangle_{\mathrm{Av}}$ means the average with respect to the ion velocity and the velocity of the encountering electron and the impact parameter; ν is the number of encounters per unit time.

When the ion temperature T_1 is much smaller than the electron temperature T_2, the average value of $\boldsymbol{c}_1\cdot\Delta\boldsymbol{c}_1$ can be neglected in comparison with the average value of $|\Delta\boldsymbol{c}_1|^2$; hence

$$\frac{d}{dt}kT_1=\frac{1}{3}m_1\nu\langle|\Delta\boldsymbol{c}_1|^2\rangle_{\mathrm{Av}} \qquad \text{for} \quad T_1 \ll T_2\,. \tag{2.2}$$

This is essentially diffusion due to the Brownian motion in the velocity space[2)].

The relation (2.2) can be generalized to

$$\frac{d}{dt}kT_1=\frac{1}{3}m_1\nu\langle|\Delta\boldsymbol{c}_1|^2\rangle_{\mathrm{Av}}\frac{T_2-T_1}{T_2}\,, \tag{2.3}$$

which holds not only for T_1 much smaller than T_2 but also for T_1 not far from T_2 (i.e. for $m_2T_1 \ll m_1T_2$). A proof is the following. Since $m_1 \gg m_2$ the quantity $|\Delta\boldsymbol{c}_1|^2$ averaged with respect to the velocity of the encountering electron and the impact parameter is independent of $\boldsymbol{c}_1$; but $\Delta\boldsymbol{c}_1$ so averaged depends linearly upon $\boldsymbol{c}_1$ (or is proportional to $\boldsymbol{c}_1$ if the magnetic field is absent). Hence, for constant electron temperature, $\langle|\Delta\boldsymbol{c}_1|^2\rangle_{\mathrm{Av}}$ is independent of T_1, and $\langle\boldsymbol{c}_1\cdot\Delta\boldsymbol{c}_1\rangle_{\mathrm{Av}}$ is proportional to T_1. Taking account of the fact that

$$\langle(2\boldsymbol{c}_1+\Delta\boldsymbol{c}_1)\cdot\Delta\boldsymbol{c}_1\rangle_{\mathrm{Av}}$$

vanishes for $T_1=T_2$, we finally obtain

$$2\langle\boldsymbol{c}_1\cdot\Delta\boldsymbol{c}_1\rangle_{\mathrm{Av}}=-(T_1/T_2)\langle|\Delta\boldsymbol{c}_1|^2\rangle_{\mathrm{Av}}\,,$$

by virtue of which (2.3) follows from (2.1). Here we have tacitly neglected the dependence of the shielding constant on the ion temperature. In fact, the shielding constant enters only in the argument of logarithm, and hence the dependence can be neglected.

By used of the relationship

$$\frac{d}{dt}(n_1T_1+n_2T_2)=0\,,$$

the rate of relaxation R defined by (1.1) is calculated to be

$$R=\frac{1}{3}(n_1+n_2)m_1\frac{\nu}{kT_2n_2}\langle|\Delta\boldsymbol{c}_1|^2\rangle_{\mathrm{Av}}\,. \tag{2.4}$$

§ 3. Case of No Magnetic Field

Since an ion does not greatly move during an encounter with an electron, a perturbation method can be used for the calculation of Δc_1. Let, in the absence of magnetic field, the unperturbed position of an ion and the unperturbed trajectory of an encountering electron be

$$(x_1, y_1, z_1)=(0, 0, 0)\ ,$$
$$(x_2, y_2, z_2)=(b, 0, c_2t)\ ,$$

respectively, where b is the impact parameter, t the time.

For a hot dilute plasma we need only to consider weak interactions,

$$Ze^2/b<\frac{1}{2}m_2c_2^2\ ,$$

for which

$$|\Delta \boldsymbol{c}_1|=\Delta c_{1x}=\frac{Ze^2}{m_1}\int_{-\infty}^{\infty}\frac{b}{(b^2+c_2^2t^2)^{3/2}}\,dt=\frac{2Ze^2}{m_1bc_2}\ . \tag{3.1}$$

When the impact parameter b is sufficiently smaller than the limit of weak interaction, $2Ze^2/m_2c_2^2$, the increment in ion velocity is much smaller than the right-hand side of (3.1) and can be neglected in the present degree of approximation.

The average value of $|\Delta \boldsymbol{c}_1|^2$ is given by

$$\frac{\nu}{n_2}\langle|\Delta \boldsymbol{c}_1|^2\rangle_{\rm Av}=\int_{b_0}^{l_D}db\int_0^{\infty}dc_2|\Delta \boldsymbol{c}_1|^2\left(\frac{m_2}{2\pi kT_2}\right)^{3/2}\exp\left(-\frac{m_2c_2^2}{2kT_2}\right)c_24\pi c_2^22\pi b$$
$$=8\left(\frac{2\pi m_2}{kT_2}\right)^{1/2}\left(\frac{Ze^2}{m_1}\right)^2\ln\frac{l_D}{b_0}\ .$$

Here l_D is the Debye length and b_0 is the average limit of weak interaction, $b_0\sim Ze^2/kT_2$. The rate of relaxation, therefore, is given by

$$R=\frac{8}{3}(n_1+n_2)\frac{m_2}{m_1}\left(\frac{2\pi kT_2}{m_1}\right)^{1/2}\left(\frac{Ze^2}{kT_2}\right)^2\ln\frac{kT_2l_D}{Ze^2}\ , \tag{3.2}$$

which agrees with (1.4).

§4. Case of Strong Magnetic Field

Presence of a magnetic field does not influence the result of the preceding section so far as the condition $l_D\ll r_g$ is satisfied. Here r_g is the mean gyration radius of the electrons defined by

$$r_g\equiv\frac{1}{\omega_2}\left(\frac{2kT_2}{m_2}\right)^{1/2}\ ,$$

ω_2 being the cyclotron frequency of electrons. In this section we consider the opposite case of strong magnetic field:

$$Ze^2/kT_2\sim r_g\ll l_D\ .$$

With z-axis in the direction of the magnetic field the unperturbed position of an ion and the unperturbed trajectory of an encountering electron can be chosen as

$$(x_1, y_1, z_1)=(0, 0, 0)\ ,$$
$$(x_2, y_2, z_2)=(b, 0, c_{2z}t)\ ,$$

where c_{2z} is the component of the electron velocity parallel to the magnetic field.

For a hot dilute plasma we need only to consider the range $r_g<b<|c_{2z}|/\omega_p$; in this range we have, like (3.1),

$$|\Delta \boldsymbol{c}_1|=\frac{2Ze^2}{m_1b|c_{2z}|}\ . \tag{4.1}$$

When the time of interaction, $b/|c_{2z}|$, is sufficiently larger than the period of plasma oscillation,

$2\pi/\omega_p$, or when the impact parameter b is sufficiently smaller than the gyration radius r_g the increment $|\Delta \boldsymbol{c}_1|$ in ion velocity is much smaller than the right-hand side of (4.1) and ca be neglected in the present calculation.

Then

$$(\nu/n_2)\langle|\Delta \boldsymbol{c}_1|^2\rangle_{\mathrm{Av}}=2\int_{r_g}^{l_D} db\int_{b\omega_p}^{\infty} dc_{2z}|\Delta \boldsymbol{c}_1|^2\left(\frac{m_2}{2\pi kT_2}\right)^{1/2}\exp\left(-\frac{m_2c_{2z}^2}{2kT_2}\right)c_{2z}2\pi b$$

$$=8\pi\left(\frac{m_2}{2\pi kT_2}\right)^{1/2}\left(\frac{Ze^2}{m_1}\right)^2\int_{r_g}^{l_D} db\int_{\lambda_0}^{\infty} d\lambda\frac{\exp(-\lambda)}{\lambda b}\ .$$

Here

$$\lambda_0\equiv\frac{m_2\omega_p^2b^2}{2kT_2}\sim\left(\frac{b}{l_D}\right)^2,$$

which is much smaller than unity in the dominant part of the integration domain of b. Hence the integral is replaced by

$$\int_{r_g}^{l_D}\left(\ln\frac{1}{\gamma\lambda_0}\right)\frac{db}{b}=\ln\frac{l_D}{\gamma r_g}\cdot\ln\frac{l_D}{r_g}\ .$$

Here $\ln\gamma=0.577$ is Euler's constant, which can be neglected in our approximation. The ra of relaxation for $r_g\sim Ze^2/kT_2$ is, therefore, given by

$$R=\frac{4}{3}(n_1+n_2)\frac{m_2}{m_1}\left(\frac{2\pi kT_2}{m_2}\right)^{1/2}\left(\frac{Ze^2}{kT_2}\right)^2\left(\ln\frac{l_D}{r_g}\right)^2. \tag{4.2}$$

Optical Studies on the Effect of Electric Fields on the Transitions of Barium Titanate

By Kazuo KAWABE*

Faculty of Science, Osaka University

(Received June 23, 1959)

The effect of electric fields on the three transition points of barium titanate was studied experimentally by observing the shift of the curve of the thermal transition of transparency with varying biasing fields. Transparent electrodes, thin films of stannic oxide, were used in order to observe the intensity of light transmitted through crystals to which electric fields were applied. The Curie point is raised up to a critical temperature of 132°C, the required strength of the field being 9 kv/cm, and above this point the transition of the first order no longer takes place. From this fact, the coefficient of P_z^4 in the Devonshire expression of the free-energy function is obtained, which supports the value measured by Drougard. The observed shifts of the Curie point and the 5°C transition point are in good agreement with the values calculated by using the Devonshire function of the sixth order. At the −80°C transition, the experimental value is explained by adding the terms of eighth and tenth powers of polarization to the usual Devonshire function.

The relationship between the polarization of a crystal and the intensity of the transmitted light is pointed out in the case when the crystal is placed between crossed Nichols.

Remarks are also given of the effects which the coating of electrodes has upon the shape of the curve of the thermal transition of transparency at the −80°C transition.

§ 1. Introduction

As is well known, the phase transitions of barium titanate occur at three temperatures in the vicinities of 120°C, 5°C, and −80°C. Above 120°C, the crystal has cubic symmetry, being paraelectric. In the temperature range between 120°C and 5°C, the crystal is spontaneously polarized along a ⟨100⟩ direction, accompanied with tetragonal symmetry. Between 5°C and −80°C, the crystal symmetry is orthorhombic, and the direction of the spontaneous polarization transfers to a pseudo-cubic ⟨110⟩ direction, a face diagonal of the former cubic cell. At −80°C, a further transition to rhombohedral symmetry** spontaneously polarized along a body diagonal (original ⟨111⟩ direction) takes place. If an electrostatic field is applied to this crystal, certain changes in the transition temperatures are expected admittedly to take place.

In fact, it has been found that the Curie point at 120°C is raised linearly by increasing strength of applied electric field by Kaenzig and Maikoff[2] who measured the dielectric constants with biasing fields, and also by Merz[3] who observed the double hysteresis loops. Their results are in good agreement with the value computed from the Clausius-Clapeyron relation[4],[5]. The effect of the biasing field on the transition temperature at 5°C was also estimated by Huibregtse and Young[6] by observing the triple hysteresis loops, but the agreement of their result with the Clausius-Clapeyron relation was not so good.

The present paper aims at studying the effect of the biasing field on the three transition temperatures by means of an optical method, and at treating the effect thermodynamically on the basis of Devonshire's phenomenological theory; such a treatment will give some information about the free-energy function of barium titanate.

When a BaTiO$_3$ single crystal is placed between crossed Nichols, the intensity of light transmitted through the analyzer changes abruptly at the Curie point near 120°C. The transparency of the single crystal of barium titanate for visible light also exhibits marked jumps at the two lower transition points[7),8)]. These optical phenomena have been named in terms of the *thermal transition of transparency* (as an abbreviation of this terminology, TTT is to be used throughout this paper) and are closely related to the polarization and the domain structure of a crystal. Accordingly, it is expected that the application of an electric field would have an appreciable effect upon the transparency of the crystal. Thus the TTT in dependence on the strength of the applied field may be used as a new method to observe the effect of the biasing field on the transition points.*

** Recently Jona and Pepinsky[1] suggested that the symmetry below −80°C would be monoclinic or triclinic rather than rhombohedral.

Experimentals

§ 2. Preparation of Specimens and Electrodes

A mixture of 1:1:4 molar ratio of TiO_2, $BaCO_3$, and Na_2CO_3 (flux) was heated up to about 1200°C in a nickel crucible in a reductive coal-gas atmosphere in order to avoid the oxidation of the crucible[8),9)]. After cooling and crystallization, thin plate-like tetragonal crystals were obtained that had a Curie temperature of about 118°C. Several crystals prepared by the Remeika method[10)] were also used, but the experimental data given by the crystals from both sources made no great difference.

The electrodes must be transparent or at least be translucent when an electric field is applied in the direction at a certain angle to the incident beam of light. It has been known that the thin film of SnO_2 is semiconductive and transparent for visible light. Various methods of coating materials such as glass, rock salt, or fused silica with this film have been reported[11)–13)], especially the coated glass being well-known under the name of *NESA*, and the author could evaporate this film directly on the crystal surface of barium titanate. Stannic chloride solution which was dissolved into hydrochloric acid of *ca.* 6 normals and diluted by *ca.* 50% ethyl alcohol was sprayed onto the crystal in the furnace kept at about 600°C[13)]. Large drops in the sprayed fog made the resultant film opaque. It gave a good result to spray the solution from the bottom of the furnace so as to make only fine drops reach the crystal surface on the ascending air current in the furnace[12)]. The electrical resistance of the film was about several hundred ohms per cm² at room temperature.

§ 3. Effect of Electrostatic Field on TTT

A plate of a $BaTiO_3$ single crystal was placed between crossed Nichols, and the crysta surface was inclined at a certain angle to the direction of the incident beam of light (Fig 1). The crystal was so oriented that the direction of a component P_0 of the polarization was inclined at 45° to the principal planes of the Nichols. Since the direction of an applied field makes a certain angle with the direction of the incident beam, the analyzer transmits the light due to the birefringence which is caused by the component P_0 of the polarization in the direction at right angles to the incident beam. The intensity of the transmitted light is changed as a function of the polarization when the crystal structure transforms from cubic to tetragonal. Accordingly, the cubic-to-tetragonal transition** can be studied by observing this phenomenon.

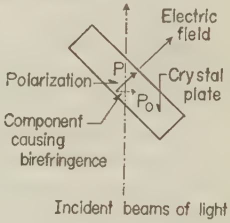

Fig. 1. Setting of the crystal.

At the two lower transition points, namely the tetragonal-to-orthorhombic and orthorhombic-to-rhombohedral transition points, the transparency of barium titanate for visible light exhibits remarkable jumps. For example, the change of the transparency at the 5°C transition is shown in Fig. 2 (a). Applying an electrostatic field to this crystal, the hysteresis loop of transparency as shown in Fig. 2 (a) shifts towards lower temperatures. Therefore, if the specimen is kept at a temperature below and near 5°C and is put under the influence of an electrostatic field, the transparency increases abruptly at the time when the applied field reaches a certain strength (Fig. 2 (b)). The rate of the change of the transition temperatures as a function of the applied field, $\Delta T_t/\Delta E$, can be obtained either by measuring these critical fields or by observing the shift itself of the TTT-curve.

---

* An optical method of studying the movement of domain walls in Rochelle salt crystal has recently been reported by Abe[21)]. He has shown that the optical method is very useful to study the characteristics of wall motion at very low frequencies.

** In the strict sense of the word, this is not the transition between cubic and tetragonal phases, but the transition between cubic- and induced-tetragonal-phases. In this paper, the term cubic-to-tetragonal transition is also used for this transition.

The experimental arrangement used for this transparency measurement has already been described in detail in the previous paper[8]. The crystal was uniformly illuminated by a continuous source and the enlarged image of the crystal was formed by a microscope on a diaphram just in front of a multiplier phototube, the photocurrent of which was magnified by a dc amplifier. The temperature of the specimen was controlled by an electric heater and liquid nitrogen in a modified Dewer flask.

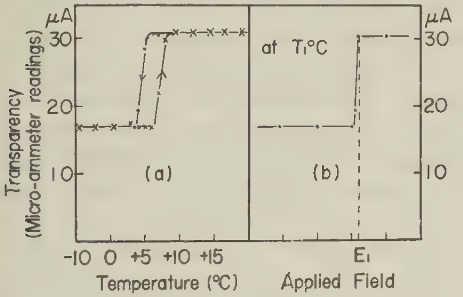

Fig. 2. (a) Thermal transition of transparency near 5°C. (b) Transparency *vs* applied field near and below 5°C.

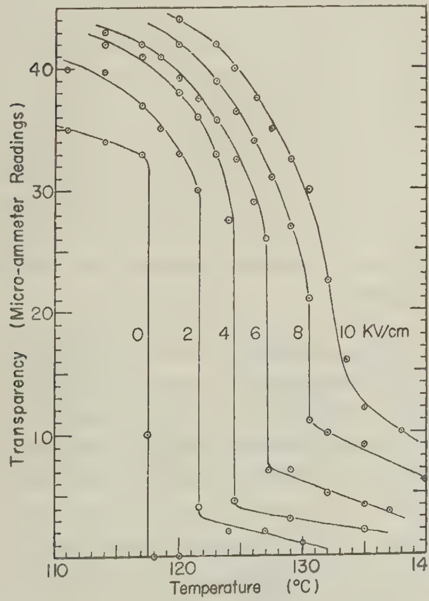

Fig. 3. Temperature-dependence of the optical transmission with various applied fields near 120°C. The numbers near the curves represent the strengths of the applied fields.

§ 4. Experimental Results

a) *Curie point*

The temperature-dependence of the optical transmission at the tetragonal-to-cubic transition with varying biasing fields is shown in Fig. 3. The transition temperature rises with increasing strength of the applied electric field, and the plot of the field strength against transition temperature shows a linear relation as is seen in Fig. 4. The results of electrical measurements are also plotted in the same figure with the intention of comparing. These electrical data were obtained from gold-electroded crystals by measuring the separation of the double hysteresis loops at 60 cps at

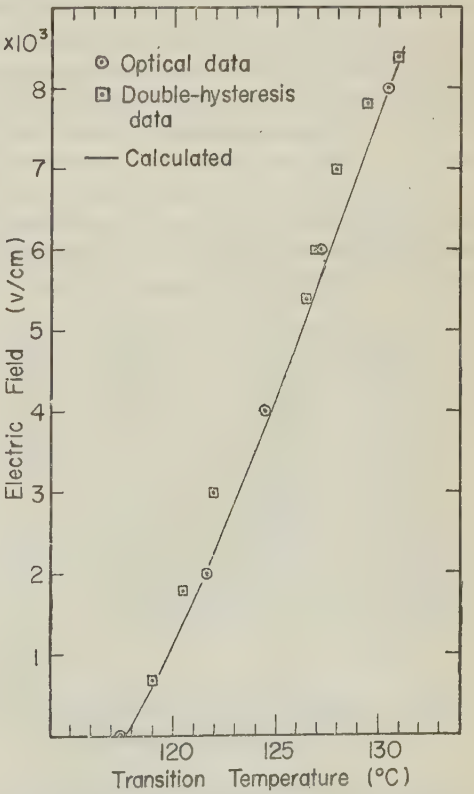

Fig. 4. Transition temperature as a function of the applied field near 120°C.

various temperatures near 120°C. This electrical method gave poorer experimental accuracy than the optical method did. The circuit used for this hysteresis test was that invented by Diamant, Drenck and Pepinsky[20]. Both data are in good agreement, giving the rate of the shift of the Curie point, or strictly speaking, of the transition point, as

$$\Delta T_t/\Delta E = (1.6 \pm 0.1) \times 10^{-3}\ \mathrm{deg/volt\ cm^{-1}}\ ,$$

which is in good agreement with the value measured by Kaenzig and Maikoff (1.2×10^{-3} deg/volt cm^{-1})[1] and with that measured by Merz (1.4×10^{-3} deg/volt cm^{-1}).

As the strength of the applied field increases, the induced polarization in the cubic state increases, and at last the magnitude of the polarization in the cubic state becomes equal to that in the tetragonal state, the transition being no longer of the first order. This critical temperature is about 132°C, and the strength of the corresponding critical field is about 9 kv/cm.

b) *Transition points near 5°C and −80°C*

The transparency of a specimen kept at T_1°C somewhat below 5°C changes as a function of the applied field as is shown in Fig. 2 (b). The critical field required to induce a sudden change of the transparency increases gradually with decreasing temperature of the crystal. If this temperature T_1 is defined as the transition point in the presence of an electric field E_1, the plots of the strength of the critical field against transition temperature become straight lines. several examples of them being shown in Fig. 5. The value of $\Delta T_t/\Delta E$ can be estimated from the inclination of such a straight line. After repeated measurements, the following value is obtained as the average value:

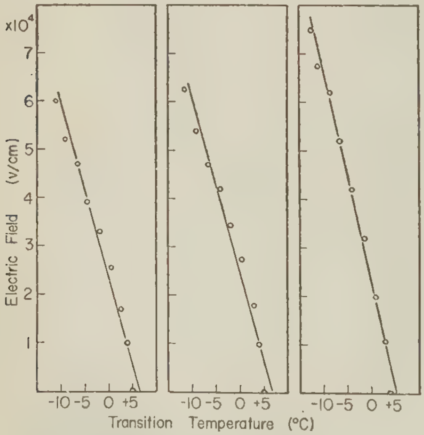

Fig. 5. Examples of the shift of the transition temperature caused by applying electric fields near 5°C.

$$\Delta T_t/\Delta E = (-2.6 \pm 0.2) \times 10^{-4}\ \mathrm{deg/volt\ cm^{-1}}\ ,$$

for the 5°C transition, which is in good agreement with the value obtained by Huibregtse and Young[6], that is -2.8×10^{-4} deg/volt cm^{-1}, from the observation on their triple hysteresis loop.

At the −80°C transition, similar curves to that shown in Fig. 5 were obtained through the similar procedure, but in this case the transition of transparency with field was poorly defined, and the experimental accurary was not so good in this way. At this lowest transition point, the observation on the shift itself of the hysteresis loop of transparency gave better results on the effect of the biasing field. As the field strength increases, the hysteresis loop, and consequently the transition point, shifts towards lower temperatures.

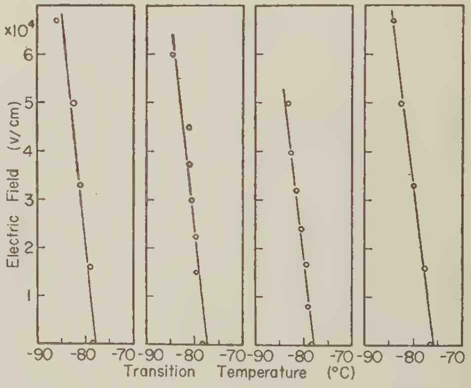

Fig. 6. Examples of the shift of the transition temperature caused by applying electric fields near −80°C.

From this shift the value of $\Delta T_t/\Delta E$ can readily be estimated. It is seen in Fig. 6 that a linear relation holds again between the transition temperature and the strength of the applied field, and the following value is obtained:

$$\Delta T_t/\Delta E = (-1.2 \pm 0.2) \times 10^{-4}\ \mathrm{deg/volt\ cm^{-1}}\ ,$$

for the −80°C transition.

§ 5. Remarks on the TTT-curve near −80°C in the Presence of an Electric Field

It has been shown in the previous report[7] that the TTT at the −80°C transition is characterized by the decrease in the transparency in the lowest phase as shown in Fig. 7 (a). But in the study on the effect of biasing fields for coated crystals, an increase in the transparency took place in the rhombohedral phase (Fig. 7 (b)).

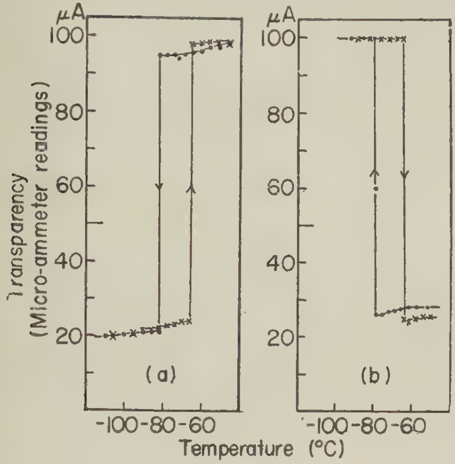

Fig. 7. Thermal transition of transparency near −80°C (a) without and (b) with electrodes.

The following test would give some information about this contradiction. A specimen which had displayed the TTT-curve as shown in Fig. 7 (a) (normal form) in its unelectroded condition was coated over one surface with the transparent electrode and was put under the TTT-test without applying any external electric field, and then both sides were coated and the same procedure was repeated.

In the case of thin crystals (for instance, 14μ in thickness), the normal TTT was made to disappear on account of the coating over one of the plate surfaces, and the coating over both surfaces reversed the form of the TTT (Fig. 7 (b)), that is, transparency increased in the lowest phase. On the contrary, in the case of a relatively thick srystal (for instance, 50μ in thickness) no remarkable electrode-effect presented itself, but after alternate applications and removals of strong electrostatic fields, and only then, the reversed form of the TTT could call the attention.

It has been observed that the displacements of the domain walls in Rochelle-salt crystals caused by thermal motions occur much more freely when they are immersed in an electrolytic solution than when their surfaces are dry, because the surface charge and thus the restoring force cannot develop in the electrolytic solution⁵⁾. If a situation which is to a certain extent similar to the case of Rochelle salt should be expected to take place in the case of coating $BaTiO_3$ crystals with semiconductive films, the transparent electrodes would make domain walls more easily movable in times of the phase change, especially in thin crystals which contain small stress, and consequently, there would appear different domain habits, and hence different transparency, from those without electrodes.

Discussions

§ 6. Comparison with Clausius-Clapeyron Relation

Suppose the transitions of barium titanate to be of the first order, then the well-known relation of Clausius-Clapeyron,

$$\Delta T_t/\Delta E = -\Delta P_z/\Delta S\,, \qquad (1)$$

holds for the rate of the change of the transition temperature with an external electric field, where ΔP_z represents the discontinuous jump of the component of the spontaneous polarization in the direction of the field, and ΔS is the change in the entropy at the transition. For the Curie point, as was mentioned above, this relation holds good.

At the 5°C transition, if the experimental values of ΔP_z measured by Wieder¹⁴⁾ or Huibregtse⁶⁾, and the average value of ΔS measured by several investigators⁵⁾ are used, then the Clausius-Clapeyron relation gives the value of $\Delta T_t/\Delta E$ equal to about -8×10^{-4} deg/volt cm^{-1}, which is not in so good agreement with the present experimental result. At the −80°C transition, the value computed from the Clausius-Clapeyron equation is far from agreeing with the present experimental result, and so the author cannot but consider that such a simple estimation as taking no account of the dependence of ΔP_z and ΔS upon temperature and field will no longer be within the limits of a good approximation at these lower transition points.

§ 7. Phenomenological Calculation Based on the Devonshire Function

a) *Curie point*

In computing the value of $\Delta T_t/\Delta E$ from the Clausius-Clapeyron equation at the Curie point, the experimental data without field were chosen for the numerical values of ΔP_z and ΔS. But in reality, when an electric field is applied to this crystal, the polarization in the cubic phase is no longer zero but varies with the field strength, and hence ΔP_z is not constant but a function of temperature and field strength. In fact, according to the experimental result shown in Fig. 3, ΔP_z vanishes when the transition point is elevated up to about 132°C. Hence it appears likely that ΔS also varies with temperature and field strength in order that the Clausius-Clapeyron relation may holds good.

According to the thermodynamical relation, the entropy S, related to the polarization P, is given as a derivative of the Gibbs free energy $\mathfrak{A}$ by the following formula,

$$S=-(\partial\mathfrak{A}/\partial T)_{P,X}\ , \qquad (2)$$

where T and X represent temperature and stress, respectively. According to Devonshire[4], the Gibbs function per unit volume of a stress-free crystal is expressed in terms of even powers of polarization as follows:

$$\begin{aligned}\mathfrak{A}&=\mathfrak{A}_0+AP^2+BP^4+CP^6\\ &=\mathfrak{A}_0+A_0(T-T_0)P^2+BP^4+CP^6\ , \qquad (3)\end{aligned}$$

where $\mathfrak{A}_0$ is the free energy of the crystal for zero polarization. In Eq. (3) it is assumed that only A is dependent on temperature[3]. Then S is given by $S=-A_0P^2$, and $\Delta T_t/\Delta E$ becomes a function of the polarization only, that is,

$$\Delta T_t/\Delta E=-(P_c-P_t)/(S_c-S_t)=1/[A_0(P_t+P_c)]\ , \qquad (4)$$

where the quantity to which t or c is suffixed refers to the tetragonal or cubic state, respectively. If the numerical values of P_t and P_c at various temperatures are known, the corresponding values of $\Delta T_t/\Delta E$ can be computed from (4).

One way to obtain the values of P_t and P_c is to make use of the optical data shown in Fig. 3. When a double-refractive crystal plate is placed between crossed Nichols, and when the direction of the polarization of the crystal is inclined at 45° to the principal planes of the Nichols, then the intensity of the light of wavelength λ (in air) which has passed through the analyzer, $I(\lambda)$, is given by[15]

$$I(\lambda)=I_0(\lambda)\sin^2(\delta/2)\ , \qquad (5)$$

where $I_0(\lambda)$ is the intensity of the incident light, and δ is the retardation after the light has passed through the crystal of thickness d. The definition of δ is given by the following relationship:

$$\delta=2\pi(d/\lambda)\cdot\Delta n\ , \qquad (6)$$

where Δn is the birefringence of the crystal. Since the light source used for this experiment is a continuous one excluding shorter wavelengths than the absorption edge of barium titanate (about 3800Å[16]), Δn is considered to be approximately independent on wavelength. Then the observed intensity, I_{obs}, is roughly estimated as

$$\begin{aligned}I_{\text{obs}}&=\sum_{\lambda} I(\lambda)\approx I_0\int_0^\infty \sin^2(\pi\cdot\Delta n\cdot d/\lambda)\,d\lambda\\ &=I_0(\pi^2/2)d\cdot\Delta n\ , \qquad (7)\end{aligned}$$

where $I_0(\lambda)$ is assumed to be approximately constant. On the other hand, it has been known that there exists a proportional relationship between Δn and the square of the spontaneous polarization of $BaTiO_3$,[17] *i.e.*, $\Delta n\propto P_s^2$. Therefore, the following expression may be assumed;

$$I_{\text{obs}}\propto P^2\ . \qquad (8)$$

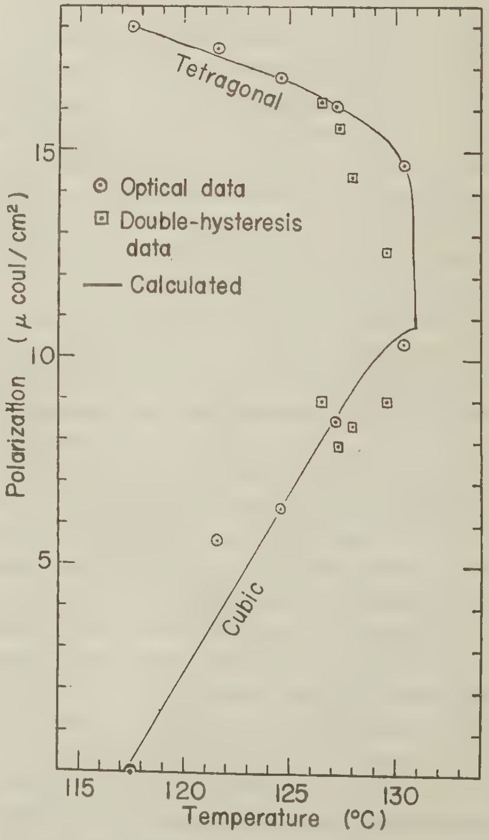

Fig. 8. Polarizations in cubic and tetragonal phases.

From this relation, the values of P_c and P_t at the transition temperatures can readily be estimated by multiplying a proportional constant to the square roots of the observed optical transmissions which are obtained from the data shown in Fig. 3. The values obtained in such a way are plotted in Fig. 8, where the values estimated from double-hysteresis data are also plotted with a view to comparing.

The other way of obtaining the values of polarizations is a calculation based on the Devonshire theory. From thermodynamic considerations, it can be shown that the applied field E is given by $\partial\mathfrak{A}/\partial P=E$,[3),4)] so that

$$E=2A_0(T-T_0)P+4BP^3+6CP^5\ , \qquad (9)$$

the plot of which gives the values of P_t and P_c, if the numerical values of the coefficients are known. These values has been given by Merz[3)], but Drougard *et al.*[18)] have obtained the different value of B showing a dependence on temperature.

To determine this B-value, the present experimental data are of use. It has been mentioned above that the transition temperature is elevated by an electric field up to a critical temperature Θ, where $P_t=P_c$, and the transition of the first order no longer takes place. In other words, the double hysteresis loop vanishes at this temperature, *i.e.*, the two points given by $dE/dP=0$ coincide with each other, that is, the quadratic equation concerning P^2 given by $dE/dP=0$ has the equal roots. For simplicity, B is assemed to be constant in the vicinity of 120°C. Putting the discriminant to be zero, the expression

$$B^2=\frac{5}{3}CA_0(\Theta-T_0) \qquad (10)$$

is obtained, in which $A_0=3.7\times10^{-5}$ cgs[3)] and $C=3.8\times10^{-23}$ cgs[3)]. From the present experiment (Fig. 3), it can readily be found that $\Theta=132$°C and $T_0=107.5$°C. The value of B computed by using these values is -2.39×10^{-13} cgs, which is in good agreement with the mean value of Drougard's data between 120°C and 130°C, that is, about -2.35×10^{-13} cgs[18)]. The propriety of these coefficients is supported by the fact that the valley of the thermodynamic potential surface near 120°C, which is drawn by making use of these coefficients (Fig. 9), coincides approximately with the observed data of the spontaneous polarization.

The values of P_c and P_t can be obtained by the plot of the polarization against the electric field, which is calculated in this way. Such values are plotted in Fig. 8 by the solid line, the agreement with the experimental values being very good. The values of $\Delta T_t/\Delta E$ thus obtained for various temperatures are shown by a solid line in Fig. 4, which is sufficient to explain the experimental results.

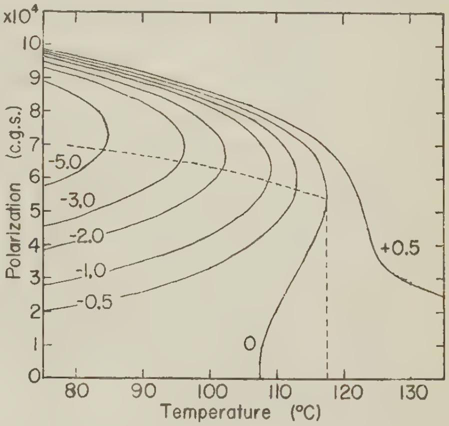

Fig. 9. Chart of the thermodynamic potential surface near the Curie point. The numbers near the contours are in cal/mol. The dotted line gives the experimental temperature dependence of the spontaneous polarization.

b) *Two lower transition points*

At a temperature near 5°C, the crystal transforms from tetragonal to orthorhombic phase, and there appears the x-component in addition to the z-component of the polarization because of the transformation of the direction of polarization from an edge to a face diagonal of the pseudo-cubic cell. The Devonshire function per unit volume is then expressed as follows:

$$\begin{aligned}\mathfrak{A}=\mathfrak{A}_0&+A(P_x^2+P_z^2)+B(P_x^4+P_z^4)\\&+C(P_x^6+P_z^6)+DP_x^2P_z^2\\&+G(P_x^2P_z^4+P_x^4P_z^2)\ , \qquad (11)\end{aligned}$$

the last cross term of the sixth order being added by Huibregtse and Young[6)] in order to obtain a satisfactory explanation of their observation on the 5°C transition. The electric field as a function of polarization is given by

$$\begin{aligned}E_z=2AP_z&+4BP_z^3+6CP_z^5+2DP_x^2P_z\\&+G(2P_x^4P_z+4P_x^2P_z^3)\ . \qquad (12)\end{aligned}$$

To plot E_z against P_z, P_x in Eq. (12) must be eliminated by an additional condition due to the fact that the electric field is applied only in the z-direction, that is, $E_x=0$, or

$$A+2BP_x^2+3CP_x^4+DP_z^2+G(2P_x^2P_z^2+P_z^4)=0\,. \qquad (13)$$

The numerical values of the coefficients have been given by Huibregtse and Young[6], and also by Drougard and Huibregtse[19]. The values of A and B are in accord with those measured by Merz[3] and by Drougard[18], respectively, and the other coefficients take the following values at 0°C: $C=12.2\times10^{-23}$[6] or 9×10^{-23}[19], $D=4\times10^{-13}$, $G=6\times10^{-23}$[6] in cgs units. On the other hand, Merz[3] reported the value of C in the neighbourhood of 120°C as 3.8×10^{-23}. This is the reason why the author considers the coefficient C also to be dependent on temperature. If a straight line is assumed for C as a function of temperature, which passed through the two points (120°C, 3.8×10^{-23} cgs) and (0°C, 11×10^{-23} cgs), then the following expression is obtained for the temperature dependence of C:

$$C=-6\times10^{-25}(T-T_2)\,,\quad T_2=183^\circ\mathrm{C}\,. \qquad (14)$$

In the vicinity of 5°C the effect of the term of CP_z^6 upon the free energy is too large to neglect the temperature dependence of this coefficient. According to Huibregtse and Young, it may also be assumed that D and G are constant. The values of the coefficients used in this calculation are listed as follows:

$$\left.\begin{aligned} &A=3.7\times10^{-5}(T-T_0)\,, \quad T_0=107.5^\circ\mathrm{C}\,.\\ &B=4.5\times10^{-15}(T-T_1)\,, \quad T_1=175^\circ\mathrm{C}\,.\\ &C=-6\times10^{-25}(T-T_2)\,, \quad T_2=183^\circ\mathrm{C}\,.\\ &D=4\times10^{-13}\,.\\ &G=6\times10^{-23}\,. \qquad \text{(in cgs units)} \end{aligned}\right\} \quad (15)$$

The plots of P_z *vs* E_z given by Eq. (12) together with those for tetragonal state are shown in Fig. 10, the temperature of the crystal being a parameter. According to the Devonshire picture, P_z varies with field along the P_z *vs* E_z curve in regions where $\partial P_z/\partial E_z$ (susceptibility) is positive. At the point where the susceptibility is infinite, P_z instantly jumps to a point where the susceptibility is again positive, which is the fundamental idea of Huibregtse on his triple hysteresis loop[6]. Accordingly, the point where $\partial P_z/\partial E_z$ becomes infinite should be considered as the transition point from orthorhombic to tetragonal in the existence of an electric field. These points are readily obtained from the curves shown in Fig. 10, and if these critical fields (at which $\partial P_z/\partial E_z\to\infty$) are plotted against the corresponding transition temperatures, the curve

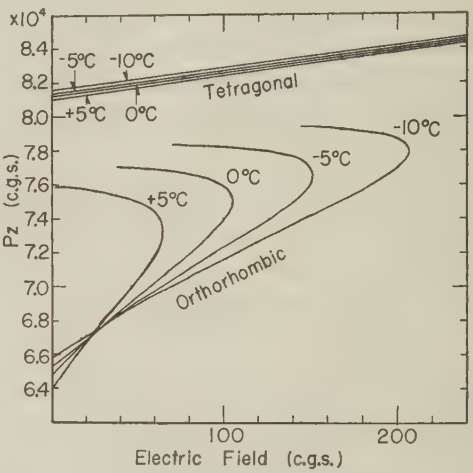

Fig. 10. The z-component of the polarization (P_z) *versus* electric field near 5°C. The numbers near the curves represent the temperature of the crystal.

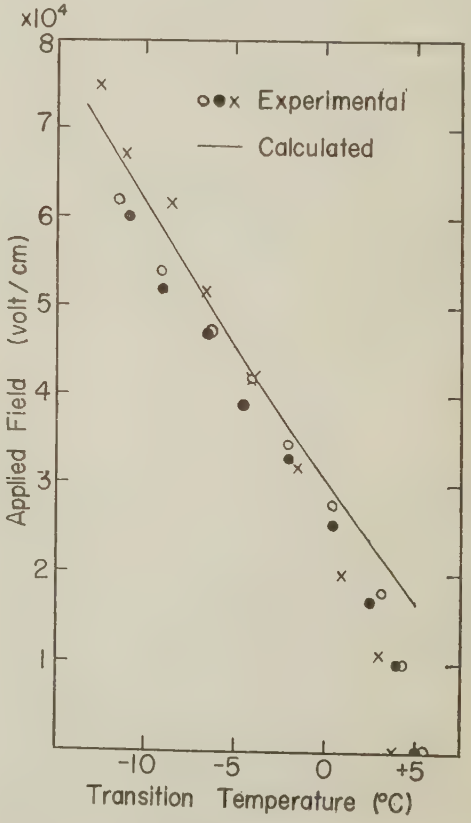

Fig. 11. Shift of the transition temperature near 5°C caused by electric fields.

drawn with solid line in Fig. 11 is obtained, which explains the experimental results satisfactorily. It will also be seen in Fig. 10 that this transition is of the first order, at least in the region of the field strengths in which the present experiment was carried out. It appears likely that the discrepancy with the Clausius-Clapeyron relation would be caused by the neglect of the effect of strong electric field on ΔP_z and ΔS.

When the crystal is cooled down to about −80°C, another transition takes place. It is stated recently that the crystal symmetry of this lowest phase would be monoclinic or triclinic[1], but the author assumes here the symmetry to be rhombohedral according to the conventional interpretation. Then the spontaneous polarization takes the direction in a body diagonal of the former cube cell, and the terms due to another component, P_y, must be added to the expression (11) of the free energy, that is,

$$\begin{aligned}\mathfrak{A}=\mathfrak{A}_0&+A(P_x^2+P_y^2+P_z^2)\\&+B(P_x^4+P_y^4+P_z^4)+C(P_x^6+P_y^6+P_z^6)\\&+D(P_x^2P_y^2+P_y^2P_z^2+P_z^2P_x^2)\\&+G(P_x^4P_y^2+P_y^4P_x^2+P_y^4P_z^2\\&+P_z^4P_y^2+P_z^4P_x^2+P_x^4P_z^2)\,. \qquad (16)\end{aligned}$$

If there exists an electric field only in the z-direction, the x- and y-direction are equivalent concerning the electric field, and therefore, it is possible to take $P_x=P_y$. The following relationship between P_z and E_z is readily derived from (16):

$$\begin{aligned}E_z=2AP_z+4BP_z^3+6CP_z^5&+4DP_zP_x^2\\&+8GP_z^3P_x^2+4GP_zP_x^4\,. \qquad (17)\end{aligned}$$

Similarly to the case of the orthorhombic phase, P_x is eliminated by using an additional condition owing to the fact that there exists no electric field in the x- and y-directions, *i.e.*, $E_x=E_y=0$, or

$$\begin{aligned}A+2BP_x^2+3CP_x^4&+D(P_x^2+P_z^2)\\&+G(3P_x^4+2P_x^2P_z^2+P_z^4)=0\,. \qquad (18)\end{aligned}$$

Eqs. (17) and (18) give the similar plot of P_z *vs* E_z to that in the orthorhombic case.

In determining the numerical values of the coefficients in the vicinity of −80°C, however, it is not assured that the temperature dependence of A, B, and C, and the numerical values of D and G, which are listed in (15), hold good as they are. Assuming that the above-cited temperature dependence of A is also correct at these low temperatures, the other four coefficients will be determined by the simultaneous equations expressing the following four relations: (i) at the transition point, the free energies of the orthorhombic and rhombohedral states have the same value, (ii) the value of P_z given by $E_z=0$ in the orthorhombic state at the transition point is equal to the z-component of the spontaneous polarization at that temperature, (iii) the corresponding statement holds also for the rhombohedral state, and (iv) $\partial P_z/\partial E_z$ is equal to the susceptibility. But the solutions of these simultaneous equations are sharply varying functions of the square of the ratio of the z-component of the spontaneous polarization in the orthorhombic state to that in the rhombohedral state, $P_z^2(\text{ortho})/P_z^2(\text{rhombo})$, presenting little reliability in determining the coefficients in this way.

Another assumption that the relations (15) hold approximately leads to very much larger critical fields than the experimental values. Since the electric field used for the present experiment is static, the switching behavior which is said to govern the ac coercive field[3] may possibly be left out of consideration.

It might be assumed that, since the polarization and the coefficients become large at these low temperatures, the terms of higher orders than sixth would be taken into consideration. If so, in an approximation, the terms

$$\alpha(P_x^8+P_y^8+P_z^8)+\beta(P_x^{10}+P_y^{10}+P_z^{10}) \qquad (19)$$

might be added to the expressions (11) and (16) of the free energies in the orthorhombic and rhombohedral states, respectively, at these low temperatures. These terms are assumed to be small at much higher temperatures than this lowest transition point. The coefficients α and β can be determined by the conditions that the free energies of the orthorhombic- and rhombohedral-states have the same value at the transition point and that the values of P_z giving the minima of the free energies are equal to the z-components of the spontaneous polarizations of the orthorhombic and rhombohedral states at the transition temperature. At that time it is assumed that the other coefficients are given by (15). Then the values $\alpha=-15\times10^{-33}$ and $\beta=10\times10^{-43}$ cgs units are obtained, giving the plots of P_z *vs* E_z as shown in Fig. 12. Similarly to the orthorhombic case, it is assumed that the polarization jumps instantly from the rhombohedral- to orthorhombic-state at the point where $\partial P_z/\partial E_z$ becomes infinite, then this point can be considered as a transition point in the existence of an electric field. These critical fields are plotted against the transition temperatures, then the curve drawn with solid line in Fig. 13 is obtained, which explains the experimental results approximately.

In this lowest phase, the crystal symmetry has not yet been decided finally, and moreover a crystal is divided into fine domains. Therefore, it may not be possible to discuss much on the basis of such a simple calculation of a single-domain crystal as mentioned above, but at least as an experimental formula, the expression of the free energy with the additional terms (19) to (16) holds approximately in the case of the lowest phase.

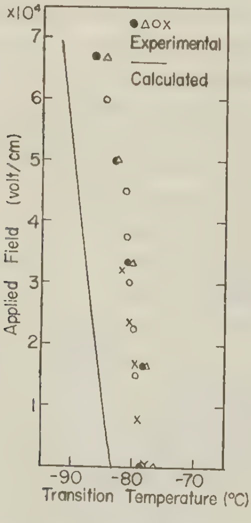

Fig. 13. Shift of the transition temperature near −80°C caused by electric fields.

Summary

(1) Up to this time, electrical measurements have been used for the methods of determining the transition points of barium titanate or of observing the effect of biasing fields on them. Electrical methods require very good specimens. For example, except for crystals with very high purity, the double hysteresis loops can hardly be observed but very curious and asymmetric loops are traced on the oscilloscope. On the other hand, any crystal can be used for the optical test utilizing the shift of the thermal transition of transparency. The only requirement is that the crystal under test is not opaque. The experimental accuracy of this method in the case of the study on the effect of biasing fields was better than that of the electrical method. What with these reasons and what with the comparative simplicity in the experimental procedure, this optical test will be of use as a new method.

(2) When a polarized plate such as a cryslal of barium titanate is placed between crossed Nichols, the plate being so oriented that the direction of the component of the polarization at right angles to the incident beam is inclined at 45° to the principal planes of the Nichols (see Fig. 1), the intensity of the continuous light transmitted through the analyzer is approximately proportional to the birefringence and hence, in the case of barium titanate, to the square of the polarization of this plate.

(3) The Curie point near 120°C is raised by an applied electric field at a rate of 1.6×10^{-3} deg/volt cm^{-1}, which is in good agreement with those measured by other investigators, and at a critical temperature of 132°C, the magnitudes of the polarizations of cubic- and tetragonal- (strictly speaking, induced-tetragonal-) phases become equal, the corresponding critical strength of the field being about 9 kv/cm. Above this critical point any tran-

sition of the first order no longer takes place. From this fact the expansion coefficient B of the free-energy function is estimated as -2.39×10^{-13} cgs units, which supports the value measured by Drougard *et al*. rather than that measured by Merz. The thermodynamic potential surface which is drawn by using this coefficient explains satisfactorily the observed temperature dependence of the spontaneous polarization.

(4) For the Curie point, the relationship

$$\Delta T_t/\Delta E=1/[A_0(P_t+P_c)]$$

is more convenient than the usual Clausius-Clapeyron relation, because the former does not contain the entropy change, ΔS, which varies also with an external electric field. Therefore, this equation yields a profit to leave the entropy change out of consideration, and $\Delta T_t/\Delta E$ can be obtained by measuring or calculating the polarization only.

(5) At the 5°C transition $\Delta T_t/\Delta E=-2.6\times10^{-4}$ deg/volt cm^{-1}, which is in good agreement with the value measured by Huibregtse and Young. The expansion coefficients A, B, and C of the free-energy function are all assumed to be dependent on temperature. For C, a linear relation, $C=-6\times10^{-25}(T-T_2)$, $T_2=183$°C, is assumed. The plots of P_z *vs* E_z based on the Devonshire function gives values of $\Delta T_t/\Delta E$ which give a satisfactory explanation of the experimental results.

(6) At the -80°C transition $\Delta T_t/\Delta E=-1.2\times10^{-4}$ deg/volt cm^{-1}. The terms of eighth and tenth powers of polarization is added to the free-energy function in order to obtain a better fit. The values of the coefficients α and β of the terms of eighth and tenth power, respectively, are obtained as $\alpha=-15\times10^{-33}$, $\beta=10\times10^{-43}$ in cgs units at the lowest transition point. The Clausius-Clapeyron relation does not give satisfactory explanation of the observations on the two lower transitions, probably because of the neglect of the effects of strong fields upon the polarization and entropy.

Acknowledgements

The most part of this work was performed when the author was at Osaka University under the guidance of Professor T. Horie, to whom he expresses his sincere gratitude. He wishes to express his thanks to Professors S. Sawada and S. Nomura of Tokyo Institute of Technology for their suggestive discussions and also for their guidance in the cource of preparation of crystals. He is indebted much to Mr. T. Iwai in Osaka University and to Dr. E. J. Huibregtse in IBM Laboratory for useful suggestions and valuable comments. He wishes also to thank Professors T. Kanda, Y. Masuda and M. Shimizu of Kobe University for their encouragement and for placing apparatus at his disposal.

Decay Properties of ZnS(Ag) Phosphors

By Tsunesaburo ASADA, Masayoshi MASUDA,
Masayuki OKUMURA and Juzo OKUMA

*Department of Physics, Faculty of Science,
University of Osaka*

(Received August 28, 1959)

The fact that a phosphor exhibits different decay times for different kinds of exciting radiation has recently been reported. This is expected to be found also in ZnS(Ag) phosphor which is often applied in photonuclear experiment. Detailed measurements of such decay properties has been carried out in the present work. It came out clear that the phosphor has two types of decay mode for a kind of radiation, one being exponential and another hyperbolic with time, and that the phosphor has different decay constants in the exponential form decay for different kinds of radiation. The decay constants were obtained to be 100 $m\mu$sec and 10 $m\mu$sec for the α-particle and γ-ray excitation, respectively. Thus, contrary to a previous work by Koontz et al.[10], an apparent difference was observed for these two kinds of excitation. Furthermore, it was observed that in the case of γ-ray excitation the decay is mainly exponential and in the case of α-particle excitation mainly hyperbolic. The difference of decay modes and the difference of the decay constants make it possible to discriminate protons or α-particles from the strong γ-ray background.

§ 1. Introduction

ZnS(Ag) phosphor is generally used in detecting heavy charged particles such as protons or α-particles in the strong γ-ray background. To measure the angular distribution in photonuclear reaction, a sufficient discrimination of the heavy particles from γ-rays is necessary. Several authors[1)-6)] have shown that the ZnS(Ag) phosphor is useful for this purpose because of its large pulse height ratio of light emission for heavy charged particles to that for γ-rays. In order to refine the techniques of photo-nuclear experiments, however, more complete discrimination of protons or neutrons in the γ-ray background is required. In our experiment of photo-nuclear reaction with a betatron using an accurate collimator and a heavy shield, the average γ-ray dose at the proton or neutron counter is very low but the pulsed γ-rays from this machine have a very high instantaneous intensity. Photons accumulated in the very short period of this pulse produce a large light pulse in the scintillation counter. This pile-up effect in scintillation pulses is one of the predominant troubles under this experimental condition and it imposes severe limitation on the kind of the target element to be measured and sometimes leads to poor experimental results.

A fast decay component of ZnS(Ag) phosphor was reported in earlier works[7)-11)] in addition to the well-known long term decay of 10^{-5} sec[12),13)]. So we first made an attempt to eliminate the pile-up effect of the γ-rays by constrncting a very fast counting system, so as to pick up only the fast decay component of the ZnS phosphors. The results proved to be unsuccessful, contrary to our expectation. A precise examination of the characteristic of ZnS phosphors from the point of view of its decay properties was therefore undertaken. The results of such experiment will be reported in the present paper. Our principal conclusion is as follows.

The fast decay component of ZnS phosphors is for the most part attributed to γ-rays and the long term decay principally to heavy charged particles.

The ZnS phosphor has long been considered as having a large ratio of the pulse height for heavy particles to that for γ-rays. This may be due to the fact that the fast decay component, which is sensitive to γ-rays, has been cut off by the use of the linear amplifier whose rise time was considerably long.

§ 2. ZnS Phosphors

The decay properties of phosphors can broadly be divided into two classes. The first is such that the decay takes place in accordance with the equation

$$I = I_0 \exp(-t/T_p) \qquad (1)$$

where I_0 is the initial intensity, I the intensity at time t and T_p the decay constant. Generally, T_p is smaller than 10^{-6} sec. In the second class, the decay takes place in accordance with the equation

$$I = I_0/(1+at)^n \qquad (2)$$

where a and n are constants.

The first decay type is called monomolecular, the luminescence taking place by a simple excitation of the active center with subsequent optical emission from it. The activation energy is stored in the center between excitation and emission. The thallium activated alkali halides belong to this type.

Most of the luminescent materials which are valued for their long decay characteristics obey a decay equation of second type, which is similar to the rate equation for a bimolecular chemical reaction. Several of such materials exhibit photoconductivity when being excited with ultraviolet light. Therefore it may be concluded that atoms become ionized during the excitation and that the luminescent radiation is emitted during recombination of the free electrons and the ionized centers.

The fact that the fast counting system failed as mentioned in § 1, led us to presume that ZnS phosphors when excited by heavy charged particles, such as protons or α-particles, would follow the power law decay scheme while they would follow the exponential decay scheme when excited by electrons or γ-rays.

§ 3. Measurements

In order to measure the value of T_p in Eq. (1), the following experiments were carried out. The block diagram of the detecting system is shown in Fig. 1. The pulse shape produced by a photomultiplier the receiving the luminescence from the ZnS was determined as a function of the resistance at the output of the photomultiplier tube. Two systems of amplifiers, fast and slow, are used in the experiment. The fast system consists of a Tektronix 517A oscilloscope preceded by Spencer Kennedy distributed amplifiers, model 202D and 214B. The slow system consists of a DuMont 301 oscilloscope and a Model 100 linear amplifier. The photomultiplier tube has 14 stages of electron multiplication and it was used in the fast system because of its large multiplication factor. The source of radiation used is either Po–α or Co^{60} of 3 curies, or both together. The ZnS(Ag) powder, type No. P4B1, was offered by Dai Nihon Toryo Co. The powder was deposited on the surface of a glass plate, which was mounted on a photomultiplier tube and covered by a semi-spherical light reflector. The output pulse of the photomultiplier tube provides information on how the luminescence is emitted as a function of time. If the luminescence decays exponentially, one should be able to obtain the time constant of decay by making the resistance smaller and smaller and taking the limit of zero resistance. The measured decay time against the resistance is shown in Fig. 2. In this case, ZnS was excited by α-particles. The observed decay time did not decrease below 100 mμsec when the resistance

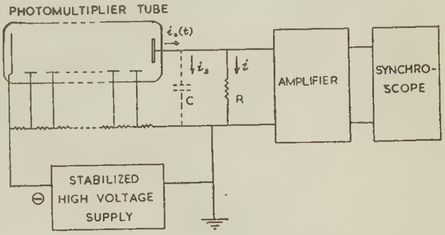

Fig. 1. Block diagram of the detecting system.

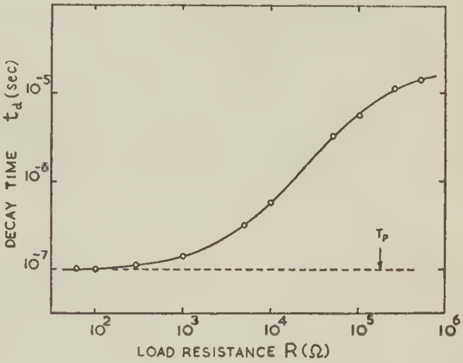

Fig. 2. Curve of the decay time of the observed pulse against the load resistance. T_p is the principal decay constant in the exponential decay.

was varied to below 300 ohms. Under γ-ray excitation, on the other hand, we obtained a principal decay time constant of 10 mμsec and no appreciably shorter decay time.

The rise time of pulses as a function of resistance is shown in Fig. 3. In order to analyse this figure, two types of decay form, exponential and power laws, were adopted for the differential equation of the RC network shown in Fig. 1. R is the load resistance and C is the stray capacitance of collector of photomultiplier tube. Referring to Fig. 1, we obtain the following equation

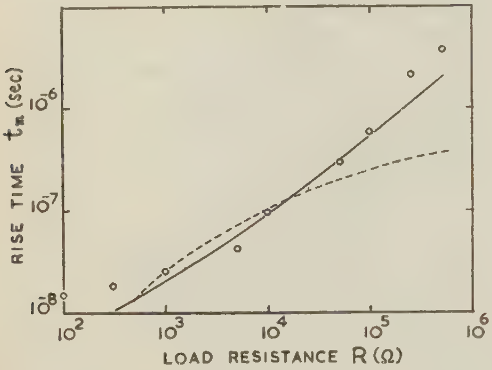

Fig. 3. Curve of the rise time of the observed pulse against the load resistance. Circular points are measured values. Solid and broken lines are calculated by assuming hyperbolic and exponential light decay, respectively.

$$i+i_2=i_0 \exp(-t/T_p) ,$$

if the exponential decay form is assumed. On the other hand, the current across the stray capacitance is expressed by

$$\frac{i_2}{C}=R\frac{di}{dt} .$$

Therefore the following two differential equations are obtained, respectively, for the two assumed types of decay.

(1) Decay form is of exponential type:

$$R\frac{di}{dt}+\frac{i}{C}=\frac{1}{C}\, i_0 \exp\left(-\frac{t}{T_p}\right) \tag{3}$$

where i is the current through R and $i_0 \exp(-t/T_p)$ is the charge flow per unit time from the electron collector to the RC network.

(2) Decay form is of power law type:

$$R\frac{di}{dt}+\frac{i}{C}=\frac{1}{C}\,\frac{i_0}{(1+at)^n} . \tag{4}$$

The solution of Eq. (3) is given by

$$i=\frac{i_0 T_p}{T_p-RC}\left\{\exp\left(-\frac{t}{T_p}\right)-\exp\left(-\frac{t}{RC}\right)\right\} . \tag{5}$$

In the case of $RC \ll T_p$,

$$i=i_0 \exp(-t/T_p) ,$$

and the observed decay should be due only to the decay of the luminescence. The pulse height in this case becomes very small. Assuming the rise time of the pulse, t_m, to be the time interval from zero to maximum amplitude, we obtain this value by differentiating Eq. (5) and putting it equal to zero,

$$t_m=\frac{RCT_p}{RC-T_p}\ln\frac{RC}{T_p} . \tag{6}$$

Namely, t_m is to be nearly proportional to $\ln R$ and a nearly straight line relationship has to exist between t_m and R in the semi-log plot if $T_p/RC \ll 1$. However, it was found difficult to explain our experimental results, assuming this value of t_m. So the assumption of another decay form is preferable. The solution of Eq. (4) is as follows if we assume $n=1$ (this assumption is not too far from the fact reported by Bailey and Prescott[11]).

$$i=\frac{i_0}{RC}\exp\left(-\frac{t}{RC}\right)\int_0^t \frac{\exp(t/RC)}{1+at}\,dt \tag{7}$$

We have not been able to deduce the value of t_m by differentiating Eq. (7). Numerical integration was therefore carried out. The result is shown in Fig. 3, where $n=1$, $a=2.1 \times 10^7$ and $C=10^{-11}$ farad. A fair agreement exists between the measured and calculated results except for a minor disagreement in the region of small R, which might be explained as introduced by the rise time of the detecting system, 7 mμsec. Judging from Fig. 3, we may conclude that the decay type of ZnS(Ag) phosphors excited by α-particles exhibits, as a whole, the power law decay and not the exponential decay except for the fast decay component of 100 mμsec.

§ 4. Discrimination of Heavy Charged Particles from γ-rays

The principal purpose of this experiment is to detect protons or neutrons in the strong γ-ray background produced by the betatron. The effect mentioned in § 3 gives the possibility of obtaining the considerable discrimination of protons or neutrons from γ-rays. In order to ascertain the validity of the picture of decay previously mentioned that protons and neutrons contribute much more to the decay form of power low than γ-rays do, we have carried out the following experiment whose results are shown in Fig. 4. This shows the pulse height curves under several conditions. The curves (a) and (b) were obtained by the slow and fast system, respectively. In this case, Co^{60} of 3 curies and Po–α were put in front of ZnS scintillator at the distance of 20 cm and 5 cm respectively.

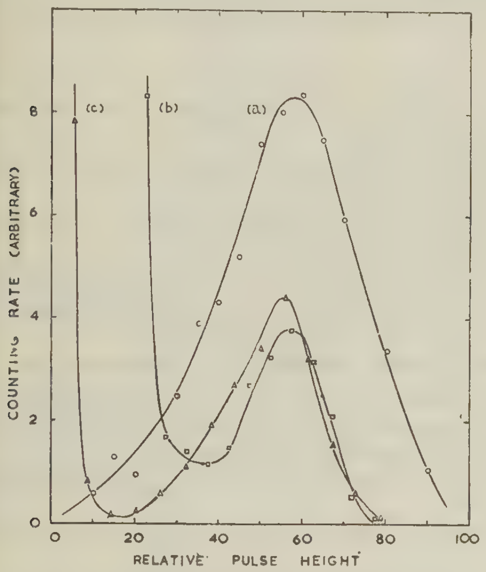

Fig. 4. Pulse height distribution curves. (a) using the slow system. (b) using the fast system. (c) using the fast system in which a condenser was coupled to the load resistance.

Comparing the slow and fast system, it was found that the former gave a better discrimination of α-particles from γ-rays, while the latter gave a good sensitivity to γ-rays. Another curve (c) shows the results of pulse height distribution when in the fast system a condenser was coupled to the load resistance of the collector of the photomultiplier tube. This curve was not useful, contrary to expectation, to eliminate the fast decay component of ZnS phosphors. This may be due to the current saturation in the photomultiplier tube or the high out-put impedance of high voltage power source, or some other reasons which we have not yet understood. A more detailed examination has to be performed to obtain the complete discrimination of heavy charged particles from γ-rays.

In order to check the discrimination properties between protons and γ-rays, experiment of photo-nuclear reaction (γ, p) is preferable. The arrangement of instrument for this purpose is shown in Fig. 5. A 24-Mev betatron was used. The thickness of ZnS powder layer deposited on a glass plate is 20 mg/cm². The proton counter was mounted at angles of 90° to X-ray direction. The pulse height distributions are shown in Fig. 6. In this case, protons were produced by the reaction of Ni(γ, p)Co. From this figure it is seen that slow amplifier system exhibits the proton peak in its pulse height distribution curve but the fast amplifier system shows the pile-up effect of γ-rays only. It was expected that the fast system was better to pick up photo-protons in the strong γ-ray background because of its possibility of eliminating the pile-up effect. However, this expectation failed. Judging from the present experiment

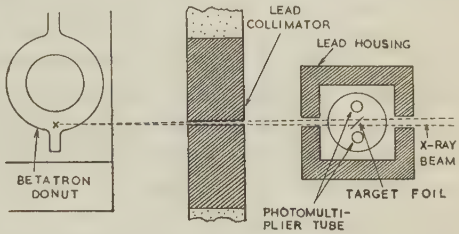

Fig. 5. Arrangement of the apparatus of photonuclear experiments.

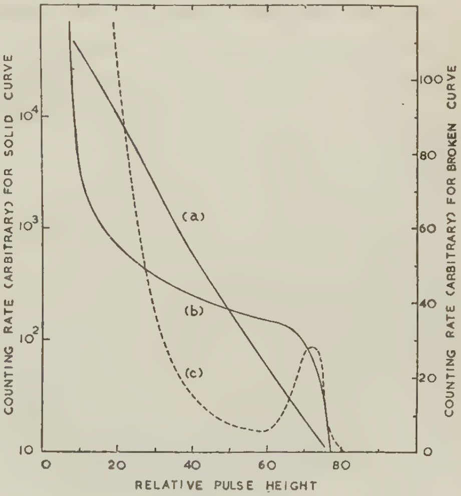

Fig. 6. Curves of pulse height distribution in (γ, p) reaction. (a) by the fast amp. system. (b) by the slow amp. system. Broken curve is obtained by differentiating the curve (b).

and the decay properties of ZnS, it is believed that a more precise examination of the electronics of the detection system would make it possible to obtain a complete discrimination of protons from γ-rays.

§ 5. Summary

First of all, we assumed that ZnS(Ag) phosphors have two types of decay, one is exponential and another hyperbolic. The former has a shorter decay constant, 10^{-7}–10^{-9} sec, and is caused almost by the single excitation by γ-rays and β-rays. The latter has a longer term decay component and is the principal decay mode of ZnS which always exists in addition to the exponential decay. The general mechanism of bimolecular decay is mentioned in § 2. More detailed explanation of the mechanism of this type of decay has been reported in reference 14. According to this, the competition between electron concentration of free electrons in conduction band and concentration of impurities decides the type of decay. The bimolecular decay takes place by the electron concentration when it wins in this competition. Such an assumption of the decay mechanism is consistent with the results of our experiment in which the bimolecular decay is caused by the heavy excitation by protons or α-particles.

The decay times in the exponential form were measured under excitation by α-particles and γ-rays. 100 mμsec and 10 mμsec were obtained as decay constant, respectively. The former agrees with that of Emmerich[9] and Hornyak[8] who reported also a value of 100 mμsec. Decay times of 0.13 and 0.34 μsec under 2.6 Mev neutron excitation have been reported[11]. But a shorter decay time has been also reported by Koontz, Keepin and Ashley[10] under α-particle excitation. The effect of neutron excitation on phosphors, decay properties could be regarded as similar to that of α-particle excitation.

For γ-ray excitation, a very short decay time of 8.5 ± 2.5 mμsec was reported by Bailey and Prescott[11]. Our results give the same information with this.

Contrary to a previous literature which reports the same decay time for γ-ray and α-particle excitation, an apparent difference was observed in our experiment. This effect was not explained by our decay picture.

An Improvement of the WKB Method in the Presence of Turning Points and the Asymptotic Solutions of a Class of Hill Equations

By Haruo MORIGUCHI

Department of Physics, Shizuoka University, Shizuoka

(Received July 31, 1959)

A method of successive approximation, which is essentially a modified form of the WKB method, is developed to express, for large values of parameter h, the asymptotic solutions of a linear second order differential equation

$$\frac{d^2y}{dx^2}-(\lambda+h^2f(x))y=0\ ,$$

in the region where the zeros of the coefficient of y are present. Several simple cases are treated as elementary examples. It is shown that a class of Hill equations is included in the category to which our method is applicable, and that their uniformly valid asymptotic solutions can be expressed in terms of Mathieu functions. The locally valid expressions are also given by means of the above method.

Introduction and Summary

It is well-known that the WKB method originated by Jeffreys, Wentzel, Kramers and Brillouin is one of very powerful methods of approximation for a class of linear second order differential equations of the form

$$\frac{d^2y}{dx^2}+h^2g(x)y=0\ .$$

This method gives the asymptotic forms of the solutions of the given equation for large values of h, and its numerical results are comparatively accurate in spite of the simplicity of expressions, if the coefficient $g(x)$ does not vanish. But when the zeros of $g(x)$ appear in the region considered, we must use more complicated asymptotic solutions or the connection formulas which give the relations between the solutions in two regions seperated by a zero of $g(x)$.

The methods for expressing the asymptotic solutions about the turning points, i.e. the zeros of $g(x)$, have been developed by several authors in the cases in which there appear, for example, a simple turning point, a second order turning point, a pair of simple turning points etc.. (The order of the zero of $g(x)$ is called the order of the turning point.)

On the other hand, the connection formulas have also been well investigated and applied to many examples. It has been pointed out that it is convenient to consider the independent variable in the complex plane for the deduction of the connection formulas and for the study of some kinds of eigenvalue problems.

Thus many problems in mathematics and mathematical physics, e.g. the asymptotic behaviour of special functions, wave motions, energy eigenvalues of quantum mechanical systems, scattering of particles, tunnel effects, compressible flows etc. have been solved successfully by means of the WKB method.

In spite of these facts, however, some problems are left to be investigated in pure and applied mathematics. One of them is to extend the method to the cases in which more complicated turning points appear.

In this paper we shall first remark that the methods ever developed to obtain the asymptotic solutions about turning points can be unified, so to speak, into a principle, which gives a set of transformations of variables for deriving simple approximate equations. These transformations are nothing but slightly modified forms of the usual WKB transformations, and they make it possible to select large terms in the given differential equation without any change of the important characters of the equation. By means of the transformed equation we can find the asymptotic solutions uniformly valid in certain region, where the turning points may appear. This procedure is applicable also to the cases never treated before; for example, the uniformly valid asymptotic solutions of a class of Hill equations can be obtained in terms of Mathieu functions. Further by the repeated use of these transformations we can proceed to the approximations of any order required.

For higher order approximations a more conventional method is also possible, in wnich the usual formal series expansion method is adopted and the connection formulas are derived. This conventional method seems to be sufficient for many of the practical problems.

We shall divide this paper in two parts. In Part I we state the fundamental idea and discuss some elementary examples. Further a note on the conventional method is added with special reference to the second order turning point. And in Part II a class of Hill equations is considered on the basis of the modified WKB transformations and the asymptotic solutions uniformly valid are expressed in terms of Mathieu functions. A few comments are also added with respect to the solutions locally valid.

It should be mentioned that, although this paper is concerned with only the real region of independent variable and the coefficient of the differential equation is supposed to be regular in the region considered, it is easy to see that the restrictions are not always necessary. Further for the purpose of clarifying the method, all the mathematical arguments on the asymptotic nature of the results are omitted and many of conditions to be satisfied are not expressed explicitly. But it would not injure the applicability of our method.

Our results can be summarized as follows. We consider a class of differential equations of the form

$$\frac{d^2y}{dx^2}-(\lambda+h^2f(x))y=0\ ,$$

where $f(x)$ is a regular function of x, h is a large parameter and λ is a constant small compared with h^2. Introducing a set of transformations of variables

$$\tau=\tau(t)=\int^x\sqrt{f(x)}\,dx\ ,\qquad y=\psi^{-1/4}y_1\ ,\qquad \psi=f/(d\tau/dt)^2\ ,$$

we have

$$\frac{d^2y_1}{dt^2}-\left(\frac{\lambda}{\psi}+h^2\left(\frac{d\tau}{dt}\right)^2+Q\right)y_1=0\ ,$$

where

$$Q=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}=-\psi^{-3/4}\frac{d^2\psi^{-1/4}}{dx^2}\ .$$

By means of suitable choice of the functional form $\tau=\tau(t)$, we can obtain an approximate equation which gives the asymptotic solutions of the first equation. And the repeated use of similar transformations accompanied with suitable translation of independent variable (which we shall call the turning point correction) leads to the higher order approximations. To the equation once transformed, the method of formal series expansion is also applicable.

The examples of the transformations are given as follows.

i) *A simple turning point at* $x=0$:

$$\lambda=0\ ,\qquad f(x)=ax+bx^2+cx^3+\cdots\ .$$

$\tau(t)$ to be used is

$$\tau(t)=\frac{2}{3}t^{3/2}=\int_0^x\sqrt{f(x)}\,dx$$

and y_1 can be approximated by Airy functions.

ii) *A second order turning point at* $x=0$:

$$|\lambda|\ll h^2\ ,\qquad f(x)=ax^2+bx^3+cx^4+\cdots\ .$$

$\tau(t)$ to be used is

$$\tau(t)=t^2/4=\int_0^x \sqrt{f(x)}\,dx\,,$$

and y_1 can be approximated by Weber functions.

iii) *A pair of simple turning points at $x=\xi$ and $x=\eta$:*

$$\lambda=0\,,\qquad f(x)=(x-\xi)(x-\eta)g(x)\,,\qquad g(x)\neq 0$$

$\tau(t)$ to be used is

$$\tau(t)=\frac{2I}{\pi}\int_{-1}^t \sqrt{t^2-1}\,dt=\int_\xi^x \sqrt{f(x)}\,dx\,,$$

where

$$I=\int_\xi^\eta \sqrt{f(x)}\,dx\,,$$

and y_1 can be approximated by Weber functions. The famous formula for the eigenvalue problem with vanishing boundary conditions at infinity and the transparency of potential wall can be refined in this way.

iv) *Hill equations with simple turning points*:

$$\lambda=0\,,\qquad f(x+2\pi)=f(x)\,,$$
$$f(\xi+2n\pi)=f(\eta+2n\pi)=0\,,\qquad f'(\xi+2n\pi)\neq 0\,,\qquad f'(\eta+2n\pi)\neq 0\,,$$
$$-\pi<\xi<\eta<\pi\,,\qquad n=0,\ \pm 1,\ \pm 2,\ \cdots\,.$$

$\tau(t)$ to be used is

$$\tau(t)=I\int_\alpha^t \sqrt{\sin 2t-q}\,dt/K=\int_\xi^x \sqrt{f(x)}\,dx\,.$$

where

$$I=\int_\xi^\eta \sqrt{f(x)}\,dx\,,\qquad K=\int_\alpha^\beta \sqrt{\sin 2t-q}\,dt\,,$$

α and β are the zeros of $\sin 2t-q$ $(0<\alpha<\beta<\pi)$, and q as well as α and β should be determined by

$$\int_\beta^{\alpha+\pi} \sqrt{\sin 2t-q}\,dt/K=\int_b^{a+2\pi} \sqrt{f(x)}\,dx/I;$$

and y_1 can be approximated by Mathieu functions.

iv) *Hill equations witn second order turning points:*

$$|\lambda|\ll h^2\,,\qquad f(x+2\pi)=f(x)\,,\qquad f(x+2n\pi)=ax^2+bx^3+\cdots\qquad (a\neq 0)\,.$$

$\tau(t)$ to be used is

$$\tau(t)=I\sin^2\frac{t}{2}=\int_0^x \sqrt{f(x)}\,dx$$

where

$$I=\int_0^{2\pi} \sqrt{f(x)}\,dx$$

and y_1 can be approximated by Mathieu functions.

In all the above expressions the branches of multivalued functions should be taken in suitable manner.

Part I An Improvement of the WKB Method about Turning Points

§ 1. An Introductory Remark on the Modified WKB Transformations

Our problem is to investigate the method for obtaining the asymptotic solutions of a class of differential equations of the form

$$\frac{d^2y}{dx^2}-(\lambda+h^2f(x))y=0, \tag{1.1}$$

where λ is a constant of $O(h^k)$ $(k<2)$, $f(x)$ is a regular function of x and h is a large parameter.

As is well-known, in a region where the coefficient $\lambda+h^2f(x)$ does not vanish, the asymptotic solutions of (I.1) for $h\to\infty$ are given by means of the following procedure.

Let us introduce a set of transformations of variables

$$\tau=\int^x P(x)dx, \qquad y=P^{-1/2}y_1 \tag{1.2}$$

where

$$P=(f(x)+\lambda/h^2)^{1/2} \tag{1.3}$$

Then (1.1) transforms into

$$\frac{d^2y_1}{d\tau^2}-(h^2+Q(\tau))y_1=0, \tag{1.4}$$

where

$$Q(\tau)=P^{-1/2}\frac{d^2}{d\tau^2}P^{1/2}=-P^{-3/2}\frac{d^2}{dx^2}P^{-1/2}.$$

Therefore, neglecting $Q=O(1)$, we have the first approximate solutions

$$y_1\sim\exp(\pm h\tau),$$

hence

$$y\sim P^{-1/2}\exp(\pm h\tau). \tag{1.5}$$

Again introducing similar transformations for (1.4)

$$\tau_1=\int^\tau P_1 d\tau, \qquad y_1=P_1^{-1/2}y_2, \tag{1.6}$$

where

$$P_1=(1+Q/h^2)^{1/2}=1+O(h^{-2}),$$

we have

$$\frac{d^2y_2}{d\tau_1^2}-(h^2+Q_1(\tau_1))y_2=0. \tag{1.7}$$

where

$$Q_1=P_1^{-1/2}\frac{d^2}{d\tau_1^2}P_1^{1/2}=-P_1^{-3/2}\frac{d^2}{d\tau^2}P_1^{-1/2}=O(h^{-2}).$$

Thus we have the second approximate solutions

$$\left.\begin{aligned} y &\sim P^{-1/2}P_1^{-1/2}\exp\left(\pm h\int(1+Q/h^2)^{1/2}d\tau\right) \\ &\sim P^{-1/2}(1-Q/4h^2)\exp\left\{\pm\left(h\tau+\frac{1}{2h}\int Q d\tau\right)\right\}\cdot(1+O(h^{-3})) \end{aligned}\right\} \tag{1.8}$$

or making use of the expansion

$$P=(f(x)+\lambda/h^2)^{1/2}=\{f(x)\}^{1/2}+\lambda/2h^2\{f(x)\}^{1/2}+O(\lambda^2h^{-4}) ,$$

we have

$$y\sim f^{-1/4}(1-\lambda/4h^2f-Q'/4h^2)\exp\left\{\pm\left(h\tau'+\lambda\int f^{-1}d\tau'/2h+\int Q'd\tau'/2h\right)\right\} , \tag{1.9}$$

where

$$\tau'=\int f^{1/2}dx , \qquad Q'=f^{-1/4}\frac{d^2}{d\tau'^2}f^{1/4} .$$

In this way we can proceed to the approximate solutions of any order required by the repeated use of similar procedure, and clearly these solutions give the asymptotic forms of the exact solutions.

These procedures, however, are not applicable in the region containing turning points, namely the zeros of $P(x)$, which transform into the singular points of the transformed equation. (If $\lambda \ll h$, the zeros of $P(x)$ are close to those of $f(x)$. Therefore the zeros of $f(x)$ will be called the turning points, when the distinction is not so important, the order of the turning point being the order of the corresponding zero.)

To avoid this difficulty and to proceed to higher order approximations, several methods have been developed since Jeffreys, Wentzel, Kramers and Brillouin, especially in the case of isolated simple or second order turning point. Some authors have adopted the idea that the leading singular terms in the transformed equation shauld be taken into account. And other authors have employed the alternative forms of the transformed equation, which is equivalent to (1.4) and contains no singular points. The latter seems to have more possibility of extension.

Now let us remember that the singularity of the transformed equation has its origin in the singularity of the transformation of the independent variable (1.2). This fact suggests us a set of transformations of the form

$$\tau=\tau(t)=\int\sqrt{f(x)}\,dx , \qquad y=\{\psi(t)\}^{-1/4}y_1 \tag{1.10}$$

and the use of independent variable t instead of τ. In fact, putting

$$\psi(t)=f\Big/\left(\frac{d\tau}{dt}\right)^2 \tag{1.11}$$

and substituting (1.9) and (1.10) into (1.1), we have the transformed equation

$$\frac{d^2y_1}{dt^2}-\left(\frac{\lambda}{\psi}+h^2\left(\frac{d\tau}{dt}\right)^2+Q\right)y_1=0 , \tag{1.12}$$

where

$$Q=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}=-\psi^{-3/4}\frac{d^2\psi^{1/4}}{dx^2} . \tag{1.13}$$

It is the main point of this paper to use (1.12) as the starting point. If $(d\tau/dt)^2$ and f have common zeros of the same order, then the transformed equation has no singularity there. Therefore in the region where $d\tau/dt \neq 0$, the transformed equation can be approximated by

$$\frac{d^2y_1}{dt^2} - h^2\left(\frac{d\tau}{dt}\right)^2 y_1 = 0 \tag{1.14}$$

and in the neighbourhood of a zero of $d\tau/dt$, say $t=\alpha$, we can replace λ/ψ and Q by their values at $t=\alpha$. Thus we have an approximate equation

$$\frac{d^2y_1}{dt^2} - \left(\frac{\lambda}{\psi(\alpha)} + Q(\alpha) + h^2\left(\frac{d\tau}{dt}\right)^2\right) y_1 = 0 \tag{1.15}$$

in the region containing $t=\alpha$ and no other zeros of $d\tau/dt$. Further when a suitable choice of the functional form $\tau=\tau(t)$ is done, the approximate equation reduces to a well investigated differential equation. Of course the addition of first few terms of Taylor expansion of λ/ψ and Q is desirable, it possible. In many examples such a choice is possible and the repeated use of the similar procedure leads to the higher order approximations.

The following three sections of this part will be devoted to rather simple examples, in which the character of our modification of the WKB transformations can be illustrated, and in Part II a class of Hill equations will be treated by means of our transformations.

Beyond the examples treated here, several cases, for example, a fixed singular point, a fixed singular point accompanied with a simple turning point etc. can be reduced to well-known differential equations. The latter leads to a refinement of the WKB phase shift formula[11]. Further if only the first approximations or formal series solutions are wanted, our transformations are applicable to many other equations.

In some cases it will be convenient to take $h^2f(x)$ in the place of $f(x)$ in (1.9).

§ 2. A Simple Turning Points and Imai's Formulas

The asymptotic solutions of a differential equation with a simple turning point have been investigated by many authors and it may be regarded as a classical example. (See, e.g. references 2, 12, 13, 14, 21.) We shall begin with this case.

Let us consider

$$\frac{d^2y}{dx^2} + h^2 f(x) y = 0\,, \tag{2.1}$$

where $f(x)$ is a regular function of x and has only one simple zero, say $x=0$, in the region considered and can be expanded as

$$f(x) = ax + bx^2 + cx^3 + \cdots\,. \qquad (a>0)\,. \tag{2.2}$$

In this case the regularity of the differential equation is conserved, if we adopt a set of transformations

$$\tau(t) = \frac{2}{3}t^{3/2} = \int_0^x \sqrt{f(x)}\,dx\,, \qquad y = \psi^{-1/4}y_1\,, \qquad \psi = f/t\,, \tag{2.3}$$

where the branches of $\sqrt{f}$ and $t^{3/2}$ should be taken so that the correspondence between x and t is one-to-one and the regions $x>0$ and $x<0$ transforms into $t>0$ and $t<0$ respectively. Then ψ is a nonvanishing positive function and (2.1) transforms into

$$\frac{d^2y_1}{dt^2} + (h^2t - Q(t))y_1 = 0\,, \tag{2.4}$$

where

$$Q = \psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2} = -\psi^{-3/4}\frac{d^2\psi^{-1/4}}{dx^2}\,, \tag{2.5}$$

$\psi^{1/4}$ being understood to designate the positive value.

In (2.4) only the first term of the coefficient is of $O(h^2)$, while in (2.1) all terms were of $O(h^2)$. Therefore we have an approximate equation

$$\frac{d^2y_1}{dt^2}+h^2ty_1=0\ ,$$

and its solutions are given by Airy functions:

$$y_1=t^{1/2}Z_{1/3}\left(\frac{2}{3}ht^{3/2}\right)$$

where $Z_{1/3}$ is the Bessel function of order one third. The asymptotic expansion for the large values of $ht^{3/2}$ give the usual WKB solution (1.4):

$$y_1\sim\text{const.}\ t^{-1/4}\exp\left(\pm i\frac{2}{3}ht^{3/2}\right)\cdot(1+O(h^{-1})) \tag{2.6}$$

$Q(t)$ in (2.4), however, contains the terms of constant and of first degree in t. For proceeding to higher order approximations it is convenient to rewrite (2.4) in the same form as the first equation (2.1). To do so, let us put

$$x_1=t-\delta \tag{2.7}$$

where δ is the zero of $h^2t-Q(t)$:

$$h^2\delta-Q(\delta)=0 \tag{2.8}$$

Then (2.4) can be written as

$$\frac{d^2y_1}{dx_1^2}+h^2(a_1x_1+R_1(x_1))y_1=0 \tag{2.9}$$

where a_1 is given by

$$h^2a_1=h^2-Q'(\delta) \tag{2.10}$$

and $R_1(x_1)$ is a function of x_1, which can be expanded as

$$R_1(x_1)=\frac{1}{h^2}(b_1x_1^2+c_1x_1^3+\cdots) \tag{2.11}$$

where

$$b_1=-\frac{1}{2}Q''(\delta)\ ,\qquad c_1=-\frac{1}{3!}Q'''(\delta)\ ,\ \cdots \tag{2.12}$$

(2.9) is of exactly the same form as (2.1), and by means of the transformations similar to (2.3) we can proceed to the second approximations. The rewriting of independent variable (or the translation of lower limit of integration in the transformation of variable) is simple but it is an important procedure, which we shall call the turning point correction. The choice of the coefficient a_1 instead of 1 is not so essential, but it gives some convenience.

The second transformations are given as

$$\tau_1(t_1)=\frac{2}{3}t_1^{3/2}=\int^{x_1}\sqrt{f_1(x_1)}dx_1\ ,\qquad y_1=\psi_1^{-1/4}y_2\ ,\qquad \psi_1=f_1/t_1 \tag{2.13}$$

where

$$f_1(x_1)=a_1x_1+R_1(x_1)$$

And the transformed equation is

$$\frac{d^2y_2}{dt_1^2}+(h^2t_1-Q_1(t_1))y_2=0\ , \tag{2.14}$$

where

$$Q_1(t_1)=\psi_1^{-1/4}\frac{d^2\psi_1^{1/4}}{dt^2}=-\psi_1^{-3/4}\ \frac{d^2\psi^{-1/4}}{dx_1^2}\ .$$

It should be noted that $R_1(x_1)/x_1$ is bounded even at $x_1=0$, and we have

$$\left.\begin{aligned}&\tau_1=\int_0^{x_1}(a_1x_1)^{1/2}\left(1+\frac{R_1(x_1)}{a_1x_1}\right)^{1/2}dx_1=\frac{2}{3}a_1^{1/2}x_1^{1/2}+\int_0^{x_1}\frac{R_1(x_1)}{(a_1x_1)^{1/2}}dx_1+O(h^{-4})\ ,\\&t_1=a_1^{1/3}x_1+O(h^{-2})\ ,\qquad f_1=a_1^{2/3}t_1+O(h^{-2})\ ,\end{aligned}\right\} \tag{2.15}$$

hence

$$\psi_1=a_1^{2/3}+O(h^{-2})\ .$$

Therefore Q_1 is $O(h^{-2})$, and a small quantity of higher order than Q in (2.4). In this way we can proceed to the approximations of any order by means of the repeated use of the turning point correction and the modified WKB transformations. It is to be noted that the turning point correction permits the expansions of the type of (2.15) in the higher order approximations. The approximate solution of each order is expressed in the form of (2.6) (with different argument). The asymptotic nature of the solution given in this way is easily varified. Further, according to Lagrange's theorem (Appendix II) δ defined by (2.8) can be expanded as

$$\delta=\frac{1}{h^2}Q(0)+\frac{1}{h^4}Q(0)Q'(0)+\cdots\ ,$$

and for a_1 we have

$$a_1=1-\frac{1}{h^2}Q'(0)-\frac{1}{h^4}Q''(0)Q(0)-\cdots\ .$$

For small values of t or x, we have, from (2.3) and (2.2),

$$\begin{aligned}\frac{2}{3}t^{3/2}=\frac{2}{3}a^{1/2}x^{3/2}+\frac{1}{5}a^{-1/2}bx^{5/2}+\frac{1}{7}\left(a^{-1/2}c-\frac{1}{4}a^{-3/2}b^2\right)x^{7/2}\\+\frac{1}{9}\left(da^{-1/2}-\frac{1}{2}a^{-3/2}bc+\frac{1}{8}a^{-5/2}b^3\right)x^{9/2}+\cdots\ ,\end{aligned}$$

which gives

$$Q(t)=\lambda'+a't+b't^2+c't^3+\cdots\ ,$$

where

$$\lambda'=-\frac{3}{7}\left(\frac{3}{5}\ \frac{b^2}{a^2}-\frac{c}{a}\right)a^{-1/3}\ ,\qquad a'=\left(\frac{4}{3}\ \frac{d}{a^2}-\frac{28}{15}\ \frac{bc}{a^3}+\frac{56}{75}\ \frac{b^3}{a^4}\right)\ ,\ \cdots$$

Therefore

$$\delta=\frac{\lambda'}{h^2}+O(h^{-4})\ ,\quad a_1=1-\frac{a'}{h^2}-O(h^{-4})\ .$$

In a similar way we have

$$b_1 = -b' - O(h^{-2})$$

and

$$\frac{2}{3} t_1{}^{3/2} = \frac{2}{3} a_1{}^{1/2} x_1{}^{3/2} + \frac{1}{5} \frac{b_1}{a_1{}^{1/2}} \frac{x_1{}^{5/2}}{h^2} + O(h^{-4})$$

Substituting these expressions into the approximate solution of (2.9)

$$y_1 = x_1{}^{1/2} Z_{1/3}\left(\frac{2}{3} a_1{}^{1/2} x_1{}^{3/2}\right),$$

we have

$$y \sim f^{-1/4} \tau^{1/6} \xi^{1/2} Z_{1/3}\left(\frac{2}{3} \kappa^{1/2} \xi^{3/2}\right),$$

where

$$\kappa = 1 - \frac{a'}{h^2}, \qquad \xi = \left(\frac{3}{2}\tau\right)^{2/3} - \frac{\lambda'}{h^2}.$$

This is the first step of the refined WKB solutions due to Imai[5)] and has been applied to the electronic theory of metals by Kuhn[11)]. From the approximate solution of (2.14)

$$y_2 = t_1{}^{1/2} Z_{1/3}\left(\frac{2}{3} h t_1{}^{3/2}\right),$$

we have

$$y \sim f^{-1/4} \tau^{1/6} f_1{}^{-1/4} t_1{}^{3/4} Z_{1/3}\left(\frac{2}{3} h t_1{}^{3/2}\right).$$

This formula corresponds to the second step of Imai's solution[6)], which has been applied to several problems in mathematical physics by himself[7),8)].

§ 3. A Turning Point of Second Order

In this section we shall consider a differential equation

$$\frac{d^2y}{dx^2} - (\lambda + h^2 f(x)) y = 0, \tag{3.1}$$

where λ is a constant of $O(h^k)$ $(k<2)$ and $f(x)$ is a regular function of x that has a zero of second order at $x=0$ and hence can be expanded as

$$f(x) = ax^2 + bx^3 + cx^4 + \cdots \qquad (a \neq 0). \tag{3.2}$$

This case has been treated, for example, by McKelvey[16)] in somewhat different manner. Our procedure leads to the essentially same results as his except that he has used the representations in terms of Whittaker's function.

Let us introduce a set of transformations

$$\tau(t) = \frac{t^2}{4} = \int_0^x \sqrt{f(x)}\, dx, \qquad y = \phi^{-1/4} y_1, \qquad \phi = \frac{4f}{t^2}, \tag{3.3}$$

where the suitable choice of the branches should be done for the one-to-one correspondence between x and t as in the preceding section. Then we have the transformed equation

$$\frac{d^2 y_1}{dt^2} - \left(\frac{\lambda}{\phi(t)} + \frac{h^2}{4} t^2 + Q(t)\right) y_1 = 0, \tag{3.4}$$

where

$$Q=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}=-\psi^{-3/4}\frac{d^2\psi^{-1/4}}{dx^2}\ .$$

Here ψ is a nonvanishing positive function and of $O(1)$. Therefore we have the first approximate equation

$$\frac{d^2y_1}{dt^2}-\left(\frac{\lambda}{\psi(0)}+Q(0)+\frac{h^2}{4}t^2\right)y_1=0\ , \tag{3.5}$$

the solutions of which are given by the Weber functions, namely

$$y_1=W_\nu(h^{1/2}t)\ , \tag{3.6}$$

where W_ν is the Weber function of order ν:

$$W_\nu(z)=cD_\nu(z)+dD_\nu(-z)$$

or

$$W_\nu(z)=cD_\nu(z)+d\mathscr{D}_\nu(z)\ ,$$

c and d being arbitrary constants and

$$\nu+\frac{1}{2}=\left(-\frac{\lambda}{h\psi(0)}-\frac{1}{h}Q(0)\right).$$

(See Appendix I)
The asymptotic form of $W_\nu(h^{1/2}t)$ is expressed as

$$W_\nu\sim\text{const.}\ e^{\pm\frac{h}{4}t^2}\,t^{\mp\left(\nu+\frac{1}{2}\right)-\frac{1}{2}}\ ,$$

and we have

$$y\sim\text{const.}\ f^{-1/4}e^{\pm\frac{h}{4}t^2}\,t^{\mp\frac{1}{h}\left(\frac{\lambda}{\psi(0)}+Q(0)\right)}\ . \tag{3.7}$$

On the other hand the usual WKB method gives

$$\begin{aligned} y&\sim\text{const.}\ f^{-1/4}\exp\left(\pm\int\sqrt{h^2f(x)+\lambda}\,dx\right)\\ &\sim\text{const.}\ f^{-1/4}\exp\left(\pm h\int\sqrt{f}\,dx\pm\frac{\lambda}{2h}\int\frac{1}{\sqrt{f}}dx\right). \end{aligned} \tag{3.8}$$

The leading terms of (3.7) and (3.8) are in accord with each other.

For obtaining more refined solutions, we should use the turning point corrections in the first place, as in the case of a simple turning point. The lack of the procedure corresponding to this turning point correction is the reason why the earlier methods due to Goldstein[4], Langer[12] etc. could not give the solutions suitable for practical applications except in the case in which λ is extremely small. Introducing a new variable x_1 given by

$$x_1=t-\delta\ , \tag{3.9}$$

where δ is the value of t for which the coefficient of y_1 in (3.5) takes the extremum value, we can rewrite (3.6) as

$$\frac{d^2y_1}{dx_1{}^2}-(\lambda_1+h^2f_1(x_1))y_1=0\ , \tag{3.10}$$

where

$$f_1(x_1)=a_1x_1^2+R_1(x_1)\ ,$$
$$R_1(x_1)=b_1x_1^3+c_1x_1^4+\cdots\ ,$$
$$\lambda_1=\frac{\lambda}{\psi(\delta)}+Q(\delta)+\frac{h^2}{4}\delta^2\ ,$$
$$a_1=\frac{1}{4}+\frac{\lambda}{2h^2}\left(\frac{d^2}{dt^2}\frac{1}{\psi(t)}\right)_{t=\delta}+\frac{1}{2h^2}Q''(\delta)\ ,$$
$$b_1=\frac{\lambda}{6h^2}\left(\frac{d^3}{dt^3}\frac{1}{\psi(t)}\right)_{t=\delta}+\frac{1}{6h^2}Q'''(\delta)\ ,$$
$$\cdots\cdots\cdots$$

and δ is given by

$$-\lambda\frac{\psi'(\delta)}{\psi^2(\delta)}+Q'(\delta)+\frac{h^2}{2}\delta=0\ .$$

or by means of Lagrange's theorem (see Appendix II)

$$\delta=\frac{2\lambda}{h^2}\frac{\psi'(0)}{\psi(0)}-\frac{2}{h^2}Q'(0)-\cdots\ .$$

(3.10) is of the same form as (3.1), but $R_1(x_1)$ is a quantity of $O(\lambda)$ or $O(1)$. (In what follows, we shall use the notation $O(\lambda)$ in the meaning of $O(1)$, if $\lambda=O(h^k)$ $(k<0)$). As well as in the preceding case, the rewriting of a_1 is not essential, but it gives a comparatively accurate solutions near the turning point.

Repeating the transformations similar to (3.3) after the turning point correction, we can obtain the higher approximations. In fact, putting

$$\tau_1(t_1)=\frac{t_1^2}{4}=\int_0^{x_1}\sqrt{f_1(x_1)}\,dx_1\ ,\qquad y_1=\psi_1^{-1/4}y_2\ ,\qquad \psi_1=4f_1/t_1^2 \tag{3.11}$$

in (3.10), we have

$$\frac{d^2y_2}{dt_1^2}-\left(\frac{\lambda_1}{\psi_1(t_1)}+\frac{h^2}{4}t_1^2+Q_1(t_1)\right)y_1=0\ , \tag{3.12}$$

where

$$Q_1(t_1)=\psi_1^{-1/4}\frac{d^2\psi_1^{1/4}}{dt_1^2}\ .$$

Here we should remember the fact that $R_1(x_1)/x_1^2$ is bounded everywhere and τ_1 can be expanded as

$$\tau_1(t_1)=\int_0^{x_1}\sqrt{a_1x_1^2}\,dx_1+\frac{1}{2}\int_0^{x_1}\frac{R_1(x_1)}{\sqrt{a_1x_1^2}}dx_1+\cdots\ .$$

Therefore

$$\psi_1=2a_1^{1/2}+O(\lambda/h^2)\ ,\qquad Q_1=O(\lambda/h^2)$$

and

$$\lambda_1/\psi_1=\lambda_1/2a_1^{1/2}+O(\lambda^2/h^2)\ .$$

Introducing x_2 given by

$$x_2=t_1-\delta_1\ ,$$

we have

$$\frac{d^2y_2}{dx_2^2}-(\lambda_2+h^2 f_2(x_2))y_2=0\ , \tag{3.13}$$

where

$$f_2(x_2)=a_2x_2^2+R_2(x_2)\ ,$$

and

$$R_2(x_2)/x_2^2=O(\lambda^2/h^4)\ .$$

is a quantity smaller than R_1. In this way we can proceed to the higher approximations of any order.

§ 4. A Pair of Simple Turning Points

When λ in the equation (3.1) becomes large and the zeros of $\lambda+h^2f(x)$ are not so close to those of $f(x)$, the method in the preceding section is not suitable. The existing method in such cases is to treat the turning points separately and then to match the two solutions with each other in the region between the turning points. However there exists a set of transformations which leads to a uniformly valid approximations in the whole region. It should be mentioned that Miller and Good[8] and Langer[15] have published these transformations previously, although they have not shown the possibility of higher approximations.

Now let us consider a differential equation

$$\frac{d^2y}{dx^2}-h^2f(x)y=0\ , \tag{4.1}$$

where $f(x)$ has two simple zeros at $x=\xi$ and $x=\eta$ $(\xi<\eta)$, and λ should be interpreted to be included in $f(x)$. Further we suppose, for simplicity, that

$$f(x)>0 \quad \text{for} \quad x<\xi \text{ and } x>\eta\ , \qquad f(x)<0 \quad \text{for} \quad \xi<x<\eta\ . \tag{4.2}$$

The case in which the sign of $f(x)$ is inverted can be treated in a similar manner.

The transformations available for this equation are

$$\tau(t)=\frac{2Ii}{\pi}\int_{-1}^{t}\sqrt{1-t^2}\,dt=\int_{\xi}^{x}\sqrt{f(x)}\,dx\ , \qquad y=\psi^{-1/4}y_1\ , \qquad \psi=-f/(1-t^2)\ , \tag{4.3}$$

where

$$I=\int_{\xi}^{\eta}\sqrt{|f(x)|}\,dx\ , \tag{4.4}$$

and the branches of the square roots should be chosen so that t is a regular function of x and the regions where $f(x)>0$ and $f(x)<0$ transform into $t^2>1$ and $t^2<1$ respectively. Then the transformed equation is

$$\frac{d^2y_1}{dt^2}+\left\{\frac{4h^2I^2}{\pi^2}(1-t^2)-Q(t)\right\}y_1=0\ , \tag{4.5}$$

where

$$Q(t)=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}=O(1)\ . \tag{4.6}$$

Therefore the first approximate solutions are given by

$$y_1=W_\nu\left(2\sqrt{\frac{hI}{\pi}}\,t\right), \tag{4.7}$$

where W_ν is the Weber function of order ν and

$$\nu+\frac{1}{2}=\frac{Ih}{\pi}\,. \tag{4.8}$$

The asymptotic expressions of (4.7) for $\sqrt{h}\,t\to\infty$ and $\nu\to\infty$ give the same leading terms as the usual WKB solutions. In Langer's paper[15] more detailed discussions are presented on the relations between the solution of the present form and of the usual WKB form in the separated regions, each of which contains one turning point respectively.

Further the eigenvalues for the vanishing boundary conditions at infinity are given by those of (4.7):

$$\nu=\frac{Ih}{\pi}-\frac{1}{2}=n=0,\ 1,\ 2,\ \cdots\,,$$

that is

$$h\int_\xi^\eta\sqrt{|f(x)|}\,dx=\left(n+\frac{1}{2}\right)\pi\,, \tag{4.9}$$

which is the well-known formula in the usual WKB method. Thus we have the approximate eigenvalues as well as the uniformly approximate eigenfunctions, in contrast to the usual WKB method. The normalization constant is given by

$$\int_{-\infty}^{\infty}|y|^2dx=\frac{2I}{\pi}\int_{-\infty}^{\infty}\frac{t^2-1}{f}y_1^2dt\,. \tag{4.10}$$

The second and higher approximations can also be obtained by the turning point correction and the transformations similar to (4.3). Let us introduce t_1 and y_2 by the transformations

$$\frac{2}{\pi}\int_{-1}^{t_1}\sqrt{1-t_1^2}\,dt_1=\frac{1}{Ii}\int_{\xi_1}^{t}\sqrt{f_1(t)}\,dt\,,\qquad y_1=\phi_1^{-1/4}y_2\,,\qquad \phi_1=-f/(1-t_1^2) \tag{4.11}$$

where

$$-f_1(t)=\frac{4I^2}{\pi^2}(1-t^2)-\frac{1}{h^2}Q(t)\,, \tag{4.12}$$

$$I_1=\int_{\xi_1}^{\eta_1}\sqrt{|f_1(t)|}\,dt\,, \tag{4.13}$$

and ξ_1 and η_1 are the zeros of $f_1(t)$ which tend to -1 and 1 respectively for $h\to\infty$. If we rewrite (4.12) as

$$f_1(t)=\frac{4I^2}{\pi^2}(t-\xi_1)(t-\eta_1)+R_1(t)\,, \tag{4.14}$$

where $R_1(t)$ is a regular function of $O(h^{-2})$ and

$$R_1(\eta_1)=R_1(\xi_1)=0\,,$$

then we have

$$i\int_{\xi_1}^{t}\sqrt{f_1(t)}\,dt=\frac{2I}{\pi}\int_{\xi_1}^{t}\sqrt{(t-\xi_1)(\eta_1-t)}\,dt+O(h^{-2})\,. \tag{4.15}$$

Therefore the second transformed equation can be approximated by Weber's equation more precisely than the first. If we choose a suitable coefficient of $(t-\eta_1)(t-\xi_1)$ in $f_1(t)$, then the first approximate solutions could be refined in the neighbourhood of, at least, one of the turning points as in § 2, although we cannot say it is a very important procedure.

The corrected turning points ξ_1 and η_1 are given as

$$\xi_1=-1+\frac{\pi^2}{8I^2h^2}Q(-1)+\cdots, \quad \eta_1=1-\frac{\pi^2}{8I^2h^2}Q(1)+\cdots, \tag{4.16}$$

by means of Lagrange's theorem (Appendix II).

It will be easily seen that these procedures lead to a refinement of the formula (4.9). This is an alternative approach to the refinement of the WKB quantum condition and the results are essentially equivalent to Dunham's formula[3]. For example, the second approximation is given by

$$\frac{2Ih}{\pi}\int_{\xi_1}^{\eta_1}\left(1-t^2-\frac{\pi^2}{4I^2h^2}Q(t)\right)^{1/2}dt=\left(n+\frac{1}{2}\right)\pi, \tag{4.17}$$

or

$$Ih-\frac{\pi^2}{4Ih}\{Q(1)+Q(-1)\}-\frac{\pi}{4Ih}\int_{-1}^{1}\frac{h^2R_1(t)}{\sqrt{1-t^2}}dt+O(h^{-3})=\left(n+\frac{1}{2}\right)\pi. \tag{4.18}$$

If the sign of $f(x)$ is inverted, a similar procedure leads to a refinement of the penetration probability in tunnel effect[9] as well as the method in § 3.

§ 5. A Conventional Method for Derivation of Connection Formulas

The method of uniform approximation developed in the preceding sections can be applied to any order required, but in practical problems we need to calculate some complicated integrals in the higher order approximations. Therefore it is desirable to find connection formulas for the usual WKB solutions valid in the region without turning points and the approximate solutions valid in the neighbourhood of the turning points. In fact, especially for the problems in an infinite region the utility of the connection formulas or similar procedures have been proved in many examples. One of the results of this kind is the famous quantum condition for an oscillator, and it can be derived without any knowledge of the explicit forms of the solutions in the neighbourhood of the turning points.

In this section we shall add a crude sketch of such a conventional method to deduce the connection formulas. The fundamental line of thought is not new and it was adopted by early authors who have contributed to the WKB method.

Let us consider a differential equation

$$\frac{d^2y}{dx^2}-h^2f(x)y=0, \tag{5.1}$$

where we suppose, for simplicity, that $f(x)$ has at most two zeros in the region considered and can be expanded as

$$f(x)=a_0+a_2x^2+a_3x^3+\cdots \tag{5.2}$$

If we start from the equation once transformed by the modified WKB transformations, we could obtain more accurate results. And this is also a reason why we take up the rather classical idea after the explanation of the possibility of uniform approximations. But here we suppose that $a_2, a_3, \cdots$ are the quantities of $O(1)$, since the *method* may not be altered by the order of magnitude of the coefficient.

Putting

$$x^2=\tau^2/2ha_2^{1/2} \tag{5.3}$$

in (5.1), we have

$$\frac{d^2y}{d\tau^2}+f_1(\tau)y=0, \tag{5.4}$$

where

$$f_1(\tau)=\nu+\frac{1}{2}-\frac{\tau^2}{4}-\frac{b_3}{h^{1/2}}\tau^3-\frac{b_3}{h}\tau^4-\cdots, \qquad b_n=(2a_2^{1/2})^{-n/2-1}a_n, \qquad \nu+\frac{1}{2}=-(2a_2^{1/2})^{-1}a_0. \tag{5.5}$$

If $\tau^2 \ll h$, we can treat the terms of the third and higher degrees of τ as the perturbation for the Weber equation

$$\frac{d^2Y_0}{d\tau^2}+\left(\nu+\frac{1}{2}-\frac{\tau^2}{4}\right)Y_0=0. \tag{5.6}$$

and the approximate solutions of (5.4) is given by the formal series expansion as

$$y=Y=Y_0+h^{-1/2}Y_1+hY_2+\cdots. \tag{5.7}$$

On the other hand if $\tau^2 \gg \tau_n^2$, where τ_n $(n=1, 2)$ are the zeros of $f_1(\tau)$, the usual WKB approximations are valid and the solution can be written as

$$y \sim f_1^{-1/4}\exp\left[\pm\left\{t+\frac{1}{2}\int Q\,dt\right\}-\frac{Q}{4}\right], \tag{5.8}$$

where

$$t=\int^{\tau}\sqrt{f_1(\tau)}\,d\tau=h\int^{x}\sqrt{f(x)}\,dx, \tag{5.9}$$

$$Q=f_1^{-1/4}\frac{d^2f_1^{1/4}}{dt^2}=-f_1^{-3/4}\frac{d^2f_1^{-1/4}}{d\tau^2}=-\frac{1}{h}f^{-3/4}\frac{d^2f^{-1/4}}{dx^2}. \tag{5.10}$$

Now, in the region where the both conditions $\tau^2 \ll h$ and $\tau^2 \gg \tau_n^2$ hold, (5.6) and (5.7) must be compatible, and we can substitute (5.2) into (5.8) and (5.9). Therefore comparing them with each other we can find the connection formulas. For representing the WKB solution in the form of the inverse power series of $h^{1/2}$ we may use the expansion

$$\left.\begin{aligned}&\sqrt{|f_1(\tau)|}=\left(\frac{\tau^2}{4}-\frac{\tau_n^2}{4}\right)^{1/2}\left\{1+\frac{4}{h^{1/2}}\frac{g_1(\tau)-g_1(\tau_n)}{\tau^2-\tau_n^2}\right\}^{1/2}=\left(\frac{\tau^2}{4}-\frac{\tau_n^2}{4}\right)^{1/2}\left\{1+\frac{2}{h^{1/2}}\frac{g_1(\tau)-g_1(\tau_n)}{\tau^2-\tau_n^2}+\cdots\right\}\\&h^{-1/2}g_1(\tau)=-f_1(\tau)-\frac{\tau^2}{4}+\nu+\frac{1}{2},\end{aligned}\right\}, \tag{5.11}$$

where τ_n is a zero of $f_1(\tau)$, and expressed as

$$\tau_{\substack{1\\2}}=\pm\left[(4\nu+2)^{1/2}-\frac{2}{h^{1/2}}(4\nu+2)^{-1/2}g_1(\pm(4\nu+2)^{1/2})+\cdots\right] \tag{5.12}$$

by means of Lagrange's theorem (Appendix II). Other formulas necessary to treat the Weber functions are enumerated in Appendix I.

Similar procedure can be applied to the equations of other forms, if the first approximate solutions have been known.

Clearly when the higher order approximations by the method in §3 or §4 are already known, the perturbation procedure is unnecessary and, even if the connection formulas are wanted, the simple procedure adopted, for example, by Kramers and Ittman[10] or present author[19] will be sufficient.

Part II The Asymptotic Solutions of a Class of Hill Equations

§6. The Uniform Asymptotic Representation in Terms of Mathieu Functions I

The second part of this paper is concerned with the uniform and local asymptotic representations for the solutions of a class of Hill equations. The study of Hill equations has been one of the subjects of the WKB method since the early stage of this method, but their uniformly valid asymptotic representations have not yet been given in any closed form.

In this and in the next section we shall show that the asymptotic solutions of a class o Hill equations can be represented uniformly in terms of Mathieu functions, when the equations possess only one simple turning point of second order or only one pair of simple turning points in each period of the coefficient.

The fundamental line of thought is the same as in § 3 and § 4. In the first place let us consider a Hill equation with second order turning points

$$\frac{d^2y}{dx^2}-(\lambda\pm h^2 f(x))y=0\,,\qquad \lambda=O(h^k)\quad (k<2)\,, \tag{6.1}$$

where, we suppose, $f(x)$ is a regular periodic function of x with period 2π and it is positive except for the zeros of second order at $x=2n\pi$ $(n=0,\pm1,\pm2,\cdots)$. Now let us introduce a set of transformations

$$\sin^2\frac{t}{2}=\frac{1}{I}\int_0^x\sqrt{f(x)}\,dx\,,\qquad y=\psi^{-1/4}y_1\,,\qquad \psi=f/\sin^2 t\,, \tag{6.2}$$

where

$$I=\int_0^{2\pi}\sqrt{f(x)}\,dx\,. \tag{6.3}$$

If we take the branch of $\sqrt{f(x)}$ as

$$\left.\begin{array}{lll}\sqrt{f(x)}>0 & \text{for} & 4n\pi<x<(4n+2)\pi\,,\\ \sqrt{f(x)}<0 & \text{for} & (4n-2)\pi<x<4n\pi\,,\\ & n=(0,\pm1,\pm2,\cdots)\,, & \end{array}\right\} \tag{6.4}$$

then the correspondence between x and t is one-to-one for all values of x, and ψ is a non-vanishing regular periodic function of t with period π. By means of (6.2), (6.1) transforms into

$$\frac{d^2y_1}{dt^2}-\left(\frac{\lambda I^2}{\psi}\pm I^2h^2\sin^2 t+Q\right)y_1=0\,, \tag{6.5}$$

where

$$Q=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}\,.$$

(6.5) is again a Hill equation with regular coefficients and the leading terms are in accord with Mathieu equation. For large values of h, only the term $I^2h^2\sin^2 t$ is dominant except in the neighbourhood of $t=n\pi$, where the other terms can be replaced by the values at $t=n\pi$.

For obtaining more refined solutions we should introduce the turning point correction. Let us put

$$x_1=t-\delta\,. \tag{6.6}$$

Here δ is the value of t, for which the bracketed coefficient of y_1 in (6.5) takes the extremum value. Then we can rewrite the coefficient of (6.5) as

$$\lambda'\pm a_1^2\sin^2 x_1+R_1(x_1)=\lambda'\pm h^2 f_1(x_1)\,, \tag{6.7}$$

where

$$\lambda'=\frac{\lambda I^2}{\psi^2(\delta)}\pm I^2h^2\sin^2\delta+Q(\delta)\,, \tag{6.8}$$

$$a_1^2=I^2h^2\cos 2\delta\pm\frac{1}{2}\lambda I^2\left(\frac{d^2}{dt^2}\frac{1}{\psi(t)}\right)_{t=\delta}\pm\frac{1}{2}Q''(\delta)\,, \tag{6.9}$$

and δ is given by

$$\pm I^2h^2 \sin 2\delta - \lambda I^2 \frac{\psi'(\delta)}{\psi^2(\delta)} + Q'(\delta) = 0 \qquad \text{or} \qquad \delta = \pm \frac{\lambda}{2h^2} \frac{\psi'(0)}{\psi^2(0)} + \cdots . \tag{6.10}$$

As is easily seen, $R_1(x_1)$ is a regular periodic function with the zeros of third order at $x_1 = n\pi$ ($n = 0, \pm 1, \pm 2, \cdots$). As well as in § 3, the rewriting of the coefficient of $\sin^2 x_1$ is not always necessary for proceeding to the higher order approximations, but it gives more accurate solutions in the neighbourhood of the turning points. Now neglecting $R_1(x_1)$ which is small everywhere, we have approximate solutions of (6.5) in terms of Mathieu functions

$$y_1 \sim M(\lambda', \pm a_1^2; x_1) , \tag{6.11}$$

where $M(b, q; x)$ is the general solution of

$$\frac{d^2M}{dx^2} - (b + q \sin^2 x)M = 0 . \tag{6.12}$$

Introducing the transformations similar to (6.2) again, we can proceed to the second approximations. In fact, putting

$$\sin^2 \frac{t_1}{2} = \frac{1}{I_1} \int_0^{x_1} \sqrt{f_1(x_1)}\, dx_1 , \qquad y_1 = \psi_1^{-1/4} y_2 , \qquad \psi_1 = f_1/\sin^2 t_1 , \tag{6.13}$$

where

$$I_1 = \int_0^{\pi} \sqrt{f_1(x_1)}\, dx_1 ,$$

we have

$$\frac{d^2y_2}{dt_1^2} - \left\{ \frac{\lambda' I_1^2}{\psi_1} \pm I^2h^2 \sin^2 t_1 + Q_1(t_1) \right\} y_2 = 0 , \tag{6.14}$$

where

$$Q_1 = \psi_1^{-1/4} \frac{d^2 \psi_1^{1/4}}{dt^2} .$$

(6.14) is again of the same form a (6.5), but Q_1 and $1/\psi_1(t_1) - 1/\psi_1(0)$ are of smaller order than the corresponding terms in (6.5), as may be varified by the consideration similar to that in § 3.

In this way we can proceed to higher order approximations by means of the repetition of similar transformations. The eigenvalues for the periodic boundary conditions are also found from the corresponding eigenvalues of Mathieu equations. Lagrange's theorem is useful also for this purpose.

§ 7. The Uniform Asymptotic Representation in Terms of Mathieu Functions II

In this section we consider a Hill equation with two simple turning points in each period of the coefficient.

When λ in (6.1) is large, it is convenient to employ the method corresponding to that in § 4. Let us write the equation to be considered as

$$\frac{d^2y}{dx^2} - h^2 f(x) y = 0 , \tag{7.1}$$

where $f(x)$ is a regular periodic function with period 2π and has two simple zero in each period:

$$\left.\begin{array}{ll} f(x+2\pi)=f(x)\,, & f(\xi+2n\pi)=f(\eta+2n\pi)=0\,, \\ f'(\xi+2n\pi)\neq 0\,, & f'(\eta+2n\pi)\neq 0\,, \\ 0<\xi<\eta<2\pi\,. & (n=0,\ >1,\ >2,\ \cdots) \end{array}\right\} \quad (7.2)$$

Further we suppose that

$$f(x)>0 \quad \text{ror} \quad \xi<x<\eta\,, \quad \text{and} \quad f(x)<0 \quad \text{for } \eta<x<\xi+2\pi\,. \quad (7.3)$$

Now let us introduce a set of transformations of variables

$$\frac{1}{K}\int_{\alpha}^{t}\sqrt{\sin 2t-q}\,dt=\frac{1}{I}\int_{\xi}^{x}\sqrt{f(x)}\,dx\,, \qquad y=\psi^{-1/4}y_1\,, \qquad \psi=f/(\sin 2t-q)\,, \quad (7.4)$$

where

$$I=\int_{\xi}^{\eta}\sqrt{f(x)}\,dx\,, \qquad K=\int_{\alpha}^{\beta}\sqrt{\sin 2t-q}\,dt\,, \quad (7.5)$$

α, β and q should be determined by the following relations

$$\left.\begin{array}{l} \sin 2\alpha-q=0\,, \qquad \sin 2\beta-q=0\,, \qquad 0<\alpha<\beta<\alpha\,, \\ \dfrac{\int_{\beta}^{\alpha+\pi}\sqrt{q-\sin 2t}\,dt}{\int_{\alpha}^{\beta}\sqrt{q-\sin 2t}\,dt}=\dfrac{\int_{\eta}^{\xi+2\pi}\sqrt{f(x)}\,dx}{\int_{\xi}^{\eta}\sqrt{f(x)}\,dx\,,} \end{array}\right\} \quad (7.6)$$

and the branches of the square roots should be taken in such a way that the correspondence between x and t is regular and one-to-one.

Then we have the transformed equation

$$\frac{d^2y_1}{dt^2}-\left\{\frac{h^2I^2}{K^2}(\sin 2t-q)+Q(t)\right\}y_1=0\,, \quad (7.7)$$

where

$$Q(t)=\psi^{-1/4}\frac{d^2\psi^{1/4}}{dt^2}\,. \quad (7.8)$$

(7.7) is again a Hill equation and can be approximated by Mathieu equation, since ψ is a nonvanishing periodic function.

We can derive more refined solutions, if we rewrite (7.7) as

$$\frac{d^2y_1}{dt^2}-h^2(\lambda+a\sin 2t+R(t))y_1=0\,. \quad (7.9)$$

Here λ and a are given by

$$\lambda+a\sin 2\alpha_1=R(\alpha_1)=0\,, \qquad \lambda+a\sin 2\beta_1=R(\beta_1)=0\,, \quad (7.10)$$

where α_1 and β_1 are the zeros of

$$f_1(t)=\frac{I^2}{K^2}(\sin 2t-q)+\frac{1}{h^2}Q(t)\,, \quad (7.11)$$

which tend to α and β respectively for $h\to\infty$. Further if we adopt a suitable coefficient a which makes $R'(\alpha_1)$ or $R'(\beta_1)$ be zero, the approximation could be more accurate near $t=\alpha_1$ or β_1. But we cannot say it is a very important procedure.

The higher approximations can be given by means of the iteration of similar procedures, making use of $f_1(t)$ in (7.7) instead of $f(x)$ in (7.1). The increasing of the accuracy of approximation can be verified by a consideration similar to those in the previous examples.

Thus it has been shown that a class of Hill equations can be solved asymptotically by means of Mathieu functions to any order wanted.

In conclusion it will be interesting to remember that Kramers and Ittmann[10] have employed Mehler's approximation formulas

$$\frac{1}{\pi}\int_{-1}^{1}\frac{f(x)}{\sqrt{1-x^2}}dx\sim\frac{1}{3}\left\{f(0)+f\left(\frac{\sqrt{3}}{2}\right)+f\left(-\frac{\sqrt{3}}{2}\right)\right\},$$

$$\frac{1}{\pi}\int_{0}^{1}f(x)\sqrt{\frac{1-x}{x}}dx\sim 0.262f(0.0495)+0.192f(0.389)+0.046f(0.812),$$

for evaluation of elliptic or hyperelliptic integrals which often appear in the WKB method.

§ 8. Supplementary Notes on the Local Approximate Expressions

The approximate solutions of Hill equations which is valid locally, that is, valid only over a single period, have been investigated by many authors since Jeffreys applied his method to Mathieu equations. Especially for Mathieu equations many useful formulas have been derived; without them the practical utility of the methods in the preceding two sections would be diminished. But the uniformity of existing asymptotic expressions seems to be incomplete even over a single period of the coefficient. Therefore it will be worthwhile to remember that the method given in § 3 or § 4 is applicable to derive the approximate solutions valid uniformly over one period of the coefficient.

We shall begin with some classical facts. Let us consider a Hill equation

$$\frac{d^2y}{dx^2}-(\lambda+h^2f(x))y=0, \tag{8.1}$$

where $f(x)$ is a regular periodic sunction of period ω. According to Floquet's theory, for a set of linearly independent solutions $u_1(x)$ and $u_2(x)$ of (8.1) there exists a constant matrix

$$A=\begin{pmatrix}a_{11} & a_{12}\\ a_{21} & a_{22}\end{pmatrix}, \tag{8.2}$$

for which

$$\begin{pmatrix}u_1(x+\omega)\\ u_2(x+\omega)\end{pmatrix}=\begin{pmatrix}a_{11} & a_{12}\\ a_{21} & a_{22}\end{pmatrix}\begin{pmatrix}u_1(x)\\ u_2(x)\end{pmatrix}. \tag{8.3}$$

The eigenvalues ν_1, ν_2 and the trace $\operatorname{tr} A$ of matrix A are independent of the selection of $u_1(x)$ and $u_2(x)$. Floquet's indices μ_1 and μ_2 are related to ν_1 and ν_2 by

$$e^{\omega\mu_1}=\nu_1, \qquad e^{\omega\mu_2}=\nu_2,$$

and Floquet's solutions are expressed as

$$e^{\mu_1 x}v_1(x), \qquad e^{\mu_2 x}v_2(x),$$

where v_1 and v_2 are periodic functions with period ω. If $|\operatorname{tr} A|>2$, then the solutions of (8.1) are unstable; if $|\operatorname{tr} A|<2$, then they are stable; and if $\operatorname{tr} A=2$ or -2, then there exists a periodic solution with period ω or 2ω respectively. Thus if we know the solutions over a single period of $f(x)$, say $0\leqq x\leqq\omega$, we can continue the solutions to any region by means of (8.3). In what follows we assume for simplicity $0\leqq f(x)\leqq 1$. Now the usual WKB solutions are given as follows:

In the region where $\lambda+h^2f(x)>0$, we have

$$y\sim\frac{1}{\sqrt[4]{\lambda+h^2f(x)}}\exp\left(\pm\int\sqrt{\lambda+h^2f(x)}\,dx\right), \tag{8.4}$$

and in the region where $\lambda+h^2f(x)<0$, we have

$$y\sim\frac{1}{\sqrt[4]{|\lambda+h^2f(x)|}}\exp\left(\pm i\int\sqrt{|\lambda+h^2f(x)|}\,dx\right). \tag{8.5}$$

By means of these approximate solutions as well as the connection formulas, we have the following results.

For $\lambda\geqslant0$,

$$\operatorname{tr}A=2\cosh\int_0^\omega\sqrt{\lambda+h^2f(x)}\,dx>2 \tag{8.6}$$

and all the solutions are unstable.

For $\lambda\leqslant-h^2$,

$$\operatorname{tr}A=2\cos\int_0^\omega\sqrt{|\lambda+h^2f(x)|}\,dx\,, \tag{8.7}$$

hence

$$|\operatorname{tr}A|\leq2\,,$$

and all the solutions are stable (this result shows that the WKB approximation cannot represent the narrow unstable regions for $\lambda\leqslant-h^2$).

And for $-h^2\leqslant\lambda\leqslant0$,

$$\operatorname{tr}A=\cos\int_\xi^\eta\sqrt{|\lambda+h^2f(x)|}\,dx\left\{2\exp\left(\int_\eta^{\xi+\omega}\sqrt{\lambda+h^2f(x)}\,dx\right)+\frac{1}{2}\exp\left(-\int_\eta^{\xi+\omega}\sqrt{\lambda+h^2f(x)}\,dx\right)\right\}, \tag{8.8}$$

where ξ and η are the adjacent zeros of $\lambda+h^2f(x)$ and we have assumed that $\lambda+h^2f(x)<0$ for $\xi<x<\eta$. For the large values of h (we have assumed so) the bracketed factor in (8.8) is large and the stable regions are restricted in the narrow ranges near $\lambda=\lambda_n$, where λ_n is given by

$$\int_\xi^\eta\sqrt{|\lambda_n+h^2f(x)|}\,dx=\left(n+\frac{1}{2}\right)\pi \qquad n=0,\,1,\,2,\,\cdots \tag{8.9}$$

(8.9) gives the asymptotic forms of the stable regions and the eigenvalues for which there exist periodic solutions with period ω. The breadth of the stable regions are asymptotically given from the gradient of λ-tr A curve at $\lambda=\lambda_n$.

When λ is close to 0 or $-h^2$, we cannot get correct informations by such a simple method and we have to apply the method in § 3.

Here we shall confine ourselves to Mathieu equation

$$\frac{d^2y}{dx^2}-(\lambda+h^2\sin^2x)y=0\,, \tag{8.10}$$

where $\lambda\leqslant h^2$. When λ is close to zero, the modified WKB transformations introduced in § 3 are

$$\frac{t^2}{4}=\int_0^x\sin x\,dx=1-\cos x\,,\qquad y=\phi^{-1/4}y_1\,,\qquad \phi=\frac{4\sin^2x}{t^2}=2-\frac{1}{4}t^2\,, \tag{8.11}$$

and the transformed equation is

$$\frac{d^2y_1}{dt^2}-\left\{\frac{\lambda}{2}\left(1-\frac{t^2}{8}\right)^{-1}+\frac{h^2}{4}t^2+Q(t)\right\}y_1=0\,. \tag{8.12}$$

where

$$Q(t)=\phi^{-1/4}\frac{d^2\phi^{1/4}}{dt^2}=-\frac{1}{16}\left(1-\frac{t^2}{8}\right)^{-1}-\frac{3}{256}t^2\left(1-\frac{t^2}{8}\right)^{-2}, \tag{8.13}$$

or after the turning point correction we have

$$\frac{d^2y_1}{dt^2}+\left\{\mu-\frac{k^2}{4}t^2+\frac{\mu}{64}\frac{t^4}{1-t^2/8}+\frac{3}{1024}t^4\frac{1+t^2/16}{(1-t^2/8)^2}\right\}y_1=0\,, \tag{8.14}$$

where

$$\mu=-\frac{1}{2}\lambda+\frac{1}{16}\,,\qquad k^2=h^2+\frac{1}{4}\lambda-\frac{5}{64}\,. \tag{8.15}$$

(8.14) corresponds to (3.10).

The region to be considered can be taken as

$$-\frac{\pi}{2}\leqq x\leqq\frac{\pi}{2}\,,$$

which corresponds to

$$-2\leqq t\leqq 2\,,$$

and in this region ϕ is bounded from zero.

The first approximate solution of (8.14) is given by

$$y_1\sim W_\nu(\sqrt{k}\,t)\,, \tag{8.16}$$

where

$$\nu+\frac{1}{2}=\frac{\mu}{k}\,.$$

The corresponding approximate value of tr A is

$$\mathrm{tr}\,A\sim-\sqrt{\frac{2}{\pi}}\,\Gamma(-\nu)\{D_\nu(2\sqrt{k})D_\nu'(2\sqrt{k})+D_\nu(-2\sqrt{k})D_\nu'(-2\sqrt{k})\}\,, \tag{8.17}$$

which is the formula filling up the gap between (8.6) and (8.8). Making use of the modified WKB transformations again for (8.14), we can proceed to higher approximations. The conventional method in § 5 is also applicable to (8.14) and the expressions given by Sips[22)] can be derived in the neighbourhood of the turning points.

When $\lambda\sim-h^2$, we can treat

$$\frac{d^2y}{dx^2}+(\lambda+h^2\sin^2 x)y=0\,, \tag{8.18}$$

instead of (8.10). Thus, putting

$$\frac{t^2}{4}=1-\cos x\,,\qquad y=\phi^{-1/4}y_1\,,\qquad \phi=2-\frac{t^2}{4}\,, \tag{8.19}$$

we have approximate solutions

$$\left.\begin{aligned}&y_1\sim W_{\nu'}(\sqrt{k'}\,t)\,,\qquad \nu'+\frac{1}{2}=\frac{\mu'}{k'}\,,\qquad \mu'=\frac{\lambda}{2}+\frac{1}{16}\,,\qquad k'^2=-h^2-\frac{1}{4}\lambda-\frac{5}{64}\,,\\ &\text{and}\\ &\mathrm{tr}\,A\sim-\sqrt{\frac{2}{\pi}}\,\Gamma(-\nu')\{D_{\nu'}(2\sqrt{k'})D_{\nu'}'(2\sqrt{k'})+D_{\nu'}(-2\sqrt{k'})D_{\nu'}'(-2\sqrt{k'})\}\,,\end{aligned}\right\} \tag{8.20}$$

which fills up the gap between (8.7) and (8.8).

Further if $-h^2 \ll \lambda \ll 0$ in (8.10) or (8.18), we can apply the method in § 4 instead of th usual WKB method which does not give any solution over one period in a closed form. Le us write the equation

$$\frac{d^2y}{dx^2} - h^2 F(x) y = 0 \, , \tag*{(8.21}$$

where

$$F(x) = \sin^2 x + \frac{\lambda}{h^2} = \sin^2 x - \lambda' \, .$$

Then, according to § 4, we have

$$y - \sqrt[4]{\frac{1-t^2}{\lambda' - \sin^2 x}} \, W_\nu \left(2 \sqrt{\frac{Ih}{\pi}} t \right) , \tag*{(8.22}$$

where

$$\nu + \frac{1}{2} = \frac{Ih}{\pi} \, , \qquad I = 2 \int_0^{x_0} \sqrt{\lambda' - \sin^2 x} \, dx \, , \qquad (x_0 = \sin^{-1} \lambda'^{1/2})$$

and

$$\frac{2}{\pi} \int_0^t \sqrt{1-t^2} \, dt = \frac{1}{I} \int_0^x \sqrt{\lambda' - \sin^2 x} \, dx \, .$$

In this way we can find the approximate solutions of Mathieu or other Hill equations with the turning points of the same character. And the repeated use of similar procedures leads to the higher order approximations without any other special techniques except the turning point correction.

Appendix I Formulas Related to Weber Functions

Some formulas related to Weber functions are enumerated here. They are useful for the treatment of the approximate solutions discussed in the text. When a divergent integral appears in the formula, it should be interpreted as the principal value or finite part, that is, when $f(x)$ is given as

$$f(x) = f_0(x) + \frac{c_{-1}}{x} + \frac{c_{-2}}{x^2} + \cdots + \frac{c_{-n}}{x^n} \, ,$$

where $f_0(x)$ is regular at $x=0$, then $\int_0^x f(x) dx$ means

$$\int_0^x f(x) dx = \int_0^x f_0(x) dx + c_{-1} \log x - \frac{c_{-2}}{x} - \cdots - \frac{1}{n-1} \frac{c_{-n}}{x^{n-1}} \, ,$$

and for $a<0$, $\int_a^x f(x) dx$ means

$$\int_a^x f(x) dx = \int_a^x f_0(x) dx + c_{-1} \log \left| \frac{x}{a} \right| - c_{-2} \left(\frac{1}{x} - \frac{1}{a} \right) - \cdots - \frac{c_{-n}}{n-1} \left(\frac{1}{x^{n-1}} - \frac{1}{a^{n-1}} \right) .$$

Further the notation $pf \frac{f(0)}{g(0)}$ means $\lim_{x \to 0} \frac{f(x)}{g(x)}$ if the limit exists, and zero if $g(0)=0$ and $f(0) \neq 0$.

1) *Definition and funpamental expressions*

$D_\nu(x)$ and $\mathscr{D}_\nu(x)$ are the linearly independent solutions of Weber's equation

$$\frac{d^2y}{dx^2} + \left(\nu + \frac{1}{2} - \frac{x^2}{4} \right) y = 0 \, . \tag{I.1}$$

We have the following formulas

$$D_\nu(x)=2^{\nu/2+1/4}x^{-1/2}W_{\nu/2+1/4,\,-1/4}\left(\frac{x^2}{2}\right), \tag{I.2}$$

$$D_\nu(x)\sim\begin{cases} e^{-x^2/4}x^\nu\left\{1-\dfrac{\nu(\nu-1)}{2x^2}+\dfrac{\nu(\nu-1)(\nu-2)(\nu-3)}{2\cdot4\cdot x^4}+\cdots\right\} & (x\to+\infty)\\ \cos\nu\pi e^{-x^2/4}|x|^\nu\left\{1-\dfrac{\nu(\nu-1)}{2x^2}+\dfrac{\nu(\nu-1)(\nu-2)(\nu-3)}{2\cdot4\cdot x^4}+\cdots\right\} & \\ \quad+\dfrac{\sqrt{2\pi}}{\Gamma(-\nu)}e^{x^2/4}|x|^{-\nu-1}\left\{1+\dfrac{(\nu+1)(\nu+2)}{2x^2}+\cdots\right\}, & (x\to-\infty)\end{cases} \tag{I.3}$$

$$D_\nu(0)=\Gamma\left(\frac{1}{2}\right)2^{\nu/2}\Big/\Gamma\left(\frac{1-\nu}{2}\right),\qquad D_\nu'(0)=\Gamma\left(-\frac{1}{2}\right)2^{(\nu-1)/2}\Big/\Gamma\left(-\frac{\nu}{2}\right), \tag{I.4}$$

$$\mathscr{D}_\nu(x)\sim e^{x^2/4}x^{-\nu-1}\left\{1+\frac{(\nu+1)(\nu+2)}{2x^2}+\cdots\right\}, \tag{I.5}$$

$$\mathscr{D}_\nu(0)=-\frac{\sin^2(\nu\pi/2)}{D_\nu'(0)},\qquad \mathscr{D}_\nu'(0)=\frac{\cos^2(\nu\pi/2)}{D_\nu(0)}, \tag{I.6}$$

$$\mathscr{D}_\nu'(x)D_\nu(x)-D_\nu'(x)\mathscr{D}_\nu(x)=1,$$

$$D_\nu(x)=\mathscr{D}_\nu(x)\int_x^\infty\frac{dx}{\{\mathscr{D}_\nu(x)\}^2},\qquad \mathscr{D}_n(x)=D_n(x)\int_0^x\frac{dx}{\{D_n(x)\}^2}\qquad(n=0,\,1,\,2\cdots), \tag{I.8}$$

The simplest special cases are the following functions:

$$D_0(x)=e^{-x^2/4},\qquad \mathscr{D}_0(x)=e^{-x^2/4}\int_0^x e^{x^2/2}dx,$$

$$D_{-1}(x)=e^{x^2/4}\int_0^x e^{-x^2/2}dx,\qquad \mathscr{D}_{-1}(x)=e^{x^2/4}.$$

If ν is not equal to a positive integer or zero, $D_\nu(x)$ and $D_\nu(-x)$ are linearly independent solutions of (I.1). Therefore we need not $\mathscr{D}_\nu(x)$ except the cases in which $\nu=n=0,\,1,\,2,\,\cdots$. In the asymptotic expansion for $x\to-\infty$ the exponentially decreasing part is meaningful only in the cases in which ν is sufficiently close to an integer.

2) *Recurrence formulas*

The following forms of recurrence relations are convenient for integration or other operations.

$$D_1D_\nu=D_0D_{\nu+1}+\nu D_0D_{\nu-1}=2D_0D_\nu'+2\nu D_0D_{\nu-1}, \tag{I.9}$$

$$2D_\nu'=D_{\nu+1}-\nu D_{\nu-1}, \tag{I.10}$$

$$\frac{d}{dx}(D_0D_\nu)=-D_0D_{\nu+1},\qquad D_0D_\nu=\int_x^\infty D_0D_{\nu+1}dx, \tag{I.11}$$

$$\frac{d}{dx}\left(\frac{D_\nu}{D_0}\right)=\nu\frac{D_{\nu-1}}{D_0}, \tag{I.12}$$

$$\frac{d}{dx}\left(\frac{1}{D_\nu D_\mu}\right)=\frac{D_{\nu+1}D_\mu-\mu D_\nu D_{\mu-1}}{D_\mu^2D_\nu^2}, \tag{I.13}$$

$$D_\mu^2\frac{d}{dx}\left(\frac{D_\nu}{D_\mu}\right)=\nu D_\mu D_{\nu-1}-\mu D_\nu D_{\mu-1}=D_\nu D_{\mu+1}-\nu D_\mu D_{\nu+1}, \tag{I.14}$$

$$\frac{d}{dx}(D_\nu D_\mu)=-D_{\nu+1}D_\mu+\mu D_\nu D_{\mu-1}=-D_{\mu+1}D_\nu+D_\mu D_{\nu-1}, \tag{I.15}$$

$$D_\nu D_{\mu+1}=D_\mu(D_{\nu+1}+\nu D_{\nu-1})-\mu D_{\mu-1}D_\nu, \tag{I.16}$$

$$D_m D_\mu = D_0 \sum_{k=0}^{m} k! \binom{m}{k}\binom{\nu}{k} D_{\nu+m-2k} \qquad (m=\text{integer}) , \tag{I.17}$$

$$x^n D_0 = D_n + \frac{n(n-1)}{2} D_{n-2} + \frac{n(n-1)(n-2)(n-3)}{2\cdot 4} D_{n-4} + \cdots$$
$$+\begin{cases} \dfrac{n!}{(n/2)!\,2^{n/2}} D_0 & (n=\text{even}) \\[2ex] \dfrac{n!}{\{(n-1)/2\}!\,2^{(n-1)/2}} & (n=\text{odd}) \end{cases} \tag{I.18}$$

$$D_1 \mathscr{D}_n = D_0 \mathscr{D}_{n-1} + (n+1) D_0 \mathscr{D}_{n+1} , \tag{I.19}$$

$$2\mathscr{D}_n' = -(n+1)\mathscr{D}_{n+1} + \mathscr{D}_{n-1} , \tag{I.20}$$

$$\frac{d}{dx}(D_0 \mathscr{D}_n) = -(n+1) D_0 \mathscr{D}_{n+1} , \tag{I.21}$$

$$\frac{d}{dx}\left(\frac{\mathscr{D}_n}{D_0}\right) = \frac{\mathscr{D}_{n-1}}{D_0} \qquad (n=\text{integer}) . \tag{I.22}$$

3) *Related functions*

$D_\nu^{(k)}(x)$ and $\mathscr{D}_\nu^{(h)}(x)$ are the particular solutions of inhomogeneous equation

$$\frac{d^2y}{dx^2} + \left(\nu + \frac{1}{2} - \frac{x^2}{4}\right) y = -D_\nu^{(k-1)}(x) , \qquad (D_\nu^{(0)}(x) = D_\nu(x)) \tag{I.23}$$

and

$$\frac{d^2y}{dx^2} + \left(\nu + \frac{1}{2} - \frac{x^2}{4}\right) y = -\mathscr{D}_\nu^{(k-1)}(x) , \qquad (\mathscr{D}_\nu^{(0)}(x) = \mathscr{D}_\nu(x)) \tag{I.24}$$

respectively. We have

$$D_\nu^{(k)}(x) = \frac{1}{k!}\,\frac{\partial^k}{\partial \nu^k} D_\nu(x) , \tag{I.25}$$

$$\mathscr{D}_\nu^{(k)}(x) = \frac{1}{k!}\,\frac{\partial^k}{\partial \nu^k} \mathscr{D}_\nu(x) , \tag{I.26}$$

$$D_1 D_\nu^{(k)} = \{D_{\nu+1}^{(k)} + \nu D_{\nu-1}^{(k)} + D_{\nu-1}^{(k-1)}\} D_0 , \tag{I.27}$$

$$D_\nu^{(k)}(x) = D_\nu(x) \int_0^\infty \frac{dx_1}{\{D_\nu(x_1)\}^2} \int_{x_1}^\infty D_\nu(x_2) D_\nu^{(k-1)}(x_2)\, dx_2 . \tag{I.28}$$

4) *Integral formulas*

$$(\nu-\mu)\int_x^\infty D_\nu D_\mu\, dx = D_\mu D_\nu' - D_\nu' D_\mu , \tag{I.39}$$

$$(\nu-\mu)\int_0^x \frac{dx_1}{\{D_\nu(x_1)\}^2} \int_{x_1}^\infty D_\nu(x_2) D_\mu(x_2)\, dx_2 = -\frac{D_\mu(x)}{D_\nu(x)} + pf\,\frac{D_\mu(0)}{D_\nu(0)} , \tag{I.30}$$

$$\begin{aligned} I_\nu(x) &= \int_x^\infty \{D_\nu(x)\}^2 dx = D_\nu(x) D_{\nu-1}(x) + \nu I_{\nu-1}(x) \\ &= \{D_\nu(x)\}^2 \frac{\partial}{\partial \nu}\left\{\frac{D_\nu'(x)}{D_\nu(x)}\right\} = \{D_\nu(x)\}^2 \frac{d}{dx}\left\{\frac{D_\nu^{(1)}(x)}{D_\nu(x)}\right\} , \end{aligned} \tag{I.31}$$

$$\left.\begin{aligned} I_n(0) &= \sqrt{\frac{\pi}{2}}\, n! , \\ I_\nu(0) &= \frac{\Gamma(1+\nu)}{2^{3/2}\pi^{1/2}}\left\{2\pi + \sin \pi\nu \left(\psi\left(1+\frac{1}{2}\nu\right) - \psi\left(\frac{1}{2}+\frac{1}{2}\nu\right)\right)\right\} . \end{aligned}\right\} \tag{I.32}$$

5) *Zeros and extrema*

$D_\nu(x)$ has no zero in $x>2\left(\nu+\frac{1}{2}\right)^{1/2}$ if ν is real.

When $n<\nu<n+1$, where $n=0, 1, 2, \cdots$, then $D_\nu(x)$ has n zeros and at most only one of them lies in $x<-2\left(\nu+\frac{1}{2}\right)^{1/2}$. If $\nu<0$, $D_\nu(x)$ has no zero.

The zeros of D_ν and $\mathscr{D}_\nu$ are simple and distributed alternatively.

If ν is larger than and sufficiently close to $n=0, 1, 2, \cdots$, then D_ν has a large negative zero, which is asymptotically expressed as

$$|x_0|\sim 2k+(2n+1)\log k+\frac{(2n+1)}{k}\log k+\cdots , \tag{I.33}$$

where

$$k=-\log(2^{-n/2}\pi^{-1/2}n!\,\nu'), , \qquad \nu'=\nu-n ,$$

If ν is smaller than and sufficiently close to $n=0, 1, 2, \cdots$, then $|D_\nu|$ takes minimum value at $x=x_m$, where x_m is asymptotically expressed as

$$-x_m=|x_m|\sim 2k'+(2n+1)\log k'+\frac{(2n+1)}{k'}\log k'+\cdots , \tag{I.34}$$

where

$$k'=-\log(2^{-n/2}\pi^{-1/2}n!\,\nu') , \qquad \nu'=n-\nu .$$

Appendix II Inversion of Transcendental Functions

For calculation of various quantities appearing in the turning point correction and for approximate determination of eigenvalues, we need inversion of transcendental functions and substitution of a transcendental function into another. For this purpose the theorem due to Lagrange* is very useful. According to it, if

$$\zeta=a+\varepsilon\varphi(\zeta) , \tag{II.1}$$

then under a suitable condition we have

$$f(\zeta)=f(a)+\sum_{n=1}^{\infty}\frac{\varepsilon^n}{n!}\frac{d^{n-1}}{da^{n-1}}[f'(a)\{\varphi(a)\}^n] . \tag{II.2}$$

As a special case of this theorem we see that if

$$w=\varphi_0(z)-\varepsilon\varphi_1(z) \tag{II.3}$$

and

$$\varphi_0(z_0)=w , \qquad \varphi_0'(z_0)\neq 0 , \tag{II.4}$$

then we have

$$z=z_0(w)+\varepsilon\frac{\varphi_1(z_0)}{\varphi_0'(z_0)}+\frac{\varepsilon^2}{2!}\frac{1}{\varphi_0'(z_0)}\frac{d}{dz_0}\left(\frac{\varphi_1^2(z_0)}{\varphi_0'(z_0)}\right)+\frac{\varepsilon^3}{3!}\left(\frac{1}{\varphi_0'(z_0)}\frac{d}{dz_0}\right)^2\left(\frac{\varphi_1^3(z_0)}{\varphi_0'(z_0)}\right)+\cdots . \tag{II.5}$$

For example, let us consider

$$h^2\delta-Q(\delta)=0 \tag{II.6}$$

or

---

* E. T. Whittaker and C. N. Watson: *A Course of Modern Analysis* (Cambridge, 1927) 132.

$$\delta-\varepsilon Q(\delta)=0\ , \qquad (\varepsilon=h^{-2})\ , \tag{II.7}$$

which appeared in (2.8) in the text. In this case we can put

$$w=0\ , \qquad \varphi_0(\delta)=\delta\ , \qquad \varphi_1(\delta)=Q(\delta)$$

in (II.3) and we have

$$\delta=0+\varepsilon\frac{Q(0)}{1}+\frac{\varepsilon^2}{2}\left(\frac{dQ^2(\delta)}{d\delta}\right)_{\delta=0}+\frac{\varepsilon^3}{3!}\left(\frac{d^2Q^3(\delta)}{d\delta^2}\right)_{\delta=0}+\cdots\ . \tag{II.8}$$

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 12, DECEMBER 1959

Further Investigation on the Transition of Two-Dimensional Separated Layer at Subsonic Speeds

By Hiroshi SATO

Aeronautical Research Institute, University of Tokyo

(Received August 3, 1959)

Experiments have been made on the artificially excited transition of two-dimensional separated layer at subsonic speeds. The response characteristics of laminar layer to the sinusoidal external disturbances are found to be in good agreement with theoretical calculations based on the Orr-Sommerfeld equation. The effect of excitation becomes maximum when the frequency of external excitation coincides with that of naturally excited sinusoidal velocity fluctuation in the laminar layer. No remarkable abrupt turbulent bursts are found in the transition region. The wave-form of velocity fluctuation changes gradually from sinusoidal to irregular patterns.

§ 1. Introduction

On the natural transition of two-dimensional separated layer, experimental investigations were carried out and reported by the present author in 1956[1]. In the transition region were found sinusoidal velocity fluctuations which were apparently caused by the dynamical instability of extremely small disturbances in the laminar layer. The non-dimensional frequency of the fluctuation lied inside the theoretical unstable zone. The author predicted that the sinusoidal fluctuation might correspond to the one which received maximum amplification in the linearized theory. At that time, however, it was not possible to confirm this prediction since theoretical and experimental results were still wanted.

Since then, in the theoretical phase, Lessen and Fox[2] extended Lessen's earlier work on the neutral disturbances in the separated layer[3] to the unstable cases assuming infinite Reynolds number. The wave speed and amplification rate of small disturbances of various wave numbers were determined by numerical calculations.

The present experimental program has been started in order to make more detailed comparisons with these theoretical results. The laminar separated layer is excited by sound from outside. The wave speed and amplification rate of excited velocity fluctuation are measured. Some features in the mechanism of transition are also clarified.

The author appreciates discussions and advices given by the Turbulence Research Group in Japan which has been conducted by Professor Itiro Tani. Acknowledgement is extended to Messrs. Y. Onda and S. Kyoya who were helpful in carrying out the experimental program.

This work was financially assisted by a grant-in-Aid for Fundamental Scientific Research from the Ministry of Education.

§ 2. Experimental Arrangement

Experiments have been carried out in a 20 cm by 60 cm low-turbulence wind-tunnel at Aeronautical Research Institute (which superseded Institute of Science and Technology in 1957). Most of the experimental arrangement and technique used in the present work have been described in reference 1.

The separated layer is created by the separation of laminar boundary layer along a flat plate from a 90-degrees rear-edge. Details of test-section are shown in Fig. 1. The

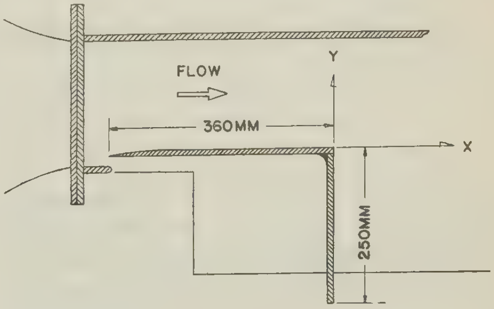

Fig. 1. Dimensions of plate used for excited transition of separated layer. (This plate corresponds to "Plate III" in reference 1).

main-stream velocity could be changed from 3 to 30 m/s. However, the general features of transition process have been found not to be influenced by the Reynolds number in the above wind-speed range if each quantity is properly non-dimensionalized. Therefore, most of the detailed measurements have been made at one wind-speed, 10 m/s. The longitudinal turbulence level of main-stream at the speed is 0.08 percent. Measurements of mean and fluctuating velocities have been made by hot-wire anemometers. The over-all frequency response of electronic equipment for the hot-wire is flat from 20 cps up to 20,000 cps. The spectral component of velocity fluctuation is observed by using a narrow-band RC-type band-pass filter. The output from amplifier is recorded by taking pictures of screen of a dual-beam cathode-ray oscilloscope.

The artificial excitation is realized by the sound from a 10-watt loudspeaker placed facing the test-section. The survey of sound field by a small microphone has proved that the intensity of sound is uniform in the test-section. No noticeable reasonance effect has been found in the frequency range from 30 to 800 cps. The background noise level determined by a standard noise-meter was 62 decibels* at the main-stream velocity, 10 m/s and the maximum intensity of sound from loudspeaker was around 100 decibels at the test-section.

The two-dimensionality of flow in the transition region was confirmed by the mean-velocity survey.

The over-all accuracy of measurement is estimated to be around 5 percent in most cases. In some special measurements, however, the accuracy might be poorer mainly because of the difficulties in reproducing the flow field. For example, the frequency of sinusoidal fluctuation varies around ±5 percent by some unknown causes. Since the origin of so-called natural transition is untraceable, some scatter of experimental data is unavoidable. There are many experimental conditions which might be responsible for the poor reproducibility of flow, such as room temperature, back-ground noise, slight vibrations, etc.

§ 3. Experimental Results

The results obtained in the previous experiment on the natural transition[1] are summarized as follows:

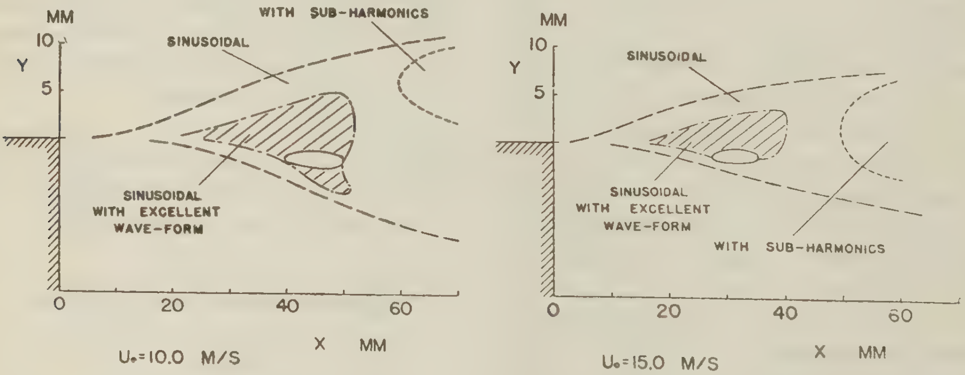

Fig. 2. Map of patterns of velocity fluctuations. U_0: main-stream velocity.

The boundary layer on the flat plate before separation is laminar and has the well-known Blasius-type velocity distribution. After the separation, the layer remains laminar in some distance and then appears the velocity fluctuation of a regular sinusoidal wave-form. The frequency of fluctuation is roughly proportional to 3/2 power of mainstream velocity. The fluctuation increases the amplitude and develops into turbulence further downstream. Fig. 2 gives a crude idea on the extent of region where the sinusoidal fluctuation is found. Inside a shaded region the wave-form is sinusoidal. Inside a small region enclosed by a full line, the amplitude of fluctuation is very small and the wave-form is not sinusoidal. There is also a region where the fundamental sinusoidal fluctuation is accompanied by a sub-harmonic component. No remarkable turbulent burst has been found in the transition region of separated layer. A detailed discussion on the above-mentioned nature of velocity fluctuation is given in the following sections.

---

* Decibel is the standard scale of sound intensity. 0 decibel $=2\times10^{-4}$ dyne/cm^2.

The increase of thickness of separated layer is gradual as far as the layer remains laminar

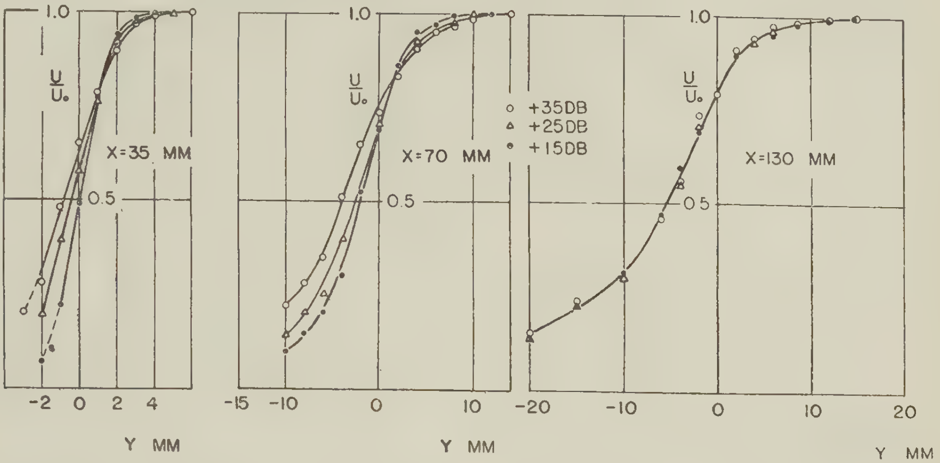

Fig. 3. Fffect of excitation on mean-velocity distribution. Main-stream velocity 10.0 m/s. Frequency of excitation 240 cps.

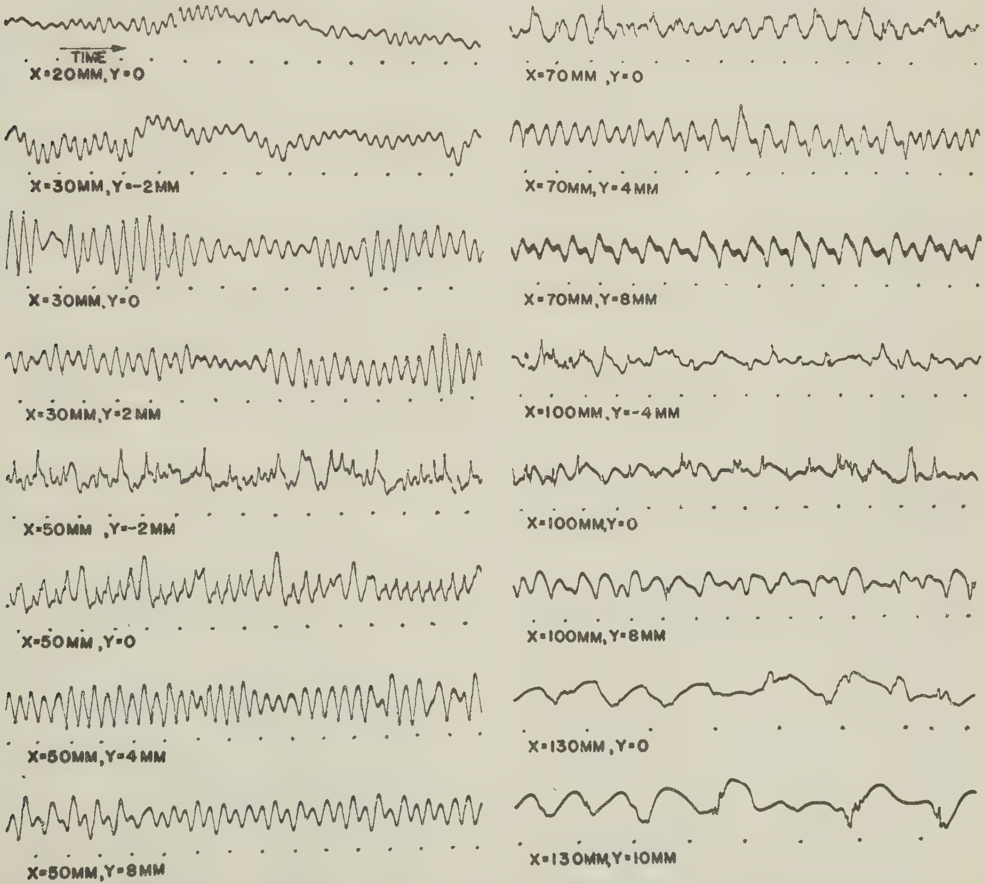

Fig. 4. Development of u-fluctuation in natural transition. Main-stream velocity 10.0 m/s. Time mark between dots 0.01 sec.

and becomes remarkable when the velocity fluctuation appears in the layer.

The effect of excitation on the transition depends strongly on the intensity and frequency of incoming sound. Generally speaking, the effect becomes noticeable as the intensity of sound is increased and is most pronounced when the frequency of sound coincides with that of above-mentioned naturally-excited sinusoidal velocity flucutuation. When these two frequencies are far different, the effect of excitation is hardly observed.

3.1 *Mean-velocity distributions*

The artificial excitation does not change so much the general feature of mean-velocity distribution. Fig. 3 shows an example. The frequency of exciting sound is 240 cps which is the frequency of naturally-excited fluctuation. The parameter for three curves is the intensity of incoming sound. For example, +35 DB means that the total sound level at the test-section is 35 decibels above the background sound noise. The origin of co-ordinate is the separation point and X- and Y-axis are parallel and perpendicular to the main-stream, respectively. The broadening of layer due to excitation is evident at two stations, $X=35$ mm and $X=70$ mm. This broadening might be caused by the high-intensity velocity fluctuations induced by sound. At $X=130$ mm, the effect of excitation is hardly detected. Stations $X=35$ mm and $X=70$ mm lie inside the region of sinusoidal fluctuations as shown in Fig. 2. On the other hand, the layer is turbulent at $X=130$ mm. Fig. 3 suggests that at $X=130$ mm, some sort of energy equilibrium has been reached and this equilibrium is universal regardless to the process of transition.

3.2 *Wave-forms of velocity fluctuations*

Fig. 4 shows patterns of u-fluctuations at

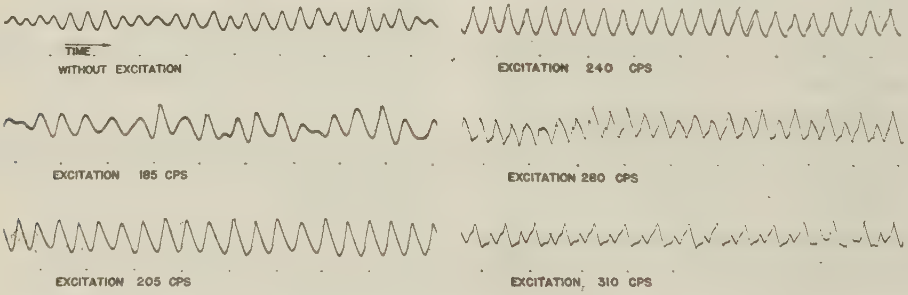

Fig. 5. Fffect of excitation on patterns of u-fluctuation. Main-stream velocity 10.0 m/s. X=35 mm, Y=1 mm.

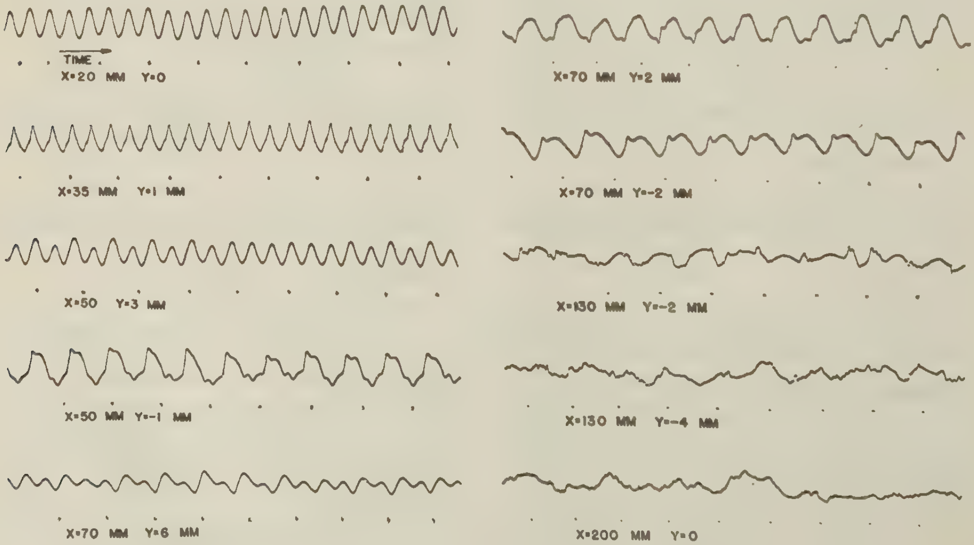

Fig. 6. Development of u-fluctuation with excitation 250 cps. Main-stream velocity 10.0 m/s.

various points in the layer without excitations. At $X=30$ mm and 50 mm, regular sinusoidal wave-forms are observed. At $X=70$ mm, the fluctuation of half frequency prevails at $Y=4$ mm and 8 mm. The turbulent pattern appears at $X=100$ mm. The intermittent burst is not so noticeable as found in the boundary layer along a solid wall.

The effect of excitation on the wave-form is illustrated in Fig. 5. The frequency of natural fluctuation is 240 cps. The effect of excitation is obvious for all cases. It should be remarked here that the output from hot-wire anemometer due to the sound itself is very small and negligible comparing with signals due to induced velocity fluctuations. With excitation frequency from 185 to 280 cps, the frequency of induced fluctuation coincides with that of incoming sound but with 310 cps, the sub-harmonic (155 cps) fluctuation is also induced.

Patterns of excited u-fluctuation at various positions are reproduced as Fig. 6 in a wide range of X and Y. The frequency of exciting sound is set equal to that of natural fluctuation—250 cps in this case. At $X=20$ mm, $Y=0$, the wave-form is purely sinusoidal. At $X=35$ mm, $Y=1$ mm, some distortion is observed. At $X=50$ mm, $Y=-1$ mm, the sub-harmonic component of half frequency and the harmonic component of doubled frequency are evidently shown. In three traces at $X=70$ mm, the predominant frequency is 125 cps. At $X=130$ mm and 200 mm, no particular frequency is observed any more. The intermittent burst is hardly pointed out in any trace. The variation of wave-form is gradual.

3.3 *Distribution of velocity fluctuations*

The effect of excitation on the intensity of velocity fluctuation is shown in Fig. 7. As the intensity of sound is increased, the value of $\sqrt{\overline{u^2}}/U_0$ increases uniformly at various Y-positions and its distribution remains nearly similar. When excited with a sound of +35 decibels, the intensity of fluctuation becomes 4 times the initial value. This fact suggests that the intensity of velocity fluctuation in the so-called natural transition region is influenced very much by the experimental arrangement, especially by the intensity and spectrum of sound noise at the test-section. Schubauer and Skramstad have already pointed out that the transition point in the boundary layer on a solid wall can be moved at will by varying the frequency and intensity of exciting sound[4)].

The extraordinary large value of $\sqrt{\overline{u^2}}/U_0$ at $Y=-2$ mm, for the excitation by the sound of +35 decibels is due to the particular amplitude distribution of certain spectral component. This point is made clear in the following section.

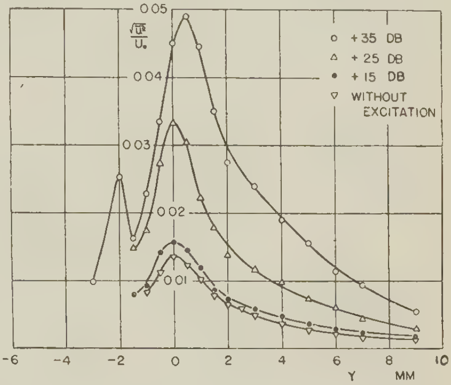

Fig. 7. Effect of excitation on velocity fluctuations. Main-stream velocity 10.0 m/s. X=30 mm. Excitation frequency 240 cps.

3.4 *Spectral components of velocity fluctuations*

Details of velocity fluctuation are revealed by the observation of spectral components. For instance, the energy spectrum such as shown in Fig. 8 is a quantitative representation of wave-form of fluctuation shown in Fig. 4. Although the definition of energy spectrum is somewhat ambiguous when a predominant frequency exists in the fluctuation, the energy spectrum in Fig. 8 is based on the usual way of definition, namely, $\overline{u}_f{}^2$ is the mean value of energy per cycle per second. This treatment might be justified by the fact that in the case of natural transition, the wave-form of fluctuation is not purely sinusoidal and the spectrum around the predominant frequency has some distribution. The scale for $\overline{u}_f{}^2$ in the figure is taken arbitrary, while relative values at three different stations are expressed correctly. At $X=35$ mm, $Y=1$ mm, there exist a high peak at 240 cps and another peak at about 500 cps. The latter apparently corresponds to the harmonic component. At $X=70$ mm, $Y=1$ mm, two peaks are clearly observed, one at 240 cps and the other at 120 cps corresponding to the sub-harmonic component. At X=130 mm, Y=0, no particular peaks are present.

It is now obvious that three spectral components are significant. They are fundamental, sub-harmonic and second-harmonic components. We are now to investigate the distribution of these components in X- and Y-direction. Fig. 9 shows some results obtained by measuring spectral components at various X-sections with the tuning frequency of band-pass filter fixed. The frequency of exciting sound is kept at 242 cps which is the frequency of naturally-excited fluctuation. The level of excitation is either +15 decibels or +35 decibels. "+0 DB" means that no artificial excitation is applied. The absolute value of root-mean-square, $\sqrt{\bar{u}_f^2}$ is not significant. Only the relative value with the same tuning frequency is to be compared. Generally speaking, with excitation level +15 decibels, the amplitude of spectral component is increased uniformly, keeping the similar distributions with those in the natural transi-

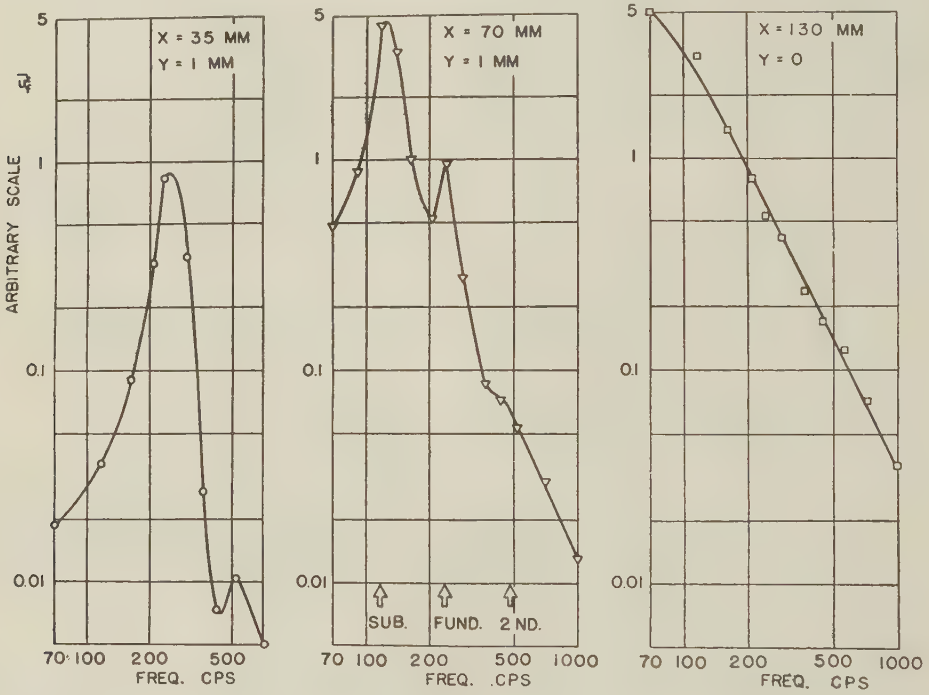

Fig. 8. Energy spectrum of u-fluctuation without artificial excitations. Main-stream velocity 10.0 m/s.

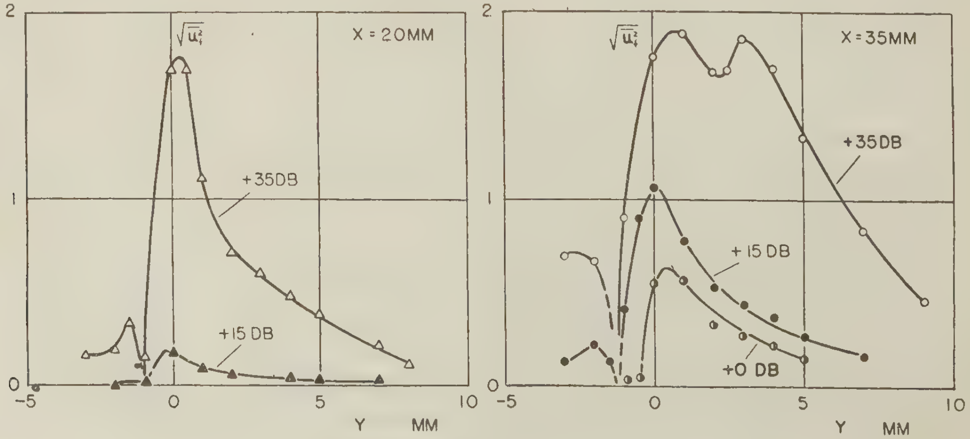

Fig. 9 (A)

tion. At $X=20$ mm, the increase of fundamental component due to excitation is remarkable. The ratio of values of $\sqrt{\overline{u_f}^2}$ with excitation +35 decibels and +0 decibels reaches around 30, while harmonic and subharmonic components are much less affected by the excitation. At $X=35$ mm, components of 121 cps and 484 cps become larger and moreover, distributions have maxima at about $Y=-1$ mm where the fundamental component is nearly zero. Thus it is clear that the wave-form near $Y=-1$ mm suffers from con-

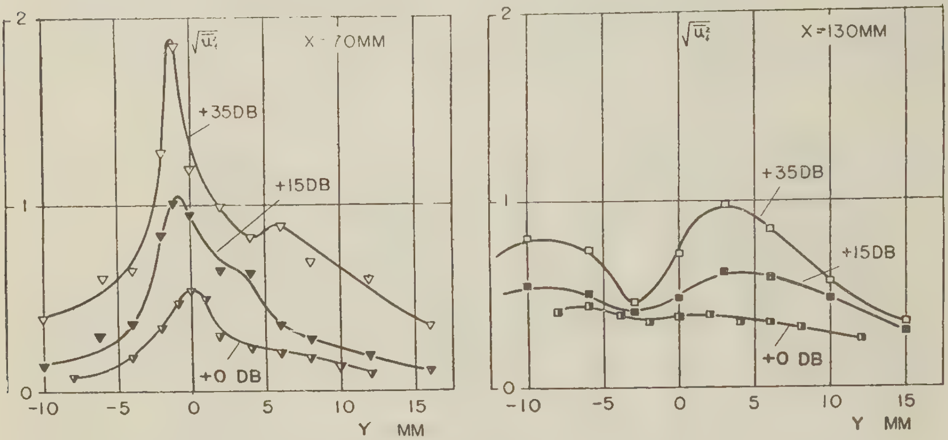

Fig. 9 (C) Distribution of sub-harmonic component (121 cps) with excitation 242 cps.

siderable distortions. This explains the fact that no sinusoidal pattern is observed inside the small region shown in Fig. 2. The somewhat curious distributions of fundamental component at $X=20$ mm and 35 mm are explained in the next section in connection with theoretical results.

At $X=70$ mm, distributions of fundamental and harmonic components are completely altered by the intense excitation. With the excitation level of +35 decibels, the maximum values of fundamental and harmonic components are reached at $X=35$ mm, while the sub-harmonic component has a maximum at $X=70$ mm. It is now apparent that the fundamental and harmonic components have a close relationship with each other. The generation of harmonic component might be the result of remarkable increase of the amplitude of fundamental component. On the other hand, the physical process in the development of sub-harmonic component is not well-known. At $X=130$ mm, the effect of excitation is small. This fact again suggests that the energy equilibrium is almost accomplished there. The layer is, therefore, called as " fully turbulent " at $X=130$ mm and further downstream.

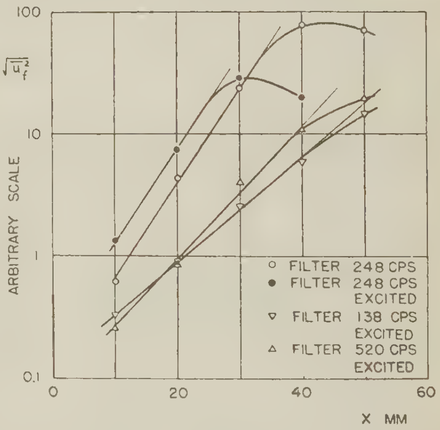

Fig. 10. Growth of spectral components in logarithmic plot. $U_0=10.0$ m/s.

The growth of spectral components in X-direction is shown in Fig. 10 in a more direct way. This is actually a plot of maximum value of $\sqrt{\overline{u_f^2}}$ at each X-section with various excitation frequencies. The tuning frequency of filter is always set equal to the frequency of exciting sound. The general trend of four curves is the same, that is, in a semi-logarithmic plot, $\sqrt{\overline{u_f^2}}$ increases linearly with X when X is not large, then it deviates from being linear, reaches maximum and decreases.

Since it was confirmed experimentally that the distribution of $\sqrt{\bar{u}_f^2}$ in Y-direction is similar at various X-section as far as $\log\sqrt{\bar{u}_f^2}$ is linear to X, the gradients of those straight lines give the rate of exponential growth. It is easily observed that the rate is maximum for the component of frequency of naturally-excited fluctuation—248 cps in this case. The quantitative discussion concerning the rate of growth is given in the following section.

An important subject in the stability theory of laminar flow is the neutral curve which discriminates the unstable zone from the stable zone, for instance, in the wave number-Reynolds number diagram. The frequency of neutral oscillation is to be determined experimentally by the use of present method of artificial excitation. When the amplitude of certain spectral component is not increased by the artificial disturbance of the same frequency, the disturbance is either damped or in neutral equilibrium. Therefore, the limit of amplification of artificial disturbance gives the neutral oscillation. Some results in the laminar separated layer are shown in Fig. 11, in which $\sqrt{\bar{u}_{fe}^2}$ and $\sqrt{\bar{u}_{fn}^2}$ denote root-mean-square values of spectral component of frequency f with and without excitation, respectively. αc_r is the frequency non-dimensionalized by the main-stream velocity U_0 and the momentum thickness θ which is calculated by

$$\theta=\int_{-\infty}^{\infty}\frac{U}{U_0}\left(1-\frac{U}{U_0}\right)\,dy\ .$$

Points for various wind-speeds drop on a single curve. When $\sqrt{\bar{u}_{fe}^2}/\sqrt{\bar{u}_{fn}^2}$ is larger than 1, the external disturbance is amplified and the limiting point on the abcissa at which $\sqrt{\bar{u}_{fe}^2}/\sqrt{\bar{u}_{fn}^2}$ approaches 1, corresponds to the frequency of neutral oscillation. An arrow in the figure indicates the theoretical prediction for the neutral frequency at infinite Reynolds number given by Lessen[3]. The agreement between experimental and theoretical results is good.

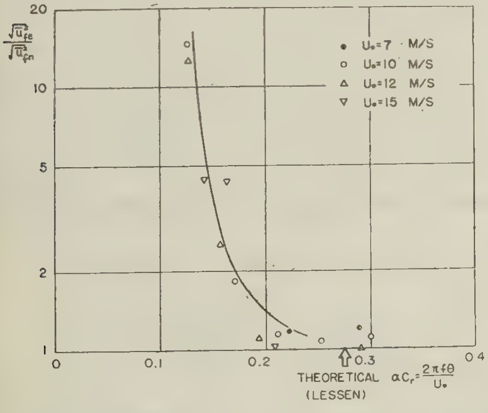

Fig. 11. Determination of the frequency of neutral oscillation.

§ 4. Comparison with Linearized Theory

As a first step of comparing above-mentioned experimental results with linearized theory, the mean-velocity distribution is considered. In the previous report, the measured mean-velocity distribution of laminar speparated layer has been proved to be in good agreement with the theoretical, so-called "similar distribution" when U/U_0 is plotted against Y/θ[1]. The agreement is also good for the present case with artificial excitations.

The existing linearized theory of small disturbance is based on the similar distribution, and the stream function of disturbance Ψ is given by

$$\Psi=\varphi(y)\exp i\alpha(x-ct)$$

where φ is the amplitude function and α is the wave number. c is usually a complex number expressed by $c=c_r+ic_i$. c_r is the wave speed in X-direction and αc_i is the amplification rate with respect to time. x, y and t are non-dimensionalized coordinates by the use of momentum thickness of layer θ as a reference length and main-stream velocity U_0 as a reference velocity. Eigenvalues α, c_r and c_i and eigenfunction $\varphi(y)$ is to be determined by the Orr-Sommerfeld equation under suitable boundary conditions. For the comparison of experimental results with the theory, x- and t-axis is related as $x=c_rt$. Then αc_r is the non-dimensional frequency and $\alpha c_i/c_r$ is the special rate of amplification—amplification rate along X-axis. Since αc_r, c_r and $\alpha c_i/c_r$ are directly deduced from the measurements, these are taken as three eigenvalues. Concerning the amplitude function, $\varphi'(y)$ is compared with the distribution of spectral components of u-fluctuation.

The frequency of sinusoidal fluctuation found in the case of natural transition is plotted in the non-dimensional form in Fig. 12, where $\alpha c_r = 2\pi f\theta / U_0$, θ being the momentum thickness at the section where the fluctuation is found. Whole data are actually taken from the previous experiment[1]. In the figure, Plate I, II and III denote three "boundary-layer plates" with different length as explained in reference 1. The neutral curve in this figure was obtained theoretically by Lessen[3]. It is worth while to note that the theoretical value of αc_r for neutral disturbance changes quite little with respect to Reynolds number within the range of experiment. This fact justifies that the present experimental results obtained at pretty high Reynolds number might be compared with theoretical results calculated for infinite Reynolds number. In the right of figure, the spacial rate of amplification $\alpha c_i / c_r$ obtained by Lessen and Fox for infinite Reynolds number is shown against αc_r. From Fig. 12, we conclude that the naturally-excited sinusoidal fluctuation is theoretically unstable and moreover, it receives maximum amplification among various disturbances in the laminar layer.

The second eigenvalue c_r, the propagation velocity of sinusoidal fluctuation is plotted against αc_r in Fig. 13. Most of the data are obtained with artificial excitations. The pro-

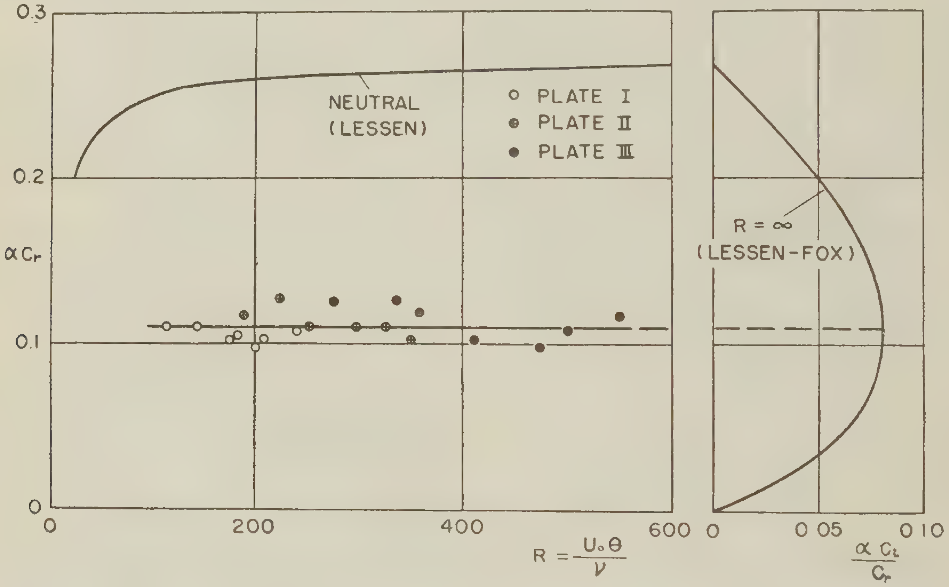

Fig. 12. Comparison of theoretical and experimental results on the frequency of sinusoidal fluctuations.

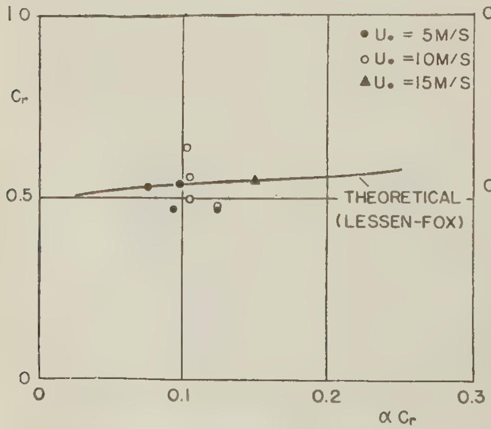

Fig. 13. Propagation velocity of sinusoidal fluctuations.

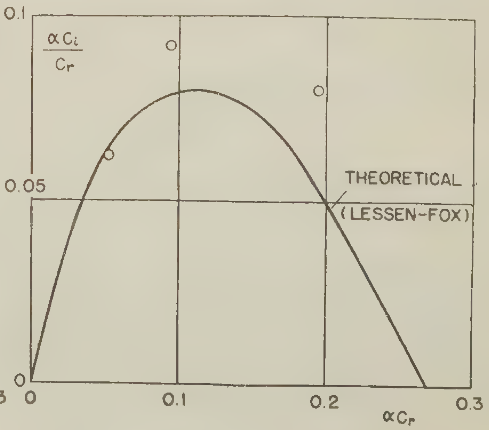

Fig. 14. Spacial rate of amplification of sinusoidal fluctuations.

pagation velocity is determined from the phase lag of signals from two hot-wires placed in the layer apart in X-direction as described in reference 1. The accuracy of determining c_r is affected much by the distortion of wave-form of fluctuation and unfortunately, some distortion was inevitable since sometimes two hot-wires had to be placed with separation of 10 mm in order to obtain a sufficient phase lag. Thus the accuracy of measured value of c_r may be around 15 percent. Considering this situation, the experimental results at three main-stream velocites show a reasonable agreement with theoretical predictions given by Lessen and Fox for infinite Reynolds number.

The comparison of spacial rate of amplification $\alpha c_i/c_r$ is shown in Fig. 14. The rate is calculated by a relation,

$$\sqrt{\overline{u_f^2}}(x_1)\exp \alpha c_i\cdot(t_2-t_1)=\sqrt{\overline{u_f^2}}(x_2)\,.$$

as proposed by Schubauer and Skramstad[4]. Assuming the relation between time and distance as $x_2-x_1=(t_2-t_1)c_r$, the spacial rate of amplification becomes

$$\frac{\alpha c_i}{c_r}=\frac{1}{x_2-x_1}\log\frac{\sqrt{\overline{u_f^2}}(x_2)}{\sqrt{\overline{u_f^2}}(x_1)}\,.$$

It is noticed here that in the present case the excitation by sound is not local but distributed in the whole flow field. However, since the growth rate of fluctuation is very large, the fluctuation directly caused by the sound at sections of measurement is very small compared with the fluctuation resulted by the amplification of excitation given further upstream. Therefore, there is no essential difference between local and distributed excitations in the case of separated layer.

The rate of amplification is calculated from the data shown in Fig. 10 and compared with theoretical results in Fig. 14. The agreement of measurement and theory is satisfactory.

These three quantities, αc_r, c_r and $\alpha c_i/c_r$ make a complete set of eigenvalues in the linearized equation of small disturbance. The wave length of sinusoidal fluctuations in the natural transition calculated from αc_r and c_r is about 30 in θ unit. Considering that the whole thickness of separated layer is about 6θ, the wave length is around 5 times the layer thickness. These numbers may find some practical use.

The distribution of amplitude of sinusoidal fluctuation is shown in Fig. 15. Measurements were made without artificial excitations, tuning the filter with the frequency of natural fluctuation. The root-mean-square values of spectral component at $X=35$ mm and 70 mm are plotted against $y=Y/\theta$ taking maximum value as unity. These experimental distributions are, therefore, those of amplified oscillations and quite unfortunately, the theoretical calculation on the amplitude function for amplified oscillation is not available. Thus the direct comparison is not possible. In the figure, $\varphi'(y)$ for neutral oscillation for infinite Reynolds number is shown. The theoretical distribution becomes zero at about $y=0.4$ and a 180-degrees phase reversal takes place at the point. For the experimental distribution, such a sharp phase reversal is not possible,

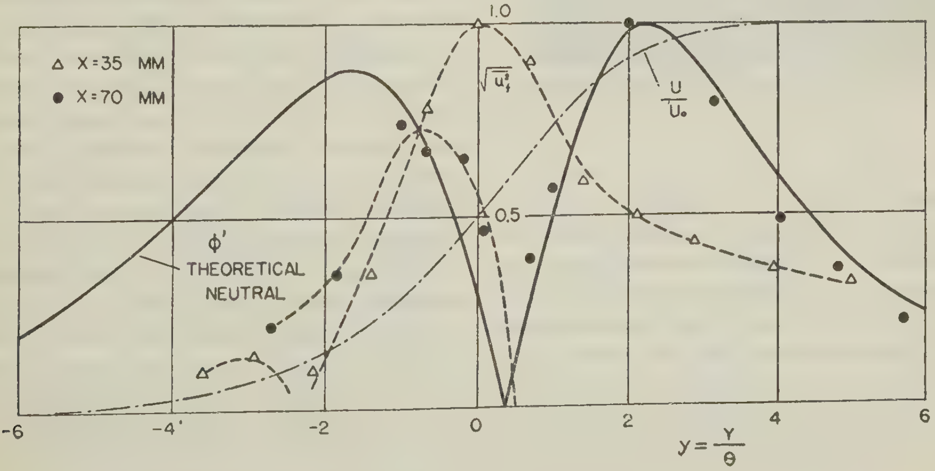

Fig. 15. Amplitude function of sinusoidal velocity fluctuation.

since in the case of amplified oscillation the phase gradually changes in Y-direction. Nevertheless, a large phase shift is observed around $y=-2.3$ for the distribution at $X=35$ mm. Curious distributions as shown in Figs. 7 and 9 (A) at about $Y=-1$ mm are mainly due to this large phase shift in the fundamental component.

Since $\varphi'(y)$ for amplified oscillation can be pretty different from that of neutral oscillation, no concrete conclusion is drawn from Fig. 15. It might be a misunderstanding if one states that at $X=70$ mm the theoretical and experimental distribution is in fair agreement. In fact, at $X=70$ mm, the growth of $\sqrt{\overline{u_f^2}}$ in X-direction is no more exponential. The computation of amplitude function for the amplified oscillation is wanted in order to make more detailed discussion.

A general view of whole flow field was obtained by taking a picture of stream-lines in a water tank. A plate similar to the one used in the wind-tunnel experiment was held fixed in a moving stream. Fine aluminum powder was scattered on the surface of water for the visualization of flow. Fig. 16 shows a single row of vortices in the separated layer.

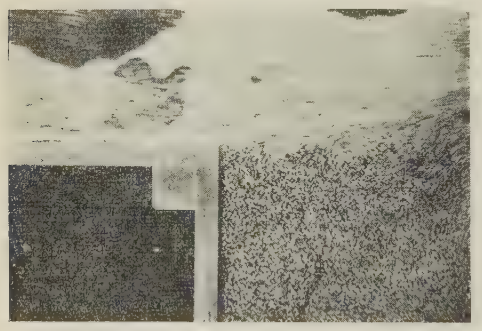

Fig. 16. Picture of stream-line of separated layer taken in a water tank, main-stream velocity, 10 cm/s. Flow from left to right.

Only three vortices are visible since vortex is destroyed further downstream. This kind of configuration of vortices is equivalent to the distribution of amplitude shown in Fig. 15. By a rough estimate, the wave length—distance between two adjacent vortices—is about 35 times of momentum thickness of layer. This number coincides well with that observed in the wind-tunnel by hot-wire anemometers.

§ 5. General Feature of Transition Region

The sinusoidal velocity fluctuation in the separated layer is weak at first and is amplified as the distance downstream is increased. The growth of disturbance is exponential as far as the amplitude remains small. As the fluctuation is amplified more, it gradually changes its wave-form and at the same time, the growth of amplitude becomes more gradual than being exponential. This is clearly illustrated in Fig. 17 in which $(\sqrt{\overline{u^2}}/U_0)_{\max}$ the maximum value of fluctuation level at each X-section is plotted against X. The growth is nearly exponential until $(\sqrt{\overline{u^2}}/U_0)_{\max}$ reaches about 0.03. This linearity limit indicates a point where the non-linear interaction of velocity fluctuations begins. Before the linearity limit is reached, each Fourier component of fluctuation grows independently each other. Beyond this linearity limit, the conventional linearized equation is no more valid and the non-linear interaction should be taken into account. Since the interaction characterizes the turbulent motion, this point where the non-linearity begins, may be appropriately called "transition point". This, however, does not mean that the transition takes place at a point. This definition of transition point seems to be more definite and reasonable than other definitions. In reference 5, it is shown that the same definition is also applicable for the two-dimensional jet as well as the boundary-layer along a flat plate.

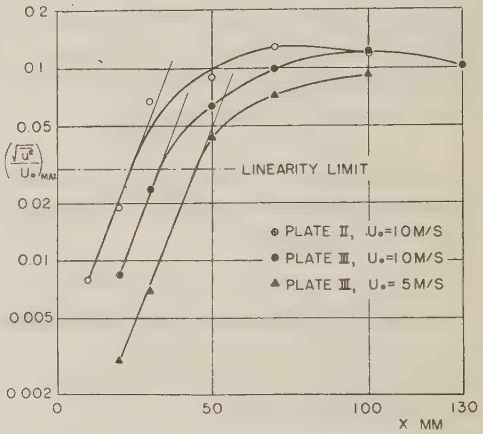

Fig. 17. Logarithmic plot of maximum intensity of velocity fluctuation.

The transition distance determined by the above definition is approximately in agreement with those determined in reference 1 in two ways, one from the growth of thickness of layer and the other from the energy of velocity fluctuation integrated throughout the layer.

Thus the flow field is classified into four regions, namely

(1) Laminar region—There exist no velocity fluctuations.

(2) Linear region—The two-dimensional sinusoidal fluctuation grows exponentially.

(3) Non-linear region—Non-linear interaction and the three-dimensionality of fluctuations are remarkable.

(4) Fully-developed turbulent region—Energy equilibrium is reached.

This classification is applicable for other types of flow which involve transition.

The intermittent burst is not clearly observed in the separated layer. It is true that the amplitude of flucuation does not always remain constant, but the change of amplitude does not necessarily mean the existence of turbulent spot. In fact, the abrupt change of amplitude is not remarkable and the particular pattern of turbulent spot as shown in reference 6 is not observed. As described in reference 5, the intermittent turbulent burst was not observed in the transition region of two-dimensional jet. Considerations given in reference 5 on this point can be applied for the present case.

The effect of artificial excitation in the transition region is summarized as follows:

The transition point shifts upstream as the intensity of excitation is increased. This shift is most remarkable when the frequency of excitation coincides with that of naturally-excited fluctuation. The maximum value of fluctuation in the transition region is apparently increased by artificial excitations. The excitation sometimes changes the distribution of spectral components as shown in Fig. 9. Because of these effects, resulting wave-form of fluctuation in the transition region becomes sometimes very curious as shown in Fig. 6. These all are results of non-linear interaction among spectral components of different wave length as well as components in different directions. Moreover, the dissipation of energy due to viscosity becomes significant when the amplitude of fluctuation becomes large although the viscous effect is negligible for the velocity fluctuation in the linear region. These complicated situations in the non-linear region can not be expressed in a simple formulation, and at present, little is known about the mechanism of non-linear interaction theoretically. In the fully turbulent region, the artificial excitation gives no significant influence.

If we observe from a proper system of coordinates, the sinusoidal fluctuation found in the separated layer is a row of vortices as shown in Fig. 16. At the same time, the vortex street formed behind a cylinder is nothing but the sinusoidal velocity fluctuation if the observation is made by the use of a hot-wire anemometer. Therefore, there are no essential difference between vortex street and sinusoidal fluctuation. Sinusoidal fluctuations already found in the boundary layer along a flat plate⁴⁾ and in the jet⁵⁾ are similar in many points. The fluctuation in the separated layer obviously belongs to the same group. The vortex street formed behind a cylinder is different from these three as mentioned in reference 5.

There are slight distinctions between the boundary layer along a flat plate and the jet in the nature of transition⁵⁾. The separated layer and the jet are much alike and they belong to a same family—the free boundary-layer. A more extensive discussion on the general feature of free boundary-layer is found in reference 7.

§ 6. Conclusion

(1) The sinusoidal velocity fluctuation found in the separated layer corresponds to the disturbance which is unstable and receives maximum amplification in the linearized theory.

(2) Small disturbances superposed on the laminar separated layer grow exponentially as far as their amplitudes remain small. The propagation velocity and the rate of amplification of these disturbances are determined experimentally and they are in good agreement with results of the linearized theory.

(3) The transition point is defined as the limiting point of exponential growth of velocity fluctuation. This point divides the transition region into two parts, linear region and non-

linear region.

(4) The turbulent bursts in the separated layer are much less remarkable than those found in the boundary layer along a flat plate.

On a Method of Successive Approximations applied to the Axisymmetric Flows of an Incompressible Perfect Fluid

By Tamedi SIMASAKI and Keishiro NIU

Department of Physics, University of Osaka Prefecture,
Sakai, Osaka

(Received August 18, 1959)

The fundamental equation for the steady axisymmetric flow of an incompressible inviscid fluid is expressed in a complex form as:

$$\frac{\partial F}{\partial \xi}=\frac{F-\bar{F}}{2(\zeta-\bar{\zeta})}.$$

We here replace this by the following approximate equation:

$$F_N=\int\frac{F_{N-1}-\bar{F}_{N-1}}{2(\zeta-\bar{\zeta})}d\bar{\zeta}+g_N(\zeta)\ ,$$

where F_N and F_{N-1} are the Nth and the $(N-1)$th approximations of the complex velocity potential F respectively, and $g_N(\zeta)$ is an appropriate complementary function of ζ. Treatment of this equation is very simple and its validity is ascertained by numerical calculations for the cases of a sphere and prolate spheroid for which exact solutions are already known. In the case of a sphere, approximate solutions converge uniformly to the exact one, while in the case of a prolate spheroid it is seen that the velocity potential on the surface is rather rapidly improved step by step.

§ 1. Introduction

One of the most important problems in hydrodynamics is to know the velocity distribution around a body placed in a uniform flow. For an incompressible perfect fluid it is possible to obtain the velocity distribution around a two-dimensional body with any sectional form by the method of conformal mapping. In the three-dimensional problem, however, even for the flow around an axisymmetric body with very simple sectional form, no general and simple method exists, except for the so-called slender-body theory, the method of sources and sinks, etc.

In 1953 Imai proposed an ingenious simple method by the use of complex variables for treating axisymmetric flows.[1] On the surface of a sphere, the velocity distribution obtained by Imai's method agrees perfectly with the exact one, but in the case of a prolate spheroid agreement becomes worse as the eccentricity increases. Moreover, at a point not on the surface the agreement is not good even in the case of a sphere.

In the present paper, we develop, by extending Imai's method, a general method of successive approximations to derive the velocity distribution of higher order for the whole field of flow around an axisymmetric body with arbitrary shape.

§ 2. Fundamental Equation

We consider the steady flow of an incompressible perfect fluid past an axisymmetric body which is placed in such a manner that its axis of symmetry (taken as the ξ-axis) coincides with the direction of a uniform flow. In this case it is sufficient to consider the matter only in any one of the planes passing through the ξ-axis. In such a plane we take the η-axis perpendicular to the ξ-axis and denote the velocity components along the ξ- and η-axes by u and v respectively. Then, introducing the velocity potential Φ and Stokes' stream function Ψ, we have

$$\left.\begin{aligned} u&=\frac{\partial\Phi}{\partial\xi}=\frac{1}{\eta}\frac{\partial\Psi}{\partial\eta}\,, \\ v&=\frac{\partial\Phi}{\partial\eta}=-\frac{1}{\eta}\frac{\partial\Psi}{\partial\xi}\,, \end{aligned}\right\} \qquad (1)$$

These equations may be rewritten as:

$$\left.\begin{aligned} \frac{\partial\Phi}{\partial\xi}&=\frac{\partial}{\partial\eta}\left(\frac{\Psi}{\eta}\right)+\frac{\Psi}{\eta^2}\,, \\ \frac{\partial\Phi}{\partial\eta}&=-\frac{\partial}{\partial\xi}\left(\frac{\Psi}{\eta}\right). \end{aligned}\right\} \qquad (2)$$

We now introduce conjugate complex variables:

$$\zeta=\xi+i\eta\,,\quad \bar{\zeta}=\xi-i\eta\,, \qquad (3)$$

so that

$$\left.\begin{aligned} \frac{\partial}{\partial\zeta}&=\frac{1}{2}\left(\frac{\partial}{\partial\xi}-i\frac{\partial}{\partial\eta}\right), \\ \frac{\partial}{\partial\bar{\zeta}}&=\frac{1}{2}\left(\frac{\partial}{\partial\xi}+i\frac{\partial}{\partial\eta}\right). \end{aligned}\right\} \qquad (4)$$

Then we have, from (2),

$$\frac{\partial\Phi}{\partial\bar{\zeta}}+i\frac{\partial}{\partial\bar{\zeta}}\left(\frac{\Psi}{\eta}\right)=\frac{\Psi}{2\eta^2}\,, \qquad (5)$$

which may also be written as:

$$\frac{\partial F}{\partial\bar{\zeta}}=\frac{F-\bar{F}}{2(\zeta-\bar{\zeta})}\,, \qquad (6)$$

where

$$F=\Phi+i\frac{\Psi}{\eta}\,, \qquad (7)$$

and $\bar{F}$ is the conjugate function to F. Hereafter we call F the "complex velocity potential".

Eq. (6) is the fundamental equation for our problem to be solved under appropriate boundary conditions.

§ 3. Boundary Conditions and an Equation for Successive Approximations

The function F must satisfy not only the fundamental equation (6) but also appropriate boundary conditions, which are reduced to the following three parts:

(i) The function F must agree with the expression for the uniform flow at infinity;

(ii) The velocity components normal to the axis of symmetry as well as to the surface of the obstacle must be zero;

(iii) Stokes' stream function Ψ along the axis of symmetry as well as on the surface of the obstacle must be zero.

It is to be remarked here that the conditions (ii) and (iii) are of course synonimous to each other theoretically.

It is very difficult to find out intuitively the function F satisfying Eq. (6) subject to the above boundary conditions. In applying the boundary conditions, it will be convenient to transform the ζ-plane to a new z-plane in which the inside of the unit circle corresponds to the sectional area of the body in the ζ-plane. We denote such a transformation function by

$$\zeta=\zeta(z)\,, \qquad (8)$$

which may be obtained by the use of usual methods, such as Imai's one.[2)]

Then, with the new independent variables z and $\bar{z}$, the fundamental equation (6) is expressed by

$$\frac{\partial F}{\partial\bar{z}}=\frac{F-\bar{F}}{2(\zeta-\bar{\zeta})}\frac{d\bar{\zeta}}{d\bar{z}}\,, \qquad (9)$$

which is integrated with respect to $\bar{z}$, giving

$$F=\int\frac{F-\bar{F}}{2(\zeta-\bar{\zeta})}\frac{d\bar{\zeta}}{d\bar{z}}d\bar{z}+g(z)\,, \qquad (10)$$

where $g(z)$ is a complementary function of z alone which should be determined subjected to the boundary conditions (i) and (ii) or (i) and (iii).

Eq. (10) is an integral equation for F and there is no general method to solve it. Accordingly we adopt here a method of successive approximations or a method of iterations as follows. Namely, we replace Eq. (10) by the following equation:

$$F_N=\int\frac{F_{N-1}-\bar{F}_{N-1}}{2(\zeta-\bar{\zeta})}\frac{d\bar{\zeta}}{d\bar{z}}d\bar{z}+g_N(z), \qquad (11)$$

where F_N and F_{N-1} are the Nth and $(N-1)$th approximations of F respectively. Since, however, F_{N-1} is merely an approximation as obtained in the preceding stage of iteration, it is doubtful that the complementary function $g_N(z)$ as determined by using the conditions (i) and (ii) satisfies the remaining condition (iii) as well at the same time, and also it cannot be expected that the condition (ii) is satisfied as well in the case of using the conditions (i) and (iii) for determining the function $g_N(z)$.

Therefore, if we introduce two pairs of expressions for the velocity components along the r- and θ-directions in the ζ-plane as:

$$v_{rN}=\frac{\partial \Phi_N}{\partial r}, \qquad v_{\theta N}=\frac{1}{r}\frac{\partial \Phi_N}{\partial \theta}, \qquad (12)$$

and

$$v'_{rN}=\frac{1}{\eta}\frac{\partial \Psi_N}{r\partial \theta}, \qquad v'_{\theta N}=-\frac{1}{\eta}\frac{\partial \Psi_N}{\partial r}, \qquad (13)$$

v_{rN} will not agree with v'_{rN} and $v_{\theta N}$ will not agree with $v'_{\theta N}$.

But if we choose an appropriate zeroth approximation F_0 as the starting solution and select suitable two conditions out of the three boundary conditions (i), (ii) and (iii), we can improve the convergency of F_N.

In the present paper, we choose (i) and (iii) for the boundary conditions and check the discrepancies between each approximate solution and the exact one. Thus the remaining problem is to choose an appropriate zeroth approximation F_0. The choice of F_0 is, however, rather arbitrary. For example, we can choose as F_0 the complex velocity potential for the uniform flow which should be disturbed by the insertion of an obstacle or the potential for the flow past a sphere with diameter of the same order as the mean diameter of the obstacle concerned. We adopt here the expression for the uniform flow, since it is the simplest one.

In the subsequent sections, we shall build up concrete expressions for the complex velocity potentials and calculate numerical values of the velocity components or the velocity potentials for the cases of a sphere and prolate spheroids with various eccentricities.

§ 4. Case of a Sphere

In this case the transformation function is given by $\zeta(z)=z$. We here consider a uniform flow with unit speed along the positive direction of the x-axis.

When a sphere of unit radius is placed in the uniform flow with its center at the origin of the coordinate system, the velocity potential Φ_0 and Stokes' stream function Ψ_0 for the zeroth approximation are respectively given by

$$\Phi_0=x=\frac{1}{2}(z+\bar{z}), \qquad (14)$$

$$\Psi_0=\frac{1}{2}y^2=-\frac{1}{8}(z-\bar{z})^2, \qquad (15)$$

where

$$z=x+iy \quad \text{and} \quad \bar{z}=x-iy.$$

Then, by (7), the zeroth approximation F_0 for the complex velocity potential becomes

$$F_0=\frac{3}{4}z+\frac{1}{4}\bar{z}. \qquad (16)$$

The first approximation F_1 can be obtained by substituting F_0 in the right-hand side of Eq. (11). Thus we have

$$F_1=\int\frac{z-\bar{z}}{4(z-\bar{z})}d\bar{z}+g_1(z)=\frac{1}{4}\bar{z}+g_1(z). \qquad (17)$$

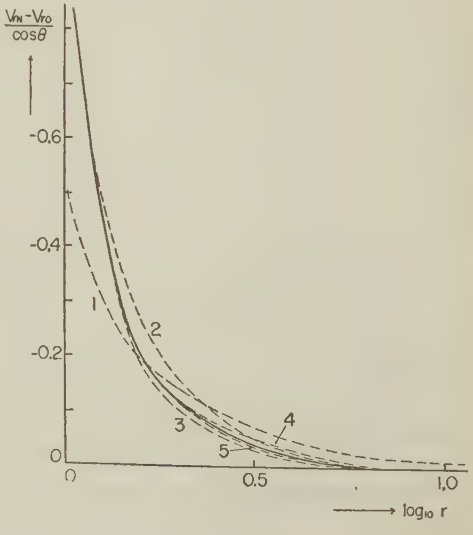

Fig. 1.

The complementary function $g_1(z)$ is easily determined by considering the relation $z\bar{z}=1$ on the surface of the sphere and the boundary conditions (i) and (iii), obtaining

$$g_1(z)=\frac{3}{4}z+\frac{1}{2z}\,. \tag{18}$$

Thus the first approximation F_1 for the complex velocity potential becomes ultimately

$$F_1=\frac{3}{4}z+\frac{1}{4}\bar{z}+\frac{1}{2z}=F_0+\frac{1}{2z}\,. \tag{19}$$

By repeating similar procedures, higher approximate solutions can be obtained step by step. Thus, we have

$$\left.\begin{aligned}
F_2&=F_1-\frac{1}{2^2\cdot 1!\,z}\log(z\bar{z})\,,\\
F_3&=F_2+\frac{1}{2^3\cdot 2!\,z}\log^2(z\bar{z})\,,\\
&\cdots\cdots\cdots\cdots\cdots\cdots\\
F_N&=F_{N-1}+(-1)^{N-1}\frac{1}{2^N\cdot(N-1)!\,z}\log^{N-1}(z\bar{z}),\\
&\cdots\cdots\cdots\cdots\cdots\cdots
\end{aligned}\right\} \tag{20}$$

The last one can easily be verified by mathematical induction.

Figs. 1 and 2 show how the velocity distributions obtained by Eqs. (19) and (20) converge to the exact one. In Fig. 1, $(v_{rN}-v_{r0})/\cos\theta$ is taken as the ordinate, where v_{r0} is the radial velocity component of the uniform flow, and $\log_{10} r$ is chosen as the abscissa, in which r is the distance from the origin. Fig. 2 shows the behaviours of the convergency in the relation $\log_{10} r$ versus $(v_{\theta N}-v_{\theta})/\sin\theta$. The curves of $(v'_{rN}-v_{r0})/2\cos\theta$ and $(v'_{\theta(N+1)}-v_{\theta 0})/\sin\theta$ coincide perfectly with the corresponding curves in Fig. 2 for the same values of N.

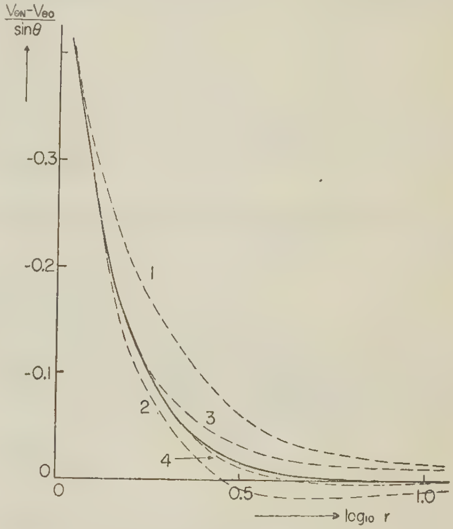

Fig. 2.

The full lines in both figures correspond to the exact solutions. All these figures indicate that our approximate solutions (19) and (20) converge rather rapidly to the exact one, and especially that the curves for the velocity component v_{rN} converge faster than those for v'_{rN} and also the curves for $v_{\theta N}$ converge faster than those for $v'_{\theta N}$. By tending N to infinity, we have, from the expression for the Nth approximate solution F_N given in (20),

$$\begin{aligned}
F_\infty&=\lim_{N\to\infty}\left[\frac{3}{4}z+\frac{1}{4}\bar{z}+\frac{1}{2^1\cdot 0!\,z}\log^0(z\bar{z})-\frac{1}{2^2\cdot 1!\,z}\log^1(z\bar{z})+\cdots\right.\\
&\qquad\left.+(-1)^{N-1}\frac{1}{2^N\cdot(N-1)!\,z}\log^{N-1}(z\bar{z})\right]\\
&=\frac{3}{4}z+\frac{1}{4}\bar{z}+\frac{1}{2z}e^{-(1/2)\log(z\bar{z})}=\frac{3}{4}z+\frac{1}{4}\bar{z}+\frac{1}{2z\sqrt{z\bar{z}}}\,.
\end{aligned} \tag{21}$$

On the other hand, the corresponding exact formulae for the velocity potential and Stokes' stream function are given by Lamb[3] in the forms:

$$\Phi_e=\left(r+\frac{1}{2r^2}\right)\cos\theta\,,\qquad \Psi_e=\frac{1}{2}\left(r^2+\frac{1}{r}\right)\sin\theta\,, \tag{22}$$

from which we obtain, by using the relations $z=re^{i\theta}$ and $\bar{z}=re^{-i\theta}$, the exact expression for the complex velocity potential as:

$$\begin{aligned}
F_e&=\Phi_e+i\frac{\Psi_e}{r\sin\theta}=r\cos\theta+\frac{i}{2}r\sin\theta+\frac{1}{2r^2}(\cos\theta+i\sin\theta)\\
&=\frac{3}{4}z+\frac{1}{4}\bar{z}+\frac{1}{2z\sqrt{z\bar{z}}}\,.
\end{aligned} \tag{23}$$

It will be seen that this expression is in complete agreement with (21).

§ 5. Case of a Prolate Spheroid

An ellipse in the ζ-plane is mapped onto the unit circle in the z-plane by Joukowski's transformation:

$$\zeta=z+\frac{\sigma^2}{z}\,, \tag{24}$$

where σ is connected with the semi-major and semi-minor axes a and b of the ellipse as:

$$a=1+\sigma^2\,, \qquad b=1-\sigma^2\,. \tag{25}$$

In this case, the expression of the complex velocity potential for the uniform flow is given by

$$F_0=\frac{3}{4}\left(z+\frac{\sigma^2}{z}\right)+\frac{1}{4}\left(\bar{z}+\frac{\sigma^2}{\bar{z}}\right). \tag{26}$$

Inserting (26) in the right-hand side of (11) and choosing the complementary function so as to satisfy the boundary conditions (i) and (iii), we get the following first approximate solution for the prolate spheroid:

$$F_1=F_0+\frac{1-\sigma^2}{2z}\,. \tag{27}$$

By similar procedures the second and third approximations can be obtained, and we have

$$\begin{aligned}F_2=F_1+\frac{1-\sigma^2}{4}\Bigg[&\frac{1}{z}+\frac{1+\sigma^2}{\sigma^2 z}\log(1-\sigma^2)+\frac{1}{\bar{z}}-\frac{z}{\sigma^2}\log(z\bar{z})\\&+\left(\frac{z}{\sigma^2}-\frac{1}{z}\right)\log(z\bar{z}-\sigma^2)\Bigg]\,,\end{aligned} \tag{28}$$

$$\begin{aligned}F_3=F_2+\frac{1-\sigma^2}{8}\Bigg[&\left\{\frac{1+\sigma^2}{\sigma^2}\log(1-\sigma^2)+\frac{1+\sigma^2}{\sigma^4}\log^2(1-\sigma^2)+\frac{1-\sigma^2}{\sigma^2}L_2(\sigma^2)\right\}\frac{1}{z}\\&+\frac{1+\sigma^2}{\sigma^2\bar{z}}\log(1-\sigma^2)+\frac{1}{2z}\log^2(z\bar{z})+\left(\frac{1}{z}-\frac{z}{\sigma^2}\right)\{\log(z\bar{z}-\sigma^2)-\log(z\bar{z})\}\log(z\bar{z}-\sigma^2)\\&+\left(\frac{1}{z}+\frac{z}{\sigma^2}\right)L_2\left(\frac{\sigma^2}{z\bar{z}}\right)-\left\{\frac{1}{\sigma^2}(z+\bar{z})+\frac{1+\sigma^2}{\sigma^4}z\log(1-\sigma^2)\right\}\log(z\bar{z})\\&+\left\{\frac{z\bar{z}-\sigma^2}{\sigma^2}\left(\frac{1}{z}+\frac{1}{\bar{z}}\right)+\frac{1+\sigma^2}{\sigma^4}\left(z+\frac{\sigma^2}{z}\right)\log(1-\sigma^2)\right\}\log(z\bar{z}-\sigma^2)\Bigg]\,,\end{aligned} \tag{29}$$

where $L_2(x)$ is Euler's dilogarithm[4)] defined by

$$L_2(x)=\sum_{\gamma=1}^{\infty}\frac{x^\gamma}{\gamma^2}=-\int_0^x\frac{\log(1-y)}{y}dy=\int_0^1\frac{\log y}{y-(1/x)}dy\,. \tag{30}$$

In this case we use the velocity potential itself instead of the velocity in order to see how these solutions converge to the exact one. In this first three stages of approximations, the perturbed velocity potentials ϕ_1, ϕ_2 and ϕ_3 on the surface of the spheroid can be obtained from (27), (28) and (29) respectively. Thus, omitting the term which corresponds to the uniform flow, we have

$$\begin{aligned}\phi_1&=\frac{1-\sigma^2}{2}\cos\theta\,,\\\phi_2&=\frac{1-\sigma^2}{2}\left[2+\frac{1}{\sigma^2}\log(1-\sigma^2)\right]\cos\theta\,,\\\phi_3&=\frac{1-\sigma^2}{2}\left[2+\frac{1}{\sigma^2}\log(1-\sigma^2)+\frac{1}{2\sigma^4}\log^2(1-\sigma^2)+\frac{1}{2\sigma^2}L_2(\sigma^2)\right]\cos\theta\,.\end{aligned} \tag{31}$$

On the other hand, the corresponding exact perturbed velocity potential ϕ_e on the surface of the prolate spheroid is given by Lamb³⁾ in the form:

$$\phi_e = \frac{(1-\sigma^2)^2\{(1+\sigma^2)\log[(1+\sigma)/(1-\sigma)]-2\sigma\}}{2\sigma(1+\sigma^2)-(1-\sigma^2)^2\log[(1+\sigma)/(1-\sigma)]}\cos\theta\ . \tag{32}$$

e	σ^2	ϕ_1/ϕ_e	ϕ_2/ϕ_e	ϕ_3/ϕ_e
0	0	1.0000	1.0000	1.0000
0.1	0.0025	1.0008	0.9994	0.9997

1.0	1.0000	∞	-∞	∞

Table I.

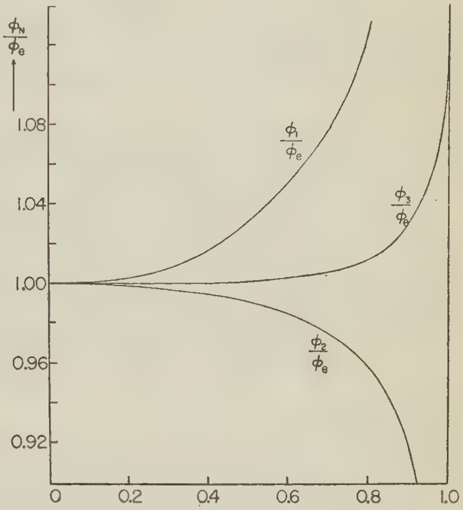

Fig. 3.

Table I and Fig. 3 show how the values of the ratio ϕ_N/ϕ_e ($N=1,\ 2,\ 3$) converge with increasing N for various values of the eccentricity e of the meridian section of the spheroid, where

$$e=\frac{\sqrt{a^2-b^2}}{a}=\frac{2\sigma}{1+\sigma^2}\ . \tag{33}$$

§ 6. Summary

We can see from numerical results obtained in the preceding two paragraphs that the expressions for the axisymmetric flows as given by the iterative use of Eq. (11) together with the boundary conditions (i) and (iii) are improved step by step with the orders of approximation and converge to the exact one in the whole field of flow. Especially in the case of a sphere, the final exact form of the complex velocity potential is obtained straightforwardly, and as for the velocity distribution on the surface, it is obtained exactly in the first stage of approximation. In the case of a prolate spheroid, on the contrary, the velocity potential on the surface is not given exactly in each stage of approximation, but the convergency in the whole field of flow is satisfactorily good.

Thus it may be concluded that the iterative use of Eq. (11) is powerful for dealing with the axisymmetric flow past any obstacle with arbitrary section.

In conclusion, the writers wish to express their cordial thanks to Prof. S. Tomotika for his continual encouragement and also for his kind inspection of the manuscript.

The W.K.B. Method for the Differential Equations of the Fourth Order

By Tomoyuki SAITO* and Isao OSHIDA**

**Tokyo University of Agriculture and Technology,*
Koganei, Tokyo
***Kobayasi Institute of Physical Research,*
Kokubunji, Tokyo

(Received August 31, 1959)

Here are studied some types of differential equations of the fourth order, to which the so-called W.K.B. method can be easily extended, and presented some exemplifying solutions up to the first order of approximation. As a physical example, the equation of lateral bending vibration of a not-completely flexible string, whose cross section of finite size is slowly varying along its length, and whose ends are both clamped, is solved. It is also shown that the terms of the first and the third differentation of a linear differential equation of the fourth order can be eliminated by a suitable transformation.

§ 1. Introduction

Not a few linear differential equations of the fourth order are encountered with in physics, which are so important as to require to be solved without diminishing their order, either in order to preserve their physical meaning or to lose no more in the degree of precision of their solutions, although there is the possibility that some of them can be simplified into those of the second order under suitable assumptions.

Although a general method of solving linear differential equations of the fourth order of a general type is not available as yet, many of them appearing in physics happen to take favorable forms or qualities, to our good luck, which make it possible to apply the W. K. B. method.[1]

Generally, a linear differential equation of the fourth order is written in the following form:

$$a(x)y''''+f(x)y'''-y''+g(x)y'-b(x)y=0, \qquad (1)$$

where a, b, f and g are generally functions of the non-dimensionalized independent variable x, and one prime above the unknown function $y(x)$ means one differentiation by x, and so on.

In physics, however, cases are often met with, where f and g are suitably small or sometimes zero, and at the same time a and b are suitably slowly varying functions. The very situation permits our application of the W.K.B. method.

As there are many cases realizing the situation, however, we confine ourselves, here, only to some exemplifying cases.

§ 2. Possibility of Getting Clear of Terms of the First and the Third Differentiation

The original differential equation (1) is written as

$$y''''+A(x)y'''+B(x)y''+C(x)y'+D(x)y=0. \qquad (2)$$

If Eq. (2) could be transformed into one without the terms of the first and the third differentiation, our task of applying the W.K. B. method would be much easier.

By changing both the dependent and independent variables, y and x, to the new ones, u and t, respectively, by the following relations:

$$y\equiv u\cdot\exp\left[-\int\{A+6\zeta)/4\}dx\right],$$

and

$$\frac{dt}{dx}\equiv\exp\left[\int\zeta dx\right],$$

where ζ may be any function of x, satisfying the following non-linear differential equation:

$$\zeta''-3\zeta\zeta'+\zeta^3-(3/5)(A'+A^2/4-2B/3)\zeta$$
$$+(A''-A^3/8+AB/2-C)=0,$$

so the new differential equation concerning $u(t)$ comes out with the intended form.

It is, however, not always possible to find such ζ exactly. Therefore we start with the general form (1). However, the terms of the first and the third differentiation are assumed to be small.

§ 3. W.K.B. Method

By means of putting

$$y \equiv \exp\left[\int \eta(x)\,dx\right],$$

Eq. (1) is transformed into the following equivalent one:

$$a(\eta^4+6\eta^2\eta'+4\eta\eta''+3\eta'^2+\eta''')$$
$$+f(\eta^3+3\eta\eta'+\eta'')-(\eta^2+\eta')+g\eta-b=0. \quad (3)$$

Our conditions are assumed to be such that a, b, f and g are so qualified as to permit the zeroth approximation η_0 on behalf of the true solution of Eq. (3) to be obtained from the following equation:

$$a\eta^4+f\eta^3-\eta^2+g\eta-b=0\,. \quad (4)$$

The first approximation η_1 will be obtained after the necessary order-estimation of the magnitude of the terms in Eq. (3), thus giving the corresponding solution

$$y_1=\exp\left[\int \eta_1 dx\right] \quad (5)$$

as the one with the approximation of the first order.

But the roots of an algebraic equation (4) of the fourth order is not generally expressed in a simple form in terms of its coefficients, and so we confine ourselves, here, to the cases where η_0 is allowed to be obtained from the following equation in the place of Eq. (4):

$$a\eta^4-\eta^2-b=0\,. \quad (6)$$

From Eq. (6) we have

$$\eta^2=(1\pm\sqrt{1+4ab})/2a\,,$$

which turns to the following, according to the value of $|ab|$:

$$\begin{array}{ll} \eta_0{}^2=1/a \text{ or } -b & \text{when } |ab|\ll 1 \\ =\pm\sqrt{b/a} & \text{when } |ab|\gg 1 \\ =(1\pm\sqrt{1+4ab})/2a & \text{when } |ab|\sim O(1)\,. \end{array}$$

These three cases are discussed separately in the following.

Case I: $|ab|\ll 1$

(a) $\eta_0=a^{-1/2}$

For this η_0 to be permitted as the zeroth approximation, the following condition is necessary and sufficient:

$|a'/a^{1/2}|\ll 1$, $|a''|\ll 1$, $|a^{1/2}a'''|\ll 1$, $|f/a^{1/2}|\ll 1$,
$|a^{1/2}g|\ll 1$, besides $|ab|\ll 1$.

There are many variations of cases satisfying the above condition. Among them the following case is examined as typical one.

Example:
When

$$ab\sim a'/a^{1/2}\sim f/a^{1/2}\sim a^{1/2}g\sim O(\epsilon)\,,$$
$$a''\sim O(\epsilon^2)\,, \qquad a^{1/2}a'''\sim O(\epsilon^3)\,,$$

where ϵ means a small quantity compared to unity, then the first approximation (5) is given by

$$y_1=a^{5/4}\exp\left[\int(a^{-1/2}+a^{1/2}b/2-f/2a-g/2)\,dx\right].$$

(b) $\eta_0=(-b)^{1/2}$

The condition for this η_0 to be the zeroth approximation is:

$|b'/b^{3/2}|\ll 1$, $|(b''/b^2)\cdot ab|\ll 1$, $|(b'''/b^{5/2})\cdot ab|\ll 1$,
$|b^{1/2}f|\ll 1$, $|(b''/b^2)\cdot b^{1/2}f|\ll 1$, $|g/b^{1/2}|\ll 1$,

besides

$$|ab|\ll 1\,.$$

Example:
If

$$ab\sim b'/b^{3/2}\sim b^{1/2}f\sim g/b^{1/2}\sim O(\epsilon)\,,$$

and

$$|b''/b^2|\lesssim O(\epsilon)\,, \qquad |b'''/b^{5/2}|\lesssim O(\epsilon)\,,$$

then

$$y_1=b^{-1/4}\exp\left[\int\{(-b)^{1/2}+a(-b)^{3/2}/2-bf/2$$
$$+g/2\}\,dx\right],$$

being correct to the order of ϵ.

It is noted here that the conditions concerning f and g in (a) are different from those in (b), respectively. Under the condition $|ab|\ll 1$, the conditions $|b^{1/2}f|\ll 1$ and $|a^{1/2}g|\ll 1$ follow from the ones $|f/a^{1/2}|\ll 1$ and $|g/b^{1/2}|\ll 1$, respectively.

Therefore, when (a) and (b) are combined to yield the four η_0's, $\pm a^{-1/2}$ and $\pm(-b)^{1/2}$, as the four zeroth-approximation solutions of Eq. (3), simultaneously, the last-mentioned conditions, $|f/a^{1/2}[\ll 1$ and $|g/b^{1/2}|\ll 1$, should replace the preceding ones, $|b^{1/2}f|\ll 1$, and $|a^{1/2}g|\ll 1$ respectively, throughout both (a) and (b).

Case II:

$$|ab|\gg 1\,, \qquad \eta_0=(b/a)^{1/4}\,.$$

If it is assumed that

$$(1/ab)\sim O(\epsilon^4)\,,$$

the condition for which this η_0 is the zeroth approximation is:

$|a'/a^{1/2}|\cdot\epsilon\ll 1$, $|a''|\cdot\epsilon^2\ll 1$, $|a^{1/2}a'''|\cdot\epsilon^3\ll 1$,
$|a^{1/2}(ab)'|\cdot\epsilon^5\ll 1$, $|a(ab)''|\cdot\epsilon^6\ll 1$,

$$|a^{3/2}(ab)'''|\cdot\epsilon^7\ll 1,\ |b'/b^{3/2}|\ll\epsilon,\ |b''/b^2|\ll\epsilon^2,$$
$$|b^{1/2}f|\,\epsilon^3\ll 1,\ |g/b^{1/2}|\cdot\epsilon\ll 1\,.$$

Example 1:

When

$$ab\sim a^{1/2}(ab)'\sim O(\epsilon^{-4}),\ \ a(ab)''\sim O(\epsilon^{-5}),$$
$$a^{3/2}(ab)'''\sim O(\epsilon^{-6}),$$
$$a'/a^{1/2}\sim O(1),\ a''\sim O(\epsilon^{-1}),\ a^{1/2}a'''\sim O(\epsilon^{-2})\,,$$
$$f/a^{1/2}\sim O(1),\ \ a^{1/2}g\sim O(\epsilon^{-2})\,,$$

and

$$b'/b^{3/2}\sim O(\epsilon^2),\ b''/b^2\sim O(\epsilon^3),\ \ b'''/b^{5/2}\sim O(\epsilon^4),$$

then the first approximation is

$$y_1=(a/b)^{3/8}\exp\,[\int(b/a)^{1/4}\{1+a''/2(ab)^{1/2} -a(ab)''/4(ab)^{3/2}+a^{1/2}a'''/8(ab)^{3/4} -a^{3/2}(ab)'''/16(ab)^{7/4}-(f/a^{1/2})/4(ab)^{1/4} -a^{1/2}g/4(ab)^{3/4}\}\,dx]\,,$$

which is correct to the order of ϵ.

Example 2:

The function

$$y=x^5\exp\,[-1/x^2]$$

is an exact solution of the differential equation

$$(x^4/4)y''''-y''-(4/x^8+1/x^4+10/x^2+30)y=0\,.$$

This equation tends to the following one for sufficiently small x:

$$(x^4/4)y''''-y''-(4/x^8)y=0 \tag{7}$$

In this case,

$$a=x^4/4,\qquad b=4/x^8,\qquad f=g=0\,,$$

and for $x\sim O(\epsilon)$,

$$ab\sim O(\epsilon^{-4}),\ a^{1/2}(ab)'\sim O(\epsilon^{-3}),\ a(ab)''\sim O(\epsilon^{-2}),$$
$$a^{3/2}(ab)'''\sim O(\epsilon^{-1}),$$
$$a'/a^{1/2}\sim O(\epsilon),\ a''\sim O(\epsilon^2),\ a^{1/2}a'''\sim O(\epsilon^9),$$
$$b'/b^{3/2}\sim O(\epsilon^3),\ b''/b^2\sim O(\epsilon^6),\ b'''/b^{5/2}\sim O(\epsilon^4).$$

The following formula, being correct to the order of ϵ^2, is obtained for the first approximation solution of Eq. (7):

$$y_1=(a/b)^{3/8}\exp\,[\int(b/a)^{1/4}\{1+1/4(ab)^{1/2}\}dx]$$
$$=\begin{cases} x^5\exp\,[-1/x^2],\qquad x^4\exp\,[1/x^2] \\ \text{and} \\ x^{9/2}\cos\,(1/x^2+\ln x/2),\ x^{9/2}\sin(1/x^2+\ln x/2). \end{cases}$$

Case III:

$$|ab|\sim O(1),\qquad \eta_0=(1\pm\sqrt{1+4ab})/2a.$$

Here the condition for the validity of the zeroth approximation is:

$$|a'/a^{1/2}|\ll 1,\quad |a''|\ll 1,\quad |a^{1/2}a'''|\ll 1,$$
$$|a^{1/2}(ab)'|\ll 1,\quad |a(ab)''|\ll 1,\quad |a^{3/2}(ab)'''|\ll 1,$$
$$|f/a^{1/2}|\ll 1,\quad |a^{1/2}g|\ll 1,\quad \text{besides }|ab|\sim O(1$$

Example:

When

$$|a^{1/2}a'''|\ll|a''|\ll|a'/a^{1/2}|\ll 1,$$
$$|a^{3/2}(ab)'''|\ll|a(ab)''|\ll|a^{1/2}(ab)'|\ll 1,\ |ab|\sim O(1$$

and accordingly

$$|b'''/b^{5/2}|\ll|b''/b^2|\ll|b'/b^{3/2}|\ll 1\,,$$

their magnitudes being of the order of ϵ^3, ϵ and ϵ, respectively, according to their arra from left to right, and moreover

$$f/a^{1/2}\sim a^{1/2}g\sim O(\epsilon),$$

then the first approximation is

$$y_1=\exp\Bigg[\int\Bigg\{\left(\frac{1\pm\sqrt{1+4ab}}{2a}\right)^{1/2}-\frac{1\pm(3/2)\sqrt{1+4ab}}{1\pm\sqrt{1+4ab}}\cdot\frac{(ab)'}{1+4ab}+\left(1\pm\frac{2}{3}\cdot\frac{1}{\sqrt{1+4ab}}\right)\frac{3}{4}\frac{a'}{a} -\left(1\pm\frac{1}{\sqrt{1+4ab}}\right)\frac{f}{4a}-\frac{1}{(\pm\sqrt{1+4ab})}\cdot\frac{g}{2}\Bigg\}dx\Bigg],$$

being correct to the order of ϵ.

Of the signs + and − in front of the root $\sqrt{1+4ab}$, the same ones are to be chosen. For each case of the plus or the minus sign, there are two alternative solutions corresponding to + and − in front of $\{(1\pm\sqrt{1+4ab})/2a\}^{1/2}$.

§ 4. Lateral Bending Vibration of a String Not-Completely Flexible with Finite Cross Section

The lateral bending vibration of a string with finite cross section S, under the tension T, obeys the following differential equation:

$$\rho S\frac{\partial^2 y}{\partial t^2}=\frac{\partial}{\partial s}\left(T\frac{\partial y}{\partial s}\right)-\frac{\partial^2}{\partial s^2}\left(ESk^2\frac{\partial^2 y}{\partial s^2}\right),$$

where ρ is the density, E the Young's modulus of elasticity, ρSk^2 the moment of inertia of the cross section of unit thickness around the line through its center perpendicular to both the string and the displacement y, and s measures the distance along the string.

When the cross section S is constant along the string, together with the other quantities ρ, T, E and k^2, the differential equation is reduced to the one with constant coefficients, and can be solved immediately, giving the following result[2)] for the approximate values of the eigenfrequencies $\omega_n(0)$ of a string of length l, not-completely flexible with its cross section of finite and constant size, and with its ends both clamped:

$$\omega_n(0)\approx(n\pi/l)\sqrt{T/\rho S_0}(1+2\sqrt{ES_0k_0^2/Tl^2}) .$$

S_0 and k_0 mean the constant values of S and k, respectively, and n the order of the eigen-vibrations.

When the constancy of these coefficients breaks down, the situation develops a new phase and we find ourselves at a loss how to meet it.

It their variations upon s are not large, however, we are afforded an opportunity to apply the W.K.B. method.

For a simple illustration, we consider the case where the cross section varies with the distance s, symmetrically on both sides of the middle-point of the string, as follows:

$$S=S_0(1+\alpha x)^2\approx S_0(1+2\alpha x) ,$$
$$k=k_0(1+\alpha x) ,$$
$$|\alpha|\ll 1 , \qquad \text{where } x\equiv s/l .$$

The suffix zero is specified to the values at the middle-point ($x=0$). The other quantities ρ, T and E are assumed to be constant.

As "not-completely flexible" means that the size of the cross section is finite, but small, we assume that

$$\alpha\sim O(\epsilon^{2/3})$$

and

$$S_0/l^2\sim O(\epsilon^{1/3}) , \quad \text{accordingly} \quad k_0/l\sim O(\epsilon^{1/6}) .$$

for instance.

Then it is easily shown that the orders of magnitude of the necessary quantities are as follows:

$$ab\sim a'/a^{1/2}\sim f/a^{1/2}\sim b''/b^2\sim O(\epsilon),$$
$$b'/b^{3/2}\sim O(\epsilon^{1/2}) ,$$
$$a''\sim O(\epsilon^2) , \qquad a^{1/2}a'''\sim O(\epsilon^3), \quad b'''=g=0.$$

This case is classified to Case I.

Omitting the detail of the calculation, the resultant eigenfrequencies are correctly written to the order of $\epsilon^{2/3}$, as follows:

$$\omega_n(\alpha)\approx(n\pi/l)\cdot\sqrt{T/\rho S_0}\cdot(1+2\sqrt{ES_0k_0^2/Tl^2}-\alpha/4),$$

which coincides with $\omega_n(0)$ at the limit of vanishing α, as is expected.

§ 5. Summary

Guided by the principle of the W.K.B. method devised originally for the linear differential equations of the second order, it is considered how to solve those of the fourth order along the same line. The cases are studied, where some special qualifications of the coefficients in the equations permit successful attacks by means of the method.

Some examples are shown with corresponding solutions being correct up to the first order of approximation in each case.

As a simple illustration, the lateral bending vibration of a not-completely flexible string with finite cross section slowly varying along its length, symmetrically on both sides of its middle-point and clamped at both its ends, is discussed.

It is to be said that, in the present paper, rather small portion is surveyed of the vast area where the W.K.B. method would be applicable at least in principle. For instance, in getting η_0 as a starting function of the zeroth approximation, we have had recourse to Eq. (6) instead of Eq. (4), with preference for easiness to trouble. But in order to cover more area for application, the fullest possible use of the latter equation (4) deserves and awaits further consideration.

The authors are indebted to the Ministry of Education for the Scientific Research Fund granted to the Research Group for the Study of Atomic and Molecular Structure.

Antiferromagnetism of $Mn_{3.25}$ Ge

By Kō YASUKŌCHI

Department of Physics, Faculty of Science, University of Tokyo

Tetsuo OHOYAMA

Department of Physics, Faculty of Science, Tokyo Metoropolitan University

Kazuo KANEMATSU

(Received October 29, 1959)

It was reported by U. Zwicker et al.[1] that Mn–Ge system contained four intermetallic compounds, Mn_5Ge_3, Mn_5Ge_2, Mn_3Ge_2 and $Mn_{3.25}Ge$, and that the former two were strongly ferromagnetic, while the latter two were presumably weakly ferromagnetic.

In the course of our recent study on the magnetic properties of alloys and compounds of manganese with germanium, an antiferromagnetic behavior was found in a compound $Mn_{3.25}Ge$.

The specimen of this compound was prepared as follows; Powders of electrolytic manganese (99.9%) and germanium (seven-nine purity) were mixed in stoichiometric proportion and sealed in evacuated quartz tube, melted by an electric furnace at 1150°C, and quenched into water at 750°C. The specimen thus obtained was examined with X-ray diffractometer to ascertain its crystal structure. The diffraction lines could be indexed as a hexagonal close packed structure with the lattice constants $a=2.668\pm3$Å, $c=4.309\pm3$Å and $c/a=1.615\pm3$. The temperature dependence of the magnetic susceptibility of this compound was measured by a magnetic balance of torsion type from 90°K up to room temperature under a field of 7.5 kilo.oersteds. The result is shown in Fig. 1. Here the inverse susceptibility is plotted against temperature. This compound has a minimum in the inverse susceptibility-temperature curve and the curve shows that the Curie-Weiss law holds very well at higher temperatures. These behaviors are typical of some antiferromagnetic materials and thus the temperature corresponding to this minimum, 139°K, may be considered as the antiferromagnetic Néel point. The magnetic moment and the asymptotic Curie temperature are $5.47\,\mu_B$ per Mn atom and -266°K respectively.

Recently, Fakidov et al.[2] showed that the Mn_3Ge_2 becomes weakly ferromagnetic and its saturation magnetization disappears at low temperature, and they concluded the parastic ferromagnetism of this compound. Thus we are led to the conclusion that antiferromagnetic exchange coupling may be common in Mn–Ge compounds. The details of our present experiments and the magnetic properties of the other compounds of this system will be published later.

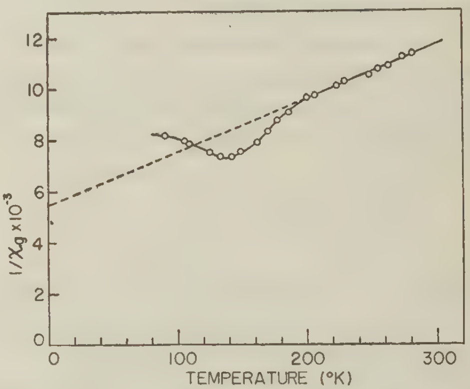

Fig. 1. Inverse susceptibility versus temperature curve of $Mn_{3.25}Ge$.

Finally, the authors wish to experess their hearty thanks to Prof. S. Kaya for his constant encouragement and are also very grateful to Dr. Y. Tomono and Dr. S. Iida who gave them facilities to achieve the work.

Absorption and Excitation Bands of KCl–Tl in the Extreme Ultraviolet Region

By Goro Kuwabara and Kiyoshi Aoyagi
Department of Physics, Faculty of Science, University of Tokyo

(Received October 16, 1959)

It is well known that KCl–Tl has three absorption and excitation bands characteristic of Tl, lying at 5.04, 5.82, and 6.20 eV, which are usually denoted as A, B, and C band, respectively. But as far as we know, no result on the experiment beyond the C band has been yet published.[1]

On the other hand, the alkali-halide crystals activated with Tl may be expected to luminesce by irradiation with light in the fundamental absorption band, because excitons or free electrons and holes produced by light are supposed to migrate through the crystal and annihilate giving their energy to the lattice or impurity centers. The investigation of this luminescence would afford important informations on the mechanism of energy transport in the crystal. Several experiments[2] along this line have been reported on alkali-iodides. In these crystals, however, the C and exciton bands lie so near to each other that it seems rather difficult to distinguish clearly the effect of the exciton and that of direct excitation of Tl, while KCl, in which both bands are separated as much as 1.3 eV, is suited for this purpose.

The KCl crystals were grown by Kyropoulos method from the melts containing 0.01∼1 mol per cent of Tl. The concentrations of Tl in the crystals were estimated from the absorption intensity in the A band to be of the order of 10^{-2} of those in the melts. The vacuum monochromator constructed in our laboratory is equipped with the concave grating (concave radius 40 cm). The light source is a hydrogen lamp with a hot cathode, and the intensity of the light below 300 mμ was measured by using the fluorescent screen of sodium salicylate. The slit width was about 3 mμ in wave length.

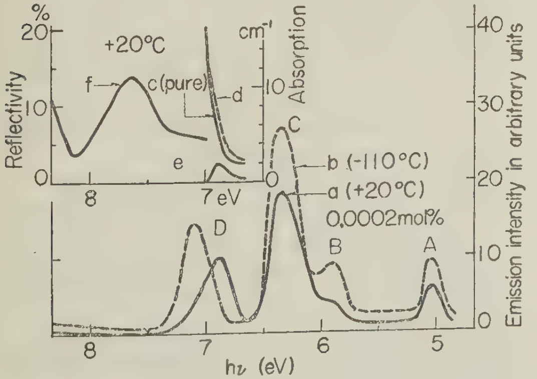

Fig. 1. Excitation spectra of KCl-Tl (0.002 mol percent) at 20°C (a) and −110°C (b). (c) and (d) are the absorption spectra of a pure and a Tl doped KCl. (f) is the reflectivity of a KCl reduced for normal incidence.

The curve (a) and (b) in Fig. 1 are the excitation spectra at 20° and −110°C measured for the normal incidence. Other than the well known three bands, a new excitation band (denoted as D) was found between the exciton (7.6 eV at room temperature cf. Fig. 1 f) and the C band.

When we plot the difference (e) of the absorption curves of a pure (c) and a Tl doped crystal (d) at room temperature, a new absorption band, which coincides precisely with the D band in the excitation spectrum, appears at 6.89 eV. Its absorption intensity is nearly the same order as that of the A band, and varies parallel with those of the A and C bands as the Tl concentration is changed. These results clearly show that the D band is closely related with the Tl center, and not with the exciton absorption in the undisturbed lattice.

The peak of the D band shifts towards higher energy side with the rate of 1.5×10^{-3} eV/deg, as the temperature is decreased, while those of other three bands remain almost at the same positions. This fact might indicate that the D band is associated with the excitation of Cl ions in the nearest neighbours of a Tl center.

In the higher energy side above the D band, the excitation spectrum gradually rises. The reflection loss of about 14 per cent (f) can not account for the low efficiency of excitation at the exciton band. Accordingly we are led to the conclusion that within the temperature and concentration ranges of our experiment the efficiency of luminescence increases monotonously in the tail of the fundamental absorption band, as the energy of an incident photon increases.

At −110°C, however, a considerable amount of emission is observed by light in the exciton band, and its quantum efficiency for the sample containing $10^{17}/\text{cm}^3$ Tl was about 1/18 of that in the C band.

Repeated Yielding of Impure Tin Crystals under Successive Impact Loading

By Ken-Ichirō Ishii

Department of Physics, Nagoya Institute of Technology

(Received October 2, 1959)

The dynamic stress-strain curves of metals under impact loading have been studied by Baron1), Maiden and Campbell2), Sakui3), and others. In the present study, the behavior of tin crystals has been examined under successive impact loading. The specimens, 24 mm long and 4.6 mm in diameter, were grown from the melt of 99 per cent tin. The impact test was made with a pair of striker pendulums weighing 180 gm each. After annealing at a high temperature, the specimen was soldered on to one of them and the other was used for loading.

When a number of impacts were applied successively at a moderate velocity of 24 cm/sec., slip took place with a series of discontinuous yields, as shown in Fig. 1a. The stress for slip gradually increased until it reached a saturation value, followed by an abrupt yield. The amount of slip between two consecutive yields was of the order of 0.01 mm. The yielding became less clear at a larger velocity of 28 cm/sec., but a tendency to general yielding was observed4). The elastic collision alone occurred after the initial rapid hardening when the velocity was less than 20 cm/sec. In a purer specimen, grown from the melt of 99.99 per cent tin, slip proceeded smoothly as in Fig. 1b, irrespective of the velocity of impact.

The repeated yielding has been observed from earlier times in mild steels5) when tested at about 200°C. Similar results have been obtained in nickel5), and in α6)- and β-brass5), etc., at moderately elevated temperatures, and in alloys such as duralumin5), β-brass6) and Cu_3Au7) alloy at room temperature. It has been also observed even at 4.2°K; Blewitt8) and his co-workers found it in copper crystals, and Wessel9) in all metals and alloys tested. There may be several mechanisms for the repeated yielding in the above cases. Some of them are quite similar in nature to the present case. They are a) mild steel10) deformed at 200°C with the formation of the Lüders band, and b) copper crystals8) irradiated with neutrons and then deformed at 4.2°K.

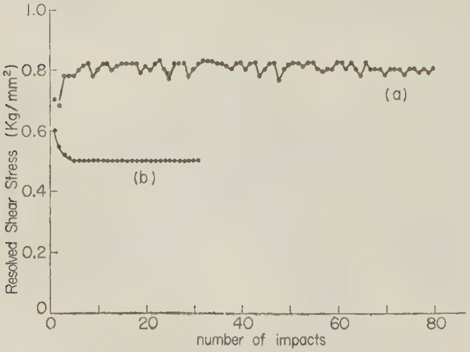

Fig. 1. Stress vs. number of impacts; a) for impure specimen, and b) for purer specimen.

In these three cases, the repeated yielding proceeds from an early stage of the plastic deformation without work-hardening, and at the same time, the yield front propagates successively. It is also noticed that the specimens contain a good amount of imperfections, i.e., solute atoms, impurities, or those produced by the irradiation. So it might be expected that a similar mechanism would be responsible for the results of this kind.

The repeated yielding of mild steels at elevated temperatures is attributed10) to some origin caused by aging and deformation occuring together, and a higher stress is required in order to propagate the front of the Lüders band.

In the case of tin crystals now observed, however, the effect of aging appears to be small. An alternative, or modified, explanation is that the slip is stopped at an obstacle such as segregations in the impure specimens used, which produces the stress concentration in front of the slipped region, and then, the dislocations locked by in the undeformed material will be released. In other words, it would be essentially the same process as the propagation of yield in the lower yield strain of polycrystalline mild steels.11)

The Crystal Structures of $KMnF_3$, $KFeF_3$, $KCoF_3$, $KNiF_3$ and $KCuF_3$

By Atsushi OKAZAKI, Yasutaka SUEMUNE
and Tsutomu FUCHIKAMI*

*Department of Physics, Faculty of Science,
Kyusyu University, Fukuoka, Japan*

(Received August 1, 1959)

The crystal structures of the antiferromagnets KMF_3, where M indicates the $3d$ transition group elements, were examined above and below their Néel temperatures (T_N) by X-ray diffraction using single crystals. The low temperature was attained by a method similar to that of Lonsdale and Smith.[1]

The lattice constants at room temperature were determined from rotation photographs about the [100]. Using high angle reflexions the final value of each lattice constant was determined by graphical extrapolation against $\cos^2\theta$.

At room temperature the structures of $KMnF_3$, $KFeF_3$, $KCoF_3$ and $KNiF_3$ are of the perovskite type and no distortion from cubic symmetry was observed, although Martin, Nyholm and Stephenson[2] have reported that these four compounds were determined as pseudo-cubic by the use of powder sample. On the other hand $KCuF_3$ crystallizes as a modification of the perovskite type, which is tetragonal ($a>c$).

At 78°K (below T_N) $KNiF_3$ and $KCuF_3$ retain their respective symmetry. From the splittings, of high angle reflexions and the relative intensities of their components, $KMnF_3$, $KFeF_3$ and $KCoF_3$ were found to become monoclinic, rhombohedral ($\alpha<90°$) and tetragonal ($a>c$), respectively, where the {400} with Fe$K\alpha$ radiation and the {222} with Cr$K\alpha$ radiation were used mainly.

The results are shown in Table I. The Néel temperatures were determined by Hirakawa and Hashimoto[3] from the magnetic susceptibility measurements.

It is interesting to compare the results of KMF_3 with those of MF_3[4),5)], LaMO_3[6)] and CaMO_3[6)], because in all the cases the dispositions of the magnetic cations relative to the intervening anions are similar. The crystal field splits the $3d$ levels of magnetic cation in an octahedral site into two groups—a set of three degenerate d_ε orbitals and a set of two d_γ orbitals of higher energy. In the case of MF_3 system Hepworth and Jack[4] have accounted for the lower symmetry of MnF_3 than that of the other MF_3 by the fact that the electronic charge distribution of Mn^{3+} ion has the d_γ symmetry. Such a lower symmetry caused by the d_γ symmetry has been discussed about some crystals by Dunitz and Orgel[7] on the basis of Jahn-Teller effect.

The divalent $3d$ ions under consideration have electronic configurations as follows:

	$3d_\varepsilon$			$3d_\gamma$	
Mn^{2+}	↑	↑	↑	↑	↑
Fe^{2+}	↑↓	↑	↑	↑	↑
Co^{2+}	↑↓	↑↓	↑	↑	↑
Ni^{2+}	↑↓	↑↓	↑↓	↑	↑
Cu^{2+}	↑↓	↑↓	↑↓	↑↓	↑

Since LaMO_3 and CaMO_3 systems are also interpreted from the above point of view, in KMF_3 system $KCuF_3$ may be expected to have lower sym-

Table I. Lattice constants and T_N of KMF_3.

	colour	at 298°K symmetry	lattice constants (Å)	at 78°K symmetry	lattice constants (Å)	T_N (°K)
$KMnF_3$	light brown	cubic	$a=4.191\pm0.001$	monoclinic	$(a, b, c)=(4.168, 4.171, 4.185)$* $\beta=89°51'\pm1'$	88
$KFeF_3$	brown	cubic	$a=4.122\pm0.001$	rhombohedral	$a=4.108\pm0.002$ $\alpha=89°51'\pm1'$	121
$KCoF_3$	rosy	cubic	$a=4.069\pm0.001$	tetragonal	$a=4.057\pm0.002$ $c=4.049\pm0.002$	136
$KNiF_3$	yellow-green	cubic	$a=4.015\pm0.001$	cubic	$a=4.002\pm0.002$	280
$KCuF_3$	pale violet	tetragonal	$a=4.140\pm0.001$ $c=3.926\pm0.002$	tetragonal	$a=4.121\pm0.002$ $c=3.913\pm0.002$	243

* For $KMnF_3$ the lower temperature measurements should be done as the present temperature was too near T_N. It could not be determined at present which of the three values in the parentheses corresponds to the letters a, b and c.

---

* On leave of absence from Saga University, Saga, Japan.

metry than the other four compounds above T_N. The expectation should be supported by our result.

Furthermore it may be worth while to compare the results of KMF_3 system with the distortion below T_N of MO system[8].

The experimental and analytical details will be published in the near future.

The single crystals used in this experiment were given by Dr. S. Ogawa of Hokkaido University and Dr. K. Hirakawa and Mr. T. Hashimoto of our laboratory through their courtesy.

Measuremert of Plasma Temperature and Electron Density

By Kiyoshi MURAKAWA and Shizuyo HASHIMOTO
Aeronautical Research Institute, University of Tokyo, Komaba-machi, Meguro-ku, Tokyo

(Received October 9, 1953)

In a previous article with the same title[1] we described a method of measuring the temperature of a plasma obtained by passing condensed discharge through a Geisler tube containing neon. From the line profiles of $H\gamma$ and NeIλ 4715 the electron density N was deduced in such a way that the wings of the profiles are fitted into the prediction of Holtsmark's theory. This method of determining the electron density was adopted by previous workers[2], but a recent calculation by Griem, Kolb and Shen[3] has shown that the above-mentioned method yields a value of N that is two times as large as the true value. In the case of our light source we get therefore $N=4.8\times10^{15}/\mathrm{cm}^3$ instead of the previous $1\times10^{16}/\mathrm{cm}^3$.

In the work l.c., the wave-length of Ne I λ 5852 emitted from condensed discharge was compared with that of the same line emitted from arc discharge, the latter wave-length being assumed to be free from the influence of the field of ions and electrons. The displacement (expressed in wave-number) of λ 5852 due to the condensed discharge is denoted as $\Delta\nu_{\mathrm{dis}}$. The half-value width due to the broadening effect of the ions and electrons (neglecting the Doppler effect) is denoted as $\Delta\nu_k$. For a line showing a quadratic Stark effect $(\Delta\nu=\gamma F^2)$ such as Ne I λ 5852, Lindholm's formula can be expressed as (the same notations as in l.c. are used)

$$\Delta\nu_k=A\gamma^{2/3}v^{1/3}N/c, \qquad (1)$$

$$\Delta\nu_{\mathrm{dis}}=B\gamma^{2/3}v^{1/3}N/c. \qquad (2)$$

Lindholm obtained $A=0.0450$ and $B=0.0387$.

If we put the values of γ, v, N (for the line Ne I λ 5852) and B in eq. (2), we get $\Delta\nu_{\mathrm{dis}}=0.058\,\mathrm{cm}^{-1}$ which is to be compared with the observed value $\Delta\nu_{\mathrm{dis}}=0.027\,\mathrm{cm}^{-1}$, showing that Lindholm's B is too large. If we determine the value of B by a purely empirical method, we get approximately $B=0.018$. Neon lines other than λ 5852 were examined in the same way as in l.c., and the result was found to yield the same value of B as proposed here.

Retaining the value of A as given by Lindholm, we get $\Delta\nu_k=0.067\,\mathrm{cm}^{-1}$, and therefore the half-value width due to the Doppler broadening effect alone is $\Delta\nu_D=0.192\,\mathrm{cm}^{-1}$. From the value of $\Delta\nu_D$ it follows that the plasma temperature is $T=4.9\times10^3\,\mathrm{K}$ instead of the previous $6.0\times10^3\,\mathrm{K}$. This deduction depends upon Lindholm's theory. In case when the value of A in Lindholm's formula has to be changed, the plasma temperature deduced here would have to be re-calculated accordingly.

Dr. McLane of the Speedway Laboratories (Linde Company) kindly gave us a copy of the article of Griem, Kolb and Shen prior to publication. We thank him heartily for his kindness and for his deep interest in our work.

Stacking Faults in Copper-Nickel Alloys

By Kôichi NAKAJIMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan

(Received October 6, 1959)

It was reported[1] that the density of stacking faults introduced by cold-working in face-centred cubic solid solutions increased with increasing the content of solute atoms, and reached a maximum at the solubility limit of the solution.

The present author examined these phenomena with copper-nickel alloys. The alloys of various compositions were pulverized at room temperature by using a stamp mill and a ball mill. The pulverization was carried out in benzine in order to prevent the samples from oxidation. The X-ray diffraction was taken with a diffractometer " XRD-5 " made by general Electric Co. by using Cu-Kα radiation. The shifts of the (111) and (200) peaks due to cold-working are sharp enough to determine the center of gravity to about ±0.01°. The methods of calculation of the stacking fault probability from the X-ray measurement were reported by some workers[2] and recently Wagner[3] proposed a theory that deformation and twin stacking faults of random distribution in the cold-worked material affect on X-ray diffraction, and showed the following equation:

$$\langle \varDelta(2\theta^\circ)\rangle_{hkl}-\langle \varDelta(2\theta^\circ)\rangle_{h'k'l'}=\mathscr{H}\alpha,$$

where

$$\mathscr{H}=(\langle G\rangle j\tan\theta^\circ)_{hkl}-(\langle G\rangle j\tan\theta^\circ)_{h'k'l'}$$

$\langle \varDelta(2\theta^\circ)\rangle_{hkl}$ shows the observed shift of the (hkl) peak and $G=90\sqrt{3}h_3/\pi^2 i_0^2$. j and $\langle G\rangle$ are the fraction of (hkl) plane and averaged values for the (hkl) reflection, which are affected by stacking faults, respectively. Fig. 1 shows the stacking fault probability calculated by the above equation, from which it will be seen that the stacking fault probability calculated by the above equation, from which it will be seen that the stacking fault probability α increases gradually, and reaches a maximum at 50-50 composition. The effective strain ξ in the matrix was calculated from the line broadening analysis discussed by Williamson and Hall.[4] The density of dislocation ρ calculated from the strain broadening is given by[5]

$$\rho=k\xi^2/Fb^2$$

where k is a constant and F is a strain energy factor. The stacking fault energy γ is obtainable from the following relation by Cottrell:[6]

$$r=\mu a^2/24\pi\gamma\ ,$$

where

$$\alpha=\rho rd$$

r is the width of the extended dislocation. μ and a are the shear modulus and the lattice parameter, respectively. The density of dislocation ρ and the faulting energy γ calculated by these equations are shown in Fig. 2. It will be seen that the faulting energy γ increases rapidly as nickel content increases above 50 per cent nickel.

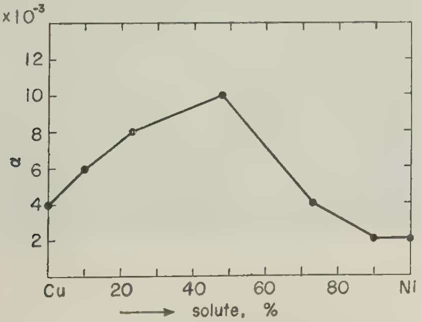

Fig. 1. Stacking fault probability, α.

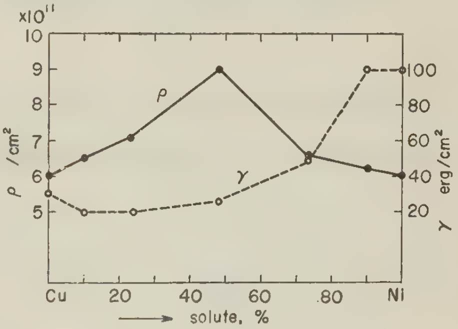

Fig. 2. Density of dislocation, ρ, and stacking fault energy, γ.

The fact that α increases gradually as shown in Fig. 1, and reaches a maximum at 50-50 composition may be interpreted from the point of view that solute atoms concentrate in the faulted layer, and prevent the movement of the stacking fault at room temperature. In fact, Suzuki[7] has pointed out that in a face-centred cubic solid solution the state of thermodynamical equilibrium in the faulted layer will be different from that of the matrix, and will result the concentration of solute atoms in the faulted layer. If this concept is valid, a small angle scattering due to the inhomogenity of the structure should be observed. Weak small angle scattering was actually observed in a specimen of copper-5% aluminium alloy annealed at 100°C after severe cold-rolling. However, the intensity of the double Bragg scattering may not all be negligible compared with some weak scatterings due to the heterogeneity of the structure. Therefore, an alternative explanation of the appearance of the weak small angle scattering may also be possible from the point of view that the scattering is due to double Bragg scattering from slightly misoriented crystals in the annealed sample, and accordingly a more detailed investigation on the small angle scattering is desirable. The full report will be shown before long.

Frequency Shift in Ammonia Absorption Lines other than (3, 3)

By Kiyokata MATSUURA

Electrotechnical Laboratory, Nagatacho Tokyo

(Received October 3, 1959)

The shift in resonance frequency of ammonia (3, 3) line with pressure has already been reported by us[1], where the shift coefficient, *a*, is given as $(1.8\pm0.1)\times10^{-2}$. The coefficieet *a* is defined in such a way that the apparent center of resonance, ν, is given by $\nu=\nu_0+a\Delta\nu_p$, where $2\Delta\nu_p$ is the width of the line due to pressure broadening.

We have now measured the shift coefficient, *a*, for lines other than (3, 3). Fig. 1 shows the value of *a* for various lines with $J=K$ at 30°C and 100°C. It is seen that *a* decreases with increasing *J* and goes finally to negative values. This would imply that the explanation of the frequency shift would require at least two competing mechanisms.

From the point of view of the accuracy of the atomic clock, it seems noteworthy that the absolute value of *a* is very small for $J=K=5$ or 6. Considering that the intensity of (6, 6) line is comparable with that of (3, 3) line, it seems advisable to use the line (6, 6) in the absorption type atomic clock.

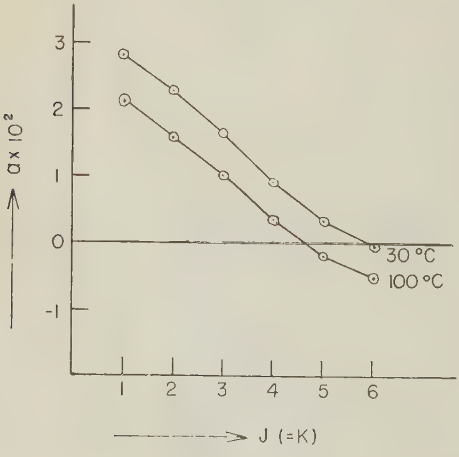

Fig. 1.

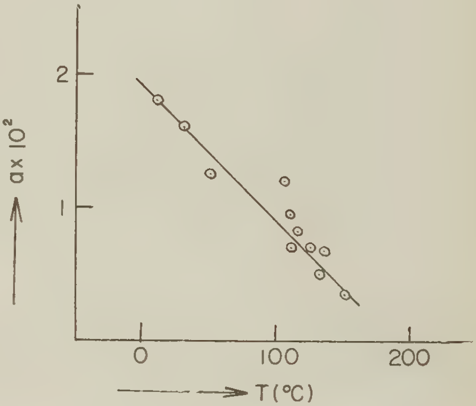

Fig. 2.

Fig. 2 shows the dependence of *a* for (3, 3) line on the temperature of the absorption cell. Other lines show similar temperature dependences. The experiment has been performed, as before, with the absorption-type atomic clock installed at the Laboratory and the absorption cell consists of 30m *K*-band wave guide. The temperature of the cell can be varied from room temperature to 150°C.

Measurements on the shift coefficient for lines with $J\neq K$ are now going on.

Diffusion of Cu into CdS Single Crystal through Dislocations

By Sumiaki IBUKI and Hirosuke YAMASHITA
Research Laboratory Mitsubishi Electric Mfg. Co., Ltd. Amagasaki, Japan

(Received October 1, 1959)

In case of discussing the diffusion of impurity into crystal, it is not improbable that the diffusion velocity through imperfections, such as vacancies, dislocations, twin boundaries and grain boundaries, is predominently high.[1)]

It is a well-known fact that Cu diffuses very easily into CdS[2)], and also the authors have experienced fairly marked diffusion of Cu at 400 ~500°C. Trying more detailed inspection, we may be able to find some locations where the diffusion of Cu is abnormally remarkable at about as low as 300°C. Moreover, CdS single crystal has some favorable characteristics to observe the above mentioned phenomenon, because as usual the crystal changes its color from transparent yellow to brown acompanied with the inclusion of Cu atoms, and Cu diffusion may be accelerated if Cl atoms are predoped in the crystal.

The authors performed following experiments. Cu and In metals are evaporated on both ends of $(11\bar{2}0)$ surface of CdS: Cl crystal $(10\times1\times0.2\ \mathrm{mm})$ to make narrow bands respectively. After several hours of heat treatment at 300°C in air, we obtained some interesting results. One of microscopic pictures showing the evaporated Cu side is given in photo. 1. Judging from the photo, Cu may be easily sucked thermally into CdS crystal through the tops of dislocations exposed at the surface, and it is expected that when the voltage is applied between each evaporated metals so as to form the positive electrode of Cu, Cu metals may be diffused into CdS only by the electric field.

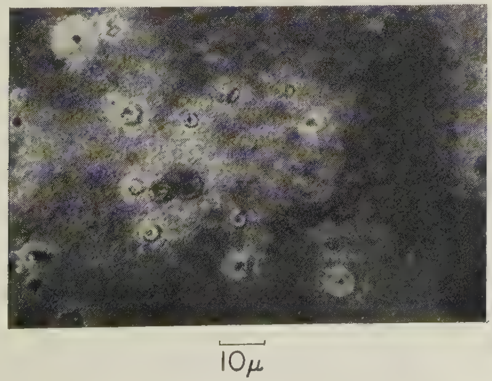

Photo. 1. Cu evaporated layer after 300°C 3 hours' heat treatment.

Several mA of current are flown continually for scores of hours through CdS crystals which have nearly above mentioned sizes and positive electrodes of Cu, then we obtained some distinct results. An example is shown in Photo. 2. It might be concluded from the photo, that the dislocations play more important parts for the electric field diffusion compared with the thermal diffusion. Under certain circumstances, it is found that the evaporated Cu layer covered upon the dislocations disappeared thoroughly, or hemi-circular erosions of Cu layer are observed along the boundary of Cu layer and crystal surface.

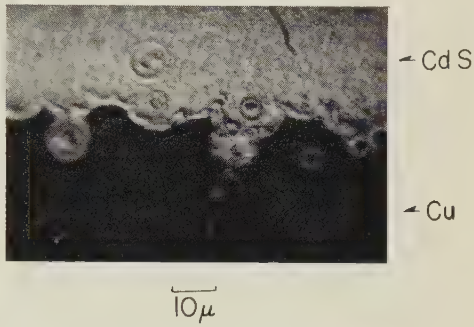

Photo. 2. Boundary between CdS and Cu evaporated layer after 2 mA 60 hr current flow (Resistance 30 Ω)

It is proved clear from those facts that the existence of dislocations influences greatly upon the impurity diffusion into crystal, that is, dislocation may be able to suck strongly impurities at their edges. Detailed reports are to be published later.

A New Device for measuring Thickness of Evaporated Metal Film by Use of X-ray Interference Fringes

By Yoshibumi Fujiki and Toshiho Yoshida

Institute of Physics, Kyoto Prefectural University of Medicine

(Received October 3, 1959)

W. Hink and W. Petzold[1] improved Kiessig's[2] X-ray interference method using the divergent beam from a micro-focused X-ray source. In their device, the oscillation of a specimen was unnecessary and the exposure time required was reduced to a few per cent of that required in the case of Kiessig's original device. However, their device requires the specially designed micro-focused X-ray source and comparatively large specimen is necessary for obtaining a sufficient number of interference fringes. To avoid these difficulties, we devised a new method.

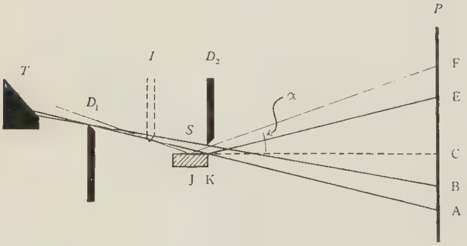

Fig. 1.

In Fig. 1, the beams from a usual line-focused X-ray source T fall on a specimen S with various glancing angles, and the interference fringes are produced on the photographic film P, if the width of the specimen is suitably small and the distance between the specimen and the photographic film is sufficiently large. The beams which would come from the source directly to the photographic film and would mask the interference fringes are screened out by the diaphragms D_1 and D_2. The glancing angle α of the beam corresponding to any interference maximum F will be given by

$$\tan\alpha = \mathrm{CF}/\mathrm{JC} = (\mathrm{AF}-\mathrm{AC})/\mathrm{JC} = (\mathrm{AF}-1/2\cdot\mathrm{AE})/\mathrm{JC}\ ,$$

where J is the mid-point of the specimen, and C the intersection of the extension of specimen surface with the photographic film. Point A is the position where the incident beam, which corresponds to the innermost reflected beam KE, would strike the photographic film directly, where K is the hind edge of the specimen. The uppermost end of the direct incident beam hits the photographic film at B and so the point A is masked. For the purpose of detecting the point A, indicator I is inserted in front of the specimen vertically from the upper side of the apparatus, as shown in Fig. 1. This is made of tungsten wire whose end is sharpened in wedge-shape. The inverted image of this indicator is imposed on the photographic film at the region below A and the errect image above A as is shown in Fig. 2, thus the intersection of these two images determines the point A. Fig. 2 is an example of interference fringes obtained from a gold film evaporated on glass substrate whose width is about 3.5 mm. The distance between the specimen and the photographic film was 40 cm. The wider the specimen width, the broader would become the width of each fringe, but the mean errors of measured values of film thickness d and the unit decrement of refractive index η were not so large for the specimen width mentioned above. Using the interference condition for maxima $(2m+1)\lambda/2=2d\sqrt{\alpha^2-2\eta}$, where m is the order of interference and λ the wavelength, the observed values of d and η were obtained from the photograph shown in Fig. 2 as follows:

$$d=319.6\pm0.8\text{Å},\quad \eta=(43.3\pm0.4)\times10^{-6}.$$

The X-rays used was $Cu\ K_\alpha$ radiation with nickel filter, applied voltage of 30 kV and tube current of 40 mA, and the exposure time required was 3 minutes, which was of the same order as that required in Hink and Petzold's method. This short exposure time makes it possible to pursue the comparatively rapid change of film thickness with aging time.

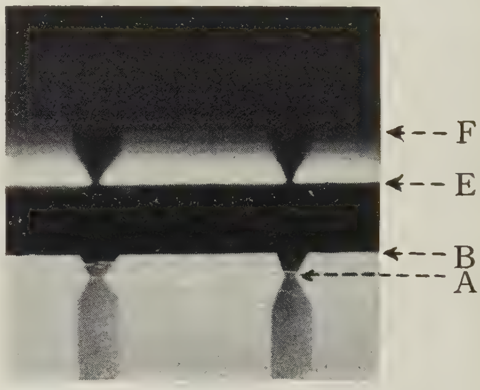

Fig. 2.

The writers are greatful to Professor K. Tanaka of Kyoto University for his valuable suggestions and advice.

Observations of Lattice Defects in Graphite by Moiré Patterns

By Kazuhiko IZUI

Chemistry Division, Japan Atomic Energy Research Institute, Tokai, Ibaraki

(Received October 5, 1959)

Since the first observation of the moiré patterns in graphite crystals,[1] moiré patterns in some other materials have been studied by several workers[2] using the electronmicroscope. The moiré patterns are not only interesting from the electronoptical point of view, but are useful for detecting lattice defects such as dislocations and grainboundaries.[3]

The present note reports some irregularities in moiré patterns in electronmicrographs from graphite, which seem to be caused from lattice defects in the crystal. The specimens used are the spectroscopically pure natural graphite SP-1 and SP-2.

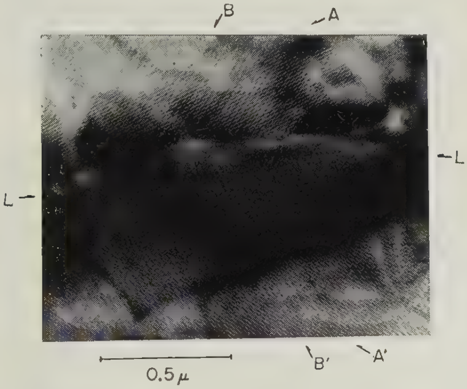

Fig. 1.

In Fig. 1, the moiré lines parallel to the directions A and B, and those parallel to A' and B' are seen respectively in the upper and lower regions bounded by the boundary L. The lines of moiré are produced by the (110), (010), $(2\bar{1}0)$ and $(1\bar{1}0)$ atomic planes of the hexagonal crystal structure, respectively. The angle between A and A' or B and B' is smaller than 60° by about 2×10^{-2} rad. This seems to indicate that within either one of the two overlapping crystals producing moiré, a part bounded by a sub-bundary L is rotated around the c-axis about 10^{-2} rad with respect to the other part. The irregular and obscure lines seen in the back ground seem to be dislocation lines which lie in the basal plane.

In Fig. 2, we can see that the moiré patterns are locally distorted along the curved lines L_1, L_2 and L_3 and the patterns are displaced in parallel by about a half moiré spacing across these lines, while no such displacement except local distortion does occur across the line M. When the incident angle of the electron beam to the specimens was changed, there took place a parallel displacement in the moiré patterns, but the lines L_1, L_2, L_3 and M were not displaced. Further, there took place no change in the contrast of the general back ground. These facts show that the lines L_1, L_2, L_3 and M are neither the extinction contour lines due to curved crystals nor the edges of some other extra overlapping crystals but are due to some lattice defects, such as dislocations. A detailed discussion based on more precise experiments will be published elsewhere in the near future.

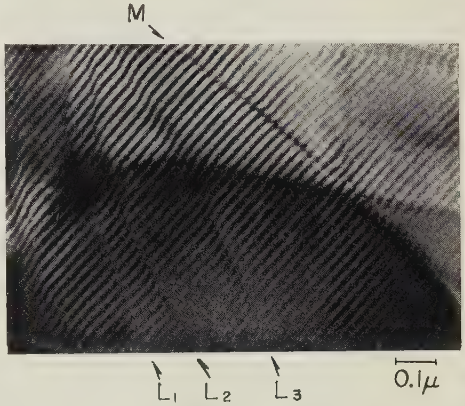

Fig. 2.

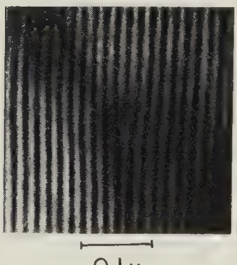

Fig. 3.

The edge dislocation-like patterns as shown in Fig. 3 were sometimes observed. However, in view of the highly anisotropic layer structure of graphite, the dislocation line perpendicular to the basal plane seems to be difficult to exist, and one should be careful to conclude its real existence. This point will be clarified by the future experiments. Recently F. E. Fujita has observed the moiré patterns even in artificial graphite. Experiments are now in progress in co-operation with his group, including the problem of irradiation effects on graphite.

The author wishes to express his sincere thanks to Dr. K. Motojima for his persistent encouragement, and Dr. H. Suzuki and Dr. F. E. Fujita for their valuable guidances and discussions, and to Mr. Ōtsu for his assistance throughout this work.

Visible Light Emission from Germanium Diffused p–n Junction

By Makoto Kikuchi
Electrotechnical Laboratory, Tokyo, Japan
and
Kenkichi Tachikawa
Research Laboratory, Meiden-sha, Shinagawa, Tokyo, Japan

(Received October 27, 1959)

It is well-known that visible light is emitted from p–n junction in silicon[1] and metal-silicon contact.[2] In both cases, the light is emitted from small spots located near the rectifying region, and the number of these spots increases as the reverse bias voltage is increased.

On the course of study of the visible light emission and the "microplasma" phenomena in silicon junction, it has been one of the key questions for the understanding of fundamental processes underlying those effects, i.e., why visible light had not been observed in germanium p–n junction. The difference in the energy gap for germanium and silicon does not play important role in this discussion, since the visible light corresponds to the region of 1.5 to 3.0 eV, and moreover, the spectral intensity of the light emitted from silicon is observed to extend far beyond the wave length corresponding to the energy gap (1.1 eV), which has been attributed to the *intra-band* transition of high energy electron.[3] If the intraband transition is really the predominant process in the light emission from p–n junction, it might well be expected that germanium junction emits visible light in the same way.

We have concentrated our interest on the differences in the extrinsic properties between germanum and silicon, and pointed out the content of oxygen as one of those factors.

Germanium crystal was melted in *quartz crucible* and kept at 1450°C for about 15 minutes and then single crystal was pulled in <111> direction doped with In. This treatment is to enrich the germanium crystal with oxygen. The crystal was then sliced and n-type layer was made by As diffusion in the thickness of 1−1.5 micron. Small p–n junction area was made by mask-etching as shown in Fig. 1(a). Visible light emission was observed at the periphery of this junction as shown in Fig. 1(b). The colour was a little more reddish than the bright spots observed in the silicon diffused junction. A bright and large white spot was observed neither on the periphery nor on the junction plane. Since the absorption coefficient is greater for germanium than for silicon, the lack of light spots on the junction plane cannot be directly attributed to the lack of event itself.

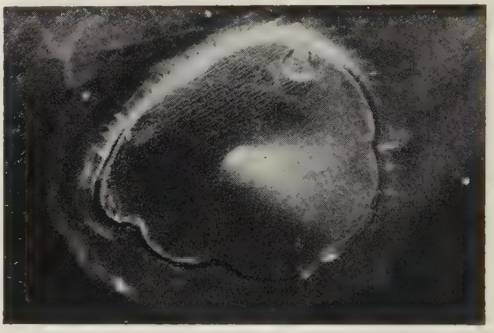

Fig. 1. (a)

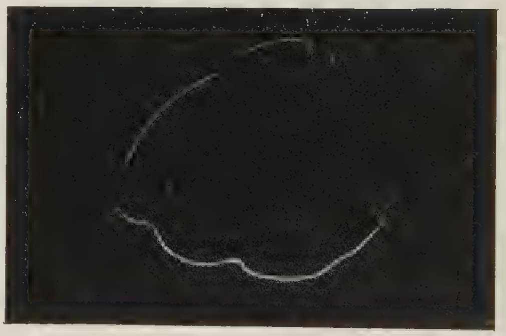

Fig. 1. (b)

Although it is not possible to conclude that the light emission is induced by oxygen only from this experimental result, it may throw light on the understanding of the light emission and microplasma phenomena in semiconductor p–n junction.

Infrared Radiation from Silicon Grown Junction

By Ichizô UCHIDA
Research Laboratory, Nippon Electric Co. Ltd., Tokyo

(Received September 26, 1959)

Since Haynes and Briggs1) succeeded in detecting the recombination radiation of silicon and germanium, several papers2)–7) have been published.

The spectral distribution of silicon recombination radiation has a peak at 1.1 μ at room temperature, the peak being due to the direct transition between the valence and conduction bands. Therefore we can observe the infrared radiation from silicon grown p-n junction in the case of forward current injection by the use of the type 1P25 image tube having Ag–Cs photocathode.

The sample resistivity is 0.08 Ω cm in the p region doped with boron and 2.4 $\Omega\cdot$cm in the n region doped with antimony.

The sample is soldered to a pair of copper-block terminals cooled by means of dry ice and put into a vacuum chamber. The junction temperature is measured by a thermocouple and cooled in the range of from 10°C to -5°C.

The radiation is too weak to be visualized when the current flow through the junction is less than 100 mA, but becomes clearly observable at 300mA. As shown in Fig. 1 the radiation diffuses away from the junction to the n region. This is caused by the fact that the most part of the current carriers consists of positive holes, as can be expected from the relation between the values of resistivity in the p and n regions.

The density of the negative film D_M is measured by means of a micro-photometer and the result is shown in Fig. 2. Fig. 3 shows the experimental results of the relation between the current and the radiation energies measured when a PbS detector is used for a junction current range of from 100 mA to 1 A. By the use of these results we can approximate the linear relation between the maximum density D_M and total radiation energy E. Consequently, the length from the junction to the point where the density is decreased to D_M/e is considered to be comparable to the diffusion length of the radiative carriers. The value is about 300 microns and the life time of holes in the n region is calculated to be 77 μ sec. This value is greater than the life time measured by the photo-conductivity decay method.

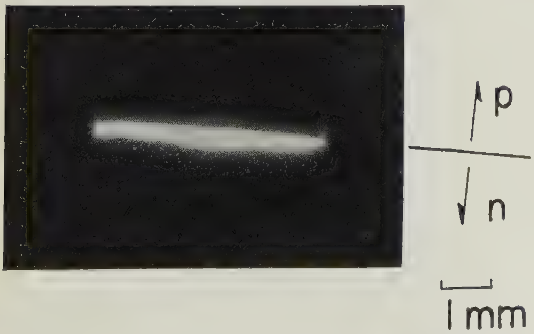

Fig. 1. Infrared radiation from Si grown p-n junction. Sample size is 4.15 $\times 0.74 \times 13.0$ mm.

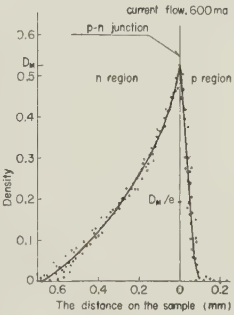

Fig. 2.

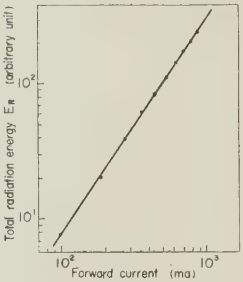

Fig. 3. Total radiation energy from the junction vs. foward current.

According to the injection efficiency calculated from the values of the resistivity, the recombination radiation in the p region must be too weak to be observed, however, the obscure radiation in the p region exists in the Fig. 1. This seems to be due to the scattering light of the internal radiation at the surface of the sample and at the fluorescent screen of the image tube.

The author would like to express his thanks to Dr. Osamu Harashima for his guidance and encouragement. He is also indebted to Mr. Naotaka Sakakibara and Mr. Takeshi Hasegawa for measurement and preparation of the samples.

An Interpretation of 550 Me Particles

By Masafumi Inoki

Physics Institute, Yamanashi University
Kofu City, Japan

(Received August 31, 1959)

It seems hardly possible that the 550 Me particles observed by Alikhanian et al.[1] should exist in cosmic rays, if one takes into account the fact observed that the several studies[2] recently carried out to check their existence have obtained the results against that. Alikhanian et al. maintained the mass of the particles to be about 550 times the electron mass, on the assumption that each of them had a unit electronic charge, e. However, the assumption was not based on any experimental evidence.

It seems to the author that the failure in detecting the 550 Me particles[2] might possibly be explained, if the particles were assumed to be charged with Ze, Z being a number. To show the idea quantitatively we shall introduce the general equrtions (1), relating the measured momentum, P_z, ionization, I_z, total number of grains in an emulsion, N_z, range, R_z and mass, $\mu(z)$, for a particle charged with Ze, moving at non-relativistic velocities,

$$\begin{aligned}\mu(z)&=Z^{0.55}[1.18P_z^{1.45}R_z^{-0.45}]=Z^{0.55}\mu_{pr}(1)\\ \mu(z)&=Z^{-0.52}[2.04P_zI_z^{0.76}]=Z^{-0.52}\mu_{pi}(1)\\ \mu(z)&=Z^{-2.88}[6.86R_zI_z^{2.44}]=Z^{-2.88}\mu_{ri}(1)\\ \mu(z)&\simeq Z^{-11.8}[bN_z^{3.45}R_z^{-2.45}]=Z^{-11.8}\mu_{rn}(1)\end{aligned} \qquad (1)$$

where $\mu_{pr}(1)$, $\mu_{pi}(1)$, $\mu_{ri}(1)$ and $\mu_{rn}(1)$ represent the simulated masses, which are obtained by assuming that the particle is charged with e, and the indices pr, pi, pi, and rn indicate that the measurement of the mass is done by the methods of momentum-range, momentum-ionization, range-ionization, and range-total grains respectively. The equations (1) were introduced from the semi-experimental curves[3] by means of the following substitution:

$$\begin{aligned}P&=ZP_z\\ I&=(1/Z^2)I_z\\ N&\simeq(1/Z^2)N_z\\ R&=Z^2R_z\end{aligned} \qquad (2)$$

where P, I, N, and R belong to a particle charged with e. It must be noted however that the momentum, P_z, is obtained from the measured radius of curvature, ρ, of the trajectry of a particle in a magnetic field, H, using the ordinary formula, $P_z=300\,H\rho$ MeV/c.

The mass of the 550 Me particles is expressed $\mu_{pr}(1)=550$ by the above notation. So far only the Princeton group has searched for the particles of $\mu_{pr}(1)=550$ with a negative result in its preliminary report.[4] Whereas the Utah,[5] the Columbia,[6] the Milano[7] and the Calcutta[8] groups searched for the particles of $\mu_{ri}(1)=550$, among which only the last one obtained a positive result at sea level.

Alikhanian et al. observed some of the 550 Me particles which were ionizing at about the minimum rate. That fact excludes the possibility of $Z>1$ for the particles. Particles charged with $Z<1$, called subionizers, were searched for by Fitz et al.[9] with a negative result in a small number of cosmic ray particles. The author has tried to find such a value of Z that the particles of $\mu_{pr}(1)=550$ could be found by Alikhanian's study but the particles had a feature to be missed by other's studies to search for the ones of $\mu_{ri}(1)=550$. Thus the author would like to propose that the 550 Me particles are the ones charged with $(Z=1/2)e$. The equations (1) can be solved as follows, if we put $Z=1/2$ and $\mu_{pr}(1)=550$ in them; $\mu(1/2)=370$, $\mu_{pi}(1)=260$, $\mu_{ri}(1)=50$, and $\mu_{rn}(1)\simeq1/10$.

Those mass values seem to explain the failure in the search for the 550 Me particles carried out by the Utah, the Coloumbia and the Milano groups, because a very small number of $\mu_{ri}(1)=50$ and $\mu_{rn}(1)\simeq1/10$ might have been treated as electrons. $\mu_{pi}(1)=260$ would also be difficult to be distinguished from π-mesons in a mass measurement. The result of the Calcutta group is difficult to explain by the above assumption. The author hopes that the reliability of the ionization measurement in the study would be checked again.

The contradiction between the study of Alikhanian and that of the Princeton group might be explained if the counter arrangement to trigger the cloud chambers in the latter had a bias against both a particle ionizing at less than the minimum rate and a slow particle of $R<7$ g/cm² of lead at the top of the counters. The ordinary counters might fail to detect the fast subionizers of $Z=1/2$, which ionize at less than the minimum rate in the region of $R>7$ g/cm² of lead.

There occurs a doubt that the particles of $Z=1/2$, if they really exist, should have been observed so far by emulsion studies. They are supposed to be produced by nuclear collisions, materializations or decay processes, all of which are observable by emulsions. The particles at relativistic velocities, however, have about 1/4 times the minimum ionization rate, which is almost impossible to be distinguished from the background in emulsions. Therefore they can escape from the observation, if the major part of them, at the place where they are produced, have relativistics velocities, corresponding to the kinetic energy larger than about 250 MeV.

In conclusion, the author should like to remark that the 550 Me particles should be carefully checked again in view of what has been described above, because there seems to be some possibility that they are subionizers, if the particles of $\mu_{pr}(1)=550$ proposed by Alikhanian et al. do really be observed without suffering from any experimental error.

Dependence of the Joshi Effect on 'Ageing' under, or and in the Absence of, Continuous Electrical Excitation

By M. VENUGOPALAN

Department of Chemistry, Banaras Hindu University (India).

(Received August 31, 1959)

Comparative studies of the JOSHI effect[1] $\pm\Delta i$, an instantaneous and reversible photovariation of the discharge current i ($+\Delta i$, enhancement and $-\Delta i$, diminution) in halogens under identical conditions of excitation and detection and for constant light intensity and frequency, from the standpoint of the kinetics of the inversion of $+\Delta i$ to $-\Delta i$ and *vice versa* under widely varied conditions of 'ageing' under, or/and in the absence of, discharge (in the former, the discharge tube is kept excited at a fixed potential for a required amount of time and in the latter, *i.e.*, the opposite process, as the system is stood over in the absence of discharge, unexcited in a 'rest period') and temperature showed that $+\Delta i$ is favoured by a temperature rise, but inhibited by a continued exposure to discharge and that in the absence of discharge it is the first to develop, the recovery being facilitated by heating. On the contrary $-\Delta i$ is disfavoured by a temperature rise, but enhanced by a continued exposure to discharge; in the absence of discharge it decreases, this decrease being facilitated by heating. Both the direct and reverse processes are found to be representable by equations of the 'first order' reaction[2].

To explain these time variations in $\pm\Delta i$ due to 'ageing' under, or/and in the absence of, electrical discharge, PRASAD and JATAR[3] suggested that a reversible reaction occurs between the glass and the gas. MOHANTY[4] explained the increase in $-\Delta i$ as due to increased photoemission from the cathode, due to decreased surface work function ϕ, as obtained by 'ageing' under discharge. JOSHI[5] contemplated the formation under discharge of an adsorptionlike photoactive electrode layer consisting of excited particles and ions and characterised by a low work function ϕ as primary to the production of $\pm\Delta i$. The other processes, subsequently leading to $\pm\Delta i$, *viz.*, photoelectron emission from the above layer, their capture or/and their multiplication are practically instantaneous and fully reversible. Evidently the formation of the above layer is the only time dependent process leading to $\pm\Delta i$.

The progressive growth of $-\Delta i$ during 'ageing' under discharge is attributed by RAMANAMOORTHY[6] to the discharge favouring an otherwise slow or practically no formation of the 'electrode layer' contemplated by JOSHI[5] as primary for $\pm\Delta i$. He has suggested[6] that this layer constitutes of (gas) molecules oriented on the 'electrode surface' probably as 'electrical' 'dipoles' possessing characteristic light absorption and low dissociation energy as distinct from those in the gas bluk. Such a discrimination was necessitated since the entire $\pm\Delta i$ could be obtained by irradiating simply the electrodes by wavelengths in and outside the selective absorption of the excited medium[2], its frequencywise variation[2] and also its non-occurrence[2] when the gap alone was illuminated keeping the electrodes screened especially in external sleeve and Geissler tube discharges.

The author[7] has shown that a van der Waals' layer's on a partially chemisorbed electrode surface is the chief seat of $+\Delta i$, whereas a chemisorbed layer on the electrode surface constitutes the chief seat of $-\Delta i$. The time variations in $\pm\Delta i$ due to 'ageing' under discharge has been attributed to a clean up of the van der Waals' layer and development, involving adsorption or/and desorption, of the chemisorbed layer, due to electrical activation caused by, and dependent on the magnitude of, the potential applied to the electrode surface. The constant values of $\pm\Delta i$ obtained at infinite time in the kinetic studies of 'ageing' under, or/and in the absence of, discharge arises out of the establishment of an equilibrium between the gas phase and the absorbed phase. The cessation of discharge is marked by an instantaneous van der Waals' adsorption on a partially chemisorbed surface. It is probable that a surface catalysed reaction[8], at low and ordinary temperatures premitting the stability of a van der Waals' layer, between adsorbed gas particles in these two layers, between adsorbed gas particles in these two layers, takes place. This seems to be improbable at high temperatures when desorption of the chemisorbed layer has set in; but an interaction[9] between two adjacent atoms or radicals in a simple competitively occupied chemisorbed layer is possible. The observed larger time intervals required under 'ageing' in the absence of discharge ('rest period') compared to the shorter periods of 'ageing' under discharge to attain constant values of $\pm \Delta i$ are due to the procesed of adsorption and desorption proceeding at much higher rates than the reaction at the surface.

The electrodes being of dielectric nature, develop active spots on the surface under electrical excitation. A strain caused either by continuation of discharge or a total removal of applied field as under 'rest' or/and any other factor will affect these spots considerably. These centres retains some residual charge after completion of a cycle, conditioned by its previous history, the charge density in various centres, the expansion of active spots and the maintenance of the charge in these spots. This will develop a strain which will be loosened or destrained when allowed to 'rest' or subjected to 'heat' treatment.

Further, RAMANAMOORTHY'S[6] interpretation of the adsorbed layer as consisting of gas molecules oriented on the 'dielectric surface', probably as the 'electrical dipoles seems to be instructive from considerations of the 'time of relaxation of a molecule'[10]. This is the time required for the dipolar molecules to revert to random distribution after the removal of an eletrical field that has caused them to become oriented in a definite direction. The 'theory of dielectric relaxation' as originally proposed by DEBYE[11] possibly explains the larger time required when the electrical field is removed, for the restoration of $\pm \Delta i$, to the original value observed prior to 'ageing' under discharge, compared to the time changes in $\pm \Delta i$ with ageing under discharge. It is also noteworthy, that, as explained above, the strain developed on the dielectric walls under discharge, can be ascribed to the orientation of the dipolar molecules and when allowed to rest, this strain is relaxed due to the oriented molecules reverting to their original distribution.

Grateful thanks of the author are due to Prof. S. S. JOSHI for his valuable suggestions.

Theory of Thermoelectric Power of Ionic Crystal, II

By Eijiro HAGA

J. Phys. Soc. Japan **14** (1959) 992

$R\equiv\sqrt{2}\,a$ in the right column line 33 should be read $R\equiv 2a$.

We later discovered mistakes in the computation of Q_c in this paper. We must adopt the following expression as the correct formula of Eq. (15):

$$eQ_c=-\frac{k}{2}\,\frac{T_0}{T}\,\frac{(2\pi\sqrt{2})^{1/2}[(1-p)c_0T_0/T]^{1/2}}{(1+4(\pi\sqrt{2})^{1/2}[(1-p)c_0T_0/T]^{1/2})^2}$$

and Eq. (12) should be omitted. Hence, Table I is revised as follows.

Table I. The value of Q_c in μv/°C in (NaCl$+c_0$ Mol–% CdCl$_2$)

°C \ c_0	0.01	0.1	1
200	−16	−26	−31
300	−14	−23	−26
400	−12	−20	−22
500	−10	−17	−19
600	− 9	−15	−17
700	− 7	−13	−15

Further, the last term in Eq. (20) should be omitted. Instead of Table II in the previous paper, the value of Q_c for AgCl doped with the $CdCl_2$ quantities used in the measurement of thermo-power is estimated as follows.

Toble II. The value of Q_c in $\mu v/°C$ in ($AgCl + c_0$ Mol–% $CdCl_2$)

	250°C				350°C			
c_0 \ R	0	a	2a	3a	0	a	2a	3a
0	+ 40	+ 40	+30	+30	+70	+60	+50	+50
0.022	− 40	− 30	−20	−20	+90	+70	+60	+60
0.068	− 90	− 70	−50	−40	+30	+20	+20	+20
0.20	−170	−100	−70	−50	−80	−50	−30	−20

If we find the values of $h_F + Q_i^* + Q_v^*$ at 250 and 350°C under consideration of Q_c with $R \equiv 2a$, the ones become larger by 10∼20% than previously found (J. Phys. Soc. Japan **14** (1959) 729)

Multiplet Structure and Hyperfine Structure of the Spectrum of Mercury

By Kiyoshi MURAKAWA

J. Phys. Soc. Japan **14** (1959) 1624, 1633

Page 1626, right compartment, lines 9 and 10 should read

$K_1 = 0.972$, $K_2 = -0.197$, $K_3 = -0.090$, $K_4 = 0.091$, $K_5 \approx 0$.

I deeply appreciate the kindness of Dr. Blaise who called my attention to the miscopy.
